Sources, seasonality, and trends of southeast US aerosol: an integrated analysis of surface, aircraft, and satellite observations with the GEOS-Chem chemical transport model

Abstract

We use an ensemble of surface (EPA CSN, IMPROVE, SEARCH, AERONET), aircraft (SEAC4RS), and satellite (MODIS, MISR) observations over the southeast US during the summer–fall of 2013 to better understand aerosol sources in the region and the relationship between surface particulate matter (PM) and aerosol optical depth (AOD). The GEOS-Chem global chemical transport model (CTM) with 25×25 km² resolution over North America is used as a common platform to interpret measurements of different aerosol variables made at different times and locations. Sulfate and organic aerosol (OA) are the main contributors to surface PM_{2.5} (mass concentration of PM finer than 2.5 μm aerodynamic diameter) and AOD over the southeast US. OA is simulated successfully with a simple parameterization, assuming irreversible uptake of low-volatility products of hydrocarbon oxidation. Biogenic isoprene and monoterpenes account for 60 % of OA, anthropogenic sources for 30 %, and open fires for 10 %. 60 % of total aerosol mass is in the mixed layer below 1.5 km, 25 % in the cloud convective layer at 1.5–3 km, and 15 % in the free troposphere above 3 km. This vertical profile is well captured by GEOS-Chem, arguing against a high-altitude source of OA. The extent of sulfate neutralization ($f = [\text{NH}_4^+]/(2[\text{SO}_4^{2-}] + [\text{NO}_3^-])$) is only 0.5–0.7 mol mol⁻¹ in the observations, despite an excess of ammonia present, which could reflect suppression of ammonia uptake by OA. This would explain the long-term decline of ammonium aerosol in the southeast US, paralleling that of sulfate. The vertical profile of aerosol extinction over the southeast US follows closely that of aerosol mass. GEOS-Chem reproduces observed total column aerosol mass over the southeast US within 6 %, column aerosol extinction within 16 %, and space-based AOD within 8–28 % (consistently biased low). The large AOD decline observed from summer to winter is driven by sharp declines in both sulfate and OA from August to October. These declines are due to shutdowns in both biogenic emissions and UV-driven photochemistry. Surface PM_{2.5} shows far less summer-to-winter decrease than AOD and we attribute this in part to the offsetting effect of weaker boundary layer ventilation. The SEAC4RS aircraft data demonstrate that AODs measured from space are consistent with surface PM_{2.5}. This implies that satellites can be used reliably to infer surface PM_{2.5} over monthly timescales if a good CTM representation of the aerosol vertical profile is available.

Abstract. We use an ensemble of surface (EPA CSN, IMPROVE, SEARCH, AERONET), aircraft (SEAC⁴RS), and satellite (MODIS, MISR) observations over the southeast US during the summer–fall of 2013 to better understand aerosol sources in the region and the relationship between surface particulate matter (PM) and aerosol optical depth (AOD). The GEOS-Chem global chemical transport model (CTM) with $25 \times 25 \text{ km}^2$ resolution over North America is used as a common platform to interpret measurements of different aerosol variables made at different times and locations. Sulfate and organic aerosol (OA) are the main contributors to

surface $\text{PM}_{2.5}$ (mass concentration of PM finer than $2.5 \mu\text{m}$ aerodynamic diameter) and AOD over the southeast US. OA is simulated successfully with a simple parameterization, assuming irreversible uptake of low-volatility products of hydrocarbon oxidation. Biogenic isoprene and monoterpenes account for 60% of OA, anthropogenic sources for 30%, and open fires for 10%. 60% of total aerosol mass is in the mixed layer below 1.5 km, 25% in the cloud convective layer at 1.5–3 km, and 15% in the free troposphere above 3 km. This vertical profile is well captured by GEOS-Chem, arguing against a high-altitude source of OA. The extent

of sulfate neutralization ($f = [\text{NH}_4^+]/(2[\text{SO}_4^{2-}] + [\text{NO}_3^-])$) is only 0.5–0.7 mol mol⁻¹ in the observations, despite an excess of ammonia present, which could reflect suppression of ammonia uptake by OA. This would explain the long-term decline of ammonium aerosol in the southeast US, paralleling that of sulfate. The vertical profile of aerosol extinction over the southeast US follows closely that of aerosol mass. GEOS-Chem reproduces observed total column aerosol mass over the southeast US within 6 %, column aerosol extinction within 16 %, and space-based AOD within 8–28 % (consistently biased low). The large AOD decline observed from summer to winter is driven by sharp declines in both sulfate and OA from August to October. These declines are due to shutdowns in both biogenic emissions and UV-driven photochemistry. Surface PM_{2.5} shows far less summer-to-winter decrease than AOD and we attribute this in part to the offsetting effect of weaker boundary layer ventilation. The SEAC⁴RS aircraft data demonstrate that AODs measured from space are consistent with surface PM_{2.5}. This implies that satellites can be used reliably to infer surface PM_{2.5} over monthly timescales if a good CTM representation of the aerosol vertical profile is available.

1 Introduction

There is considerable interest in using satellite retrievals of aerosol optical depth (AOD) to map particulate matter concentrations (PM) in surface air and their impact on public health (Liu et al., 2004; Zhang et al., 2009; van Donkelaar et al., 2010, 2015; Hu et al., 2014). The relationship between PM and AOD is a function of the vertical distribution and optical properties of the aerosol. It is generally derived from a global chemical transport model (CTM) simulating the different aerosol components over the depth of the atmospheric column (van Donkelaar et al., 2012, 2013; Boys et al., 2014). Sulfate and organic matter are the dominant sub-micron aerosol components worldwide (Murphy et al., 2006; Zhang et al., 2007; Jimenez et al., 2009), thus it is important to evaluate the ability of CTMs to simulate their concentrations and vertical distributions. Here we use the GEOS-Chem CTM to interpret a large ensemble of aerosol chemical and optical observations from surface, aircraft, and satellite platforms during the NASA SEAC⁴RS campaign in the southeast US in August–September 2013. Our objective is to better understand the relationship between PM and AOD, and the ability of CTMs to simulate it, with focus on the factors controlling sulfate and organic aerosol (OA).

The southeast US is a region of particular interest for PM air quality and for aerosol radiative forcing of climate (Goldstein et al., 2009). PM_{2.5} (the mass concentration of particulate matter finer than 2.5 μm aerodynamic diameter, of most concern for public health) is in exceedance of the current US air quality standard, 12 μg m⁻³ on an annual mean basis, in several counties (<http://www.epa.gov/airquality/>

[particlepollution/actions.html](http://www.epa.gov/airquality/particlepollution/actions.html)). Concentrations have been decreasing in response to regulations targeted at protecting public health (the Clean Air Act Amendments of 1990). Figure 1 shows the summertime (JJA) and wintertime (DJF) mean concentrations of aerosol components for 2003–2013 from surface monitoring stations in the southeast US managed by the US Environmental Protection Agency (US EPA, 1999). Summertime sulfate concentrations decreased by 60 % over the period, while OA concentrations decreased by 40 % (Hand et al., 2012b; Blanchard et al., 2013; Hidy et al., 2014). Trends in winter are much weaker. Decreasing aerosol has been linked to rapid warming in the southeast US over the past 2 decades (Leibensperger et al., 2012a, b).

The sulfate decrease is driven by the decline of sulfur dioxide (SO₂) emissions from coal combustion (Hand et al., 2012b), though the mechanisms responsible for oxidation of SO₂ to sulfate are not well quantified. Better understanding of the mechanisms is important because dry deposition competes with oxidation as a sink of SO₂, so that faster oxidation produces more sulfate (Chin and Jacob, 1996). Standard model mechanisms assume that SO₂ is oxidized to sulfate by the hydroxyl radical (OH) in the gas phase and by hydrogen peroxide (H₂O₂) and ozone in clouds (aqueous phase). A model intercomparison by McKeen et al. (2007) for the northeast US revealed a general failure of models to reproduce observed sulfate concentrations, sometimes by a factor of 2 or more. This could reflect errors in oxidation mechanisms, oxidant concentrations, or frequency of cloud processing. Laboratory data suggest that stabilized Criegee intermediates (SCIs) formed from alkene ozonolysis could be important SO₂ oxidants (Mauldin III et al., 2012; Welz et al., 2012), though their ability to produce sulfate may be limited by competing reactions with water vapor (Chao et al., 2015; Millet et al., 2015).

The factors controlling OA are highly uncertain. OA originates from anthropogenic, biogenic, and open-fire sources (de Gouw and Jimenez, 2009). It is directly emitted as primary OA (POA) and also produced in the atmosphere as secondary OA (SOA) from oxidation of volatile organic compounds (VOCs). Current models cannot reproduce observed OA variability, implying fundamental deficiencies in the model mechanisms (Heald et al., 2011; Spracklen et al., 2011; Tsigaridis et al., 2014). A key uncertainty for air quality policy is the fraction of OA that can be controlled (Carlton et al., 2010), as most of the carbon in SOA is thought to be biogenic in origin. Gas/particle partitioning of organic material depends on the pre-existing aerosol concentration (Pankow, 1994; Donahue et al., 2006), so that “biogenic” SOA may be enhanced in the presence of anthropogenic POA and SOA (Weber et al., 2007). The SOA yield from VOC oxidation also depends on the concentration of nitrogen oxide radicals (NO_x ≡ NO + NO₂) (Kroll et al., 2005, 2006; Chan et al., 2010; Hoyle et al., 2011; Xu et al., 2014). NO_x in the southeast US is mostly from fossil fuel combustion and is in decline due to emission controls (Russell et al., 2012), adding

Figure 1. Summertime and wintertime trends in mean surface $\text{PM}_{2.5}$ in the southeast US for 2003–2013. Seasonal averages for each component are calculated by combining data from the EPA CSN and IMPROVE networks over the southeast US domain defined in Fig. 2. Ammonium is only measured by CSN. Organic aerosol (OA) and black carbon (BC) are only from IMPROVE because of change in the CSN measurement protocol over the 2003–2013 period and differences in the OA measurements between the two networks (see text for details). OA is inferred here from measured organic carbon (OC) using an OA / OC mass ratio of 2.24 as measured by the Aerodyne Aerosol Mass Spectrometer (AMS) in the boundary layer over the southeast US. Note the different scales in different panels (sulfate and OA contribute most of $\text{PM}_{2.5}$). Trends are calculated using the Theil–Sen estimator (Theil, 1950) and are shown only if significant at the $\alpha = 0.05$ level. Only the sulfate trend is significant in winter.

another complication in the relationship between OA concentrations and anthropogenic sources. Oxidation of biogenic VOC by the NO_3 radical formed from anthropogenic NO_x is also thought to be an important SOA source in the southeast US (Pye et al., 2010). Reactions of organic molecules with sulfate to form organosulfates may also play a small role (Surratt et al., 2007; Liao et al., 2015).

Long-term $\text{PM}_{2.5}$ records for the southeast US are available from the EPA CSN, IMPROVE, and SEARCH networks of surface sites (Malm et al., 1994; Edgerton et al., 2005; Solomon et al., 2014). Satellite measurements of AOD from the MODIS and MISR instruments have been operating continuously since 2000 (Diner et al., 2005; Remer et al., 2005; Levy et al., 2013). Both surface and satellite observations show a strong aerosol seasonal cycle in the southeast US, with a maximum in summer and minimum in winter (Alston et al., 2012; Hand et al., 2012a; Ford and Heald, 2013). Goldstein et al. (2009) observed that the amplitude of the seasonal cycle of $\text{PM}_{2.5}$ measured at surface sites (maximum / minimum ratio of ~ 1.5 ; Hand et al., 2012a) is much smaller than the seasonal cycle of AOD measured from space (ratio of ~ 3 –4; Alston et al., 2012). They hypothesized that this could be due to a summertime source of biogenic SOA aloft. Subsequent work by Ford and Heald (2013) supported that hypothesis on the basis of spaceborne CALIOP lidar measurements of elevated light extinction above the planetary boundary layer (PBL).

The NASA SEAC⁴RS aircraft campaign in August–September 2013 (Toon et al., 2015) offers a powerful resource for better understanding the factors controlling aerosol concentrations in the southeast US and the relationship between surface PM and AOD measured from space. The aircraft payload included measurements of aerosol composition, size distribution, and light extinction along with a comprehensive suite of aerosol precursors and related chemical tracers. Flights provided dense coverage of the southeast US (Fig. 2) including extensive PBL mapping and vertical profiling. AERONET sun photometers deployed across the region provided AOD measurements (Holben et al., 1998; http://aeronet.gsfc.nasa.gov/new_web/dragon.html). Additional field campaigns focused on southeast US air quality during the summer of 2013 included SENEX (aircraft) and NOMADSS (aircraft) based in Tennessee (Warneke and the SENEX science team, 2015; http://www.eol.ucar.edu/field_projects/nomadss), DISCOVER-AQ (aircraft) based in Houston (Crawford and Pickering, 2014), SOAS (surface) based in Alabama (<http://soas2013.rutgers.edu>), and SLAQRS (surface) based in Greater St. Louis (Baasandorj et al., 2015). We use the GEOS-Chem CTM with $0.25^\circ \times 0.3125^\circ$ horizontal resolution as a platform to exploit this ensemble of observational constraints by (1) determining the consistency between different measurements, (2) interpreting the measurements in terms of their implications for the sources of sulfate and OA in the southeast US,

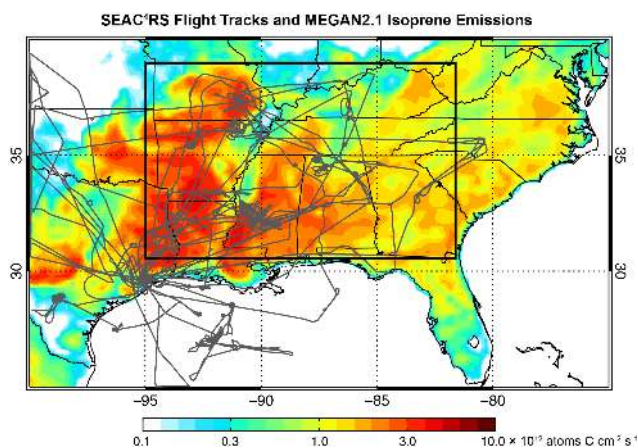

Figure 2. Flight tracks of the DC-8 aircraft during SEAC⁴RS, superimposed on mean MEGAN2.1 isoprene emissions for August–September 2013. The thick black line delineates the southeast US domain as defined in this paper (95–81.5° W, 30.5–39° N).

(3) explaining the seasonal aerosol cycle in the satellite and surface data, and (4) assessing the ability of CTMs to relate satellite measurements of AOD to surface PM.

2 The GEOS-Chem CTM

GEOS-Chem has been used extensively to simulate aerosol concentrations over the US including comparisons to observations (Park et al., 2003, 2004, 2006; Drury et al., 2010; Heald et al., 2011, 2012; Leibensperger et al., 2012a; Walker et al., 2012; L. Zhang et al., 2012; Ford and Heald, 2013). Here we use GEOS-Chem version 9-02 (<http://geos-chem.org>) with detailed oxidant-aerosol chemistry and the updates described below. Our SEAC⁴RS simulation for August–October 2013 is driven by Goddard Earth Observing System – Forward Processing (GEOS-FP) assimilated meteorological data from the NASA Global Modeling and Assimilation Office (GMAO). The GEOS-FP meteorological data have a native horizontal resolution of $0.25^\circ \times 0.3125^\circ$ ($\sim 25 \times 25 \text{ km}^2$) with 72 vertical pressure levels and 3 h temporal frequency (1 h for surface variables and mixed layer depths). The mixed layer (ML) is defined in GEOS-FP as the unstable surface-based column diagnosed from the potential temperature gradient, with a vertical resolution of $\sim 150 \text{ m}$. It is used in GEOS-Chem for surface-driven vertical mixing following Lin and McElroy (2010). The representation of clouds and their properties, such as liquid water content, are taken from the GEOS-FP assimilated meteorological fields. We use the native resolution in GEOS-Chem over North America and adjacent oceans ($130\text{--}60^\circ \text{ W}$, $9.75\text{--}60^\circ \text{ N}$) to simulate the 1 August–31 October 2013 period with a 5-minute transport time step. This is nested within a global simulation at $4^\circ \times 5^\circ$ horizontal resolution to provide dynamic boundary conditions. The global simulation is ini-

tialized on 1 June 2012 with climatological model fields and spun up for 14 months, effectively removing the sensitivity to initial conditions.

GEOS-Chem simulates the mass concentrations of all major aerosol components including sulfate, nitrate, and ammonium (SNA; Park et al., 2006; L. Zhang et al., 2012), organic carbon (OC; Heald et al., 2006, 2011; Fu et al., 2009), black carbon (BC; Wang et al., 2014), dust in four size bins (Fairlie et al., 2007), and sea salt in two size bins (Jaeglé et al., 2011). Aerosol chemistry is coupled to HO_x-NO_x-VOC-O₃-BrO_x tropospheric chemistry with recent updates to the isoprene oxidation mechanism as described by Mao et al. (2013). Gas/particle partitioning of SNA aerosol is computed with the ISORROPIA II thermodynamic module (Fontoukis and Nenes, 2007), as implemented in GEOS-Chem by Pye et al. (2009). Aerosol wet and dry deposition are described by Liu et al. (2001) and Zhang et al. (2001), respectively. OC is the carbon component of OA, and we infer simulated OA from OC by assuming OA / OC mass ratios for different OC sources as given by Canagaratna et al. (2015). Model results are presented below either as OC or OA depending on the measurement to which they are compared. Measurements from surface networks are as OC while the aircraft measurements are as OA.

Table 1 lists GEOS-Chem emissions in the continental United States (CONUS) for 2013. Values for the southeast US in August–September are in parentheses. Emissions outside the CONUS are as in Kim et al. (2013) and are used in the global simulation to derive the boundary conditions for the nested grid. US anthropogenic emissions are from the EPA National Emissions Inventory for 2010 (NEI08v2). The NEI emissions are mapped over the $0.25^\circ \times 0.3125^\circ$ GEOS-Chem grid and scaled to the year 2013 by the ratio of national annual totals (<http://www.epa.gov/ttnchie1/trends/>). For BC and SO₂ this implies 3 and 10 % decreases from 2010 to 2013, but we prescribe instead a 30 % decrease for both to better match observed BC concentrations and trends in sulfate wet deposition. Our SO₂ emission adjustment is more consistent with the latest version of the EPA inventory (NEI11v1), which indicates a 34 % decline between 2010 and 2013, and with the observed trend in surface concentrations from the SEARCH network, which indicates a ~ 50 % decline in the southeast US over the same years (Hidy et al., 2014). The NEI08 NH₃ emissions are scaled to $2^\circ \times 2.5^\circ$ gridded monthly totals from the MASAGE inventory, which provides a good simulation of ammonium wet deposition in the US (Paulot et al., 2014).

Open fires have a pervasive influence on OA and BC over the US (Park et al., 2007). During SEAC⁴RS, the southeast US was affected by both long-range transport of smoke from wildfires in the west (Peterson et al., 2015; Saide et al., 2015) and local agricultural fires. We use the Quick Fire Emissions Dataset (QFED2; Darmenov and da Silva, 2013), which provides daily open-fire emissions at $0.1^\circ \times 0.1^\circ$ resolution. Diurnal-scale factors, which vary by an order of mag-

Table 1. Contiguous US (CONUS) emissions for 2013^a.

Source	NO _x (Tg N)	CO (Tg)	SO ₂ (Tg S)	NH ₃ (Tg)	BC (Tg)	OC (Tg)	Isoprene ^b (Tg C)	Monoterpenes ^b (Tg C)

^a Annual totals. Emissions in the southeast US for the 2-month SEAC⁴RS period (August–September) are shown in parentheses. The southeast US domain is as defined in Fig. 2. ^b Biogenic VOC emissions are from the MEGAN2.1 inventory (Guenther et al., 2012) with isoprene emissions decreased by 15 % (see text). ^c Anthropogenic emissions are from the EPA National Emissions Inventory (NEI08v2) scaled nationally to 2013 and with additional adjustments described in the text. ^d Agricultural ammonia emissions are from the MASAGE inventory on a 2° × 2.5° grid (Paulot et al., 2014), and are distributed on the 0.25° × 0.3125° grid following NEI08v2 as described in the text. ^e Open-fire emissions are from the Quick Fire Emissions Dataset (Darmonov and da Silva, 2013), with adjustments described in the text. ^f Soil and fertilizer NO_x emissions are from the BDSNP algorithm (Hudman et al., 2012). Fertilizer emissions are included in the anthropogenic total.

nitude between midday and evening and peak at 10:00–19:00 local time, are applied to the QFED2 daily emissions following recommendations from the Western Regional Air Partnership (WRAP, 2005) as in Saide et al. (2015). Following previous results from Turquety et al. (2007) and Fischer et al. (2014) for extratropical fires, we inject 35 % of fire emissions above the boundary layer between 680 and 450 hPa to account for plume buoyancy.

Biogenic VOC emissions are from the MEGAN2.1 inventory of Guenther et al. (2012) implemented in GEOS-Chem as described by L. Hu et al. (2015). Isoprene emissions are decreased by 15 % to better match SEAC⁴RS observations of isoprene and formaldehyde concentrations and surface fluxes (Travis et al., 2015; Wolfe et al., 2015; Zhu et al., 2015). Figure 2 shows the SEAC⁴RS DC-8 flight tracks superimposed on the distribution of isoprene emissions. Total emissions over the southeast US (domain outlined in Fig. 2) during the 2-month SEAC⁴RS period were 2.2 Tg C for isoprene and 0.5 Tg C for monoterpenes. Monoterpene emissions did not exceed isoprene emission anywhere.

Sulfate was too low in our initial simulations of the SEAC⁴RS observations. We addressed this problem by including SCIs as additional SO₂ oxidants in the model as previously implemented in GEOS-Chem by Pierce et al. (2013). Oxidation of isoprene and monoterpenes provides a large source of SCIs in the southeast US in summer. Sipilä et al. (2014) estimated SCI molar yields from ozonolysis of 0.58 ± 0.26 from isoprene, 0.15 ± 0.07 from α -pinene, and 0.27 ± 0.12 from limonene. Sarwar et al. (2014) previously found that simulation of sulfate with the CMAQ CTM compared better with summertime surface observations in the southeast US when SCI + SO₂ reactions were included in the chemical mechanism. However, production of sulfate from

SCI chemistry may be severely limited by competition for SCIs between SO₂ and water vapor, and depends on the respective reaction rate constants (Welz et al., 2012; Li et al., 2013; Newland et al., 2014; Sipilä et al., 2014; Stone et al., 2014). Here we use SCI chemistry from the Master Chemical Mechanism (MCMv3.2; Jenkin et al., 1997; Saunders et al., 2003) with the SCI + SO₂ and SCI + H₂O rate constants from Stone et al. (2014), using CH₂OO as a proxy for all SCIs, such that the SCI + SO₂ pathway dominates. This would not be the case using the standard SCI + H₂O and significantly slower (~ 1000 ×) SCI + SO₂ rate constants in MCM (Millet et al., 2015) or if reaction with the water vapor dimer is important (Chao et al., 2015). Given these crude approximations coupled with the uncertain SCI kinetics, the simulated SCI contribution to SO₂ oxidation can be viewed as a proxy for missing oxidant or insufficient cloud processing in GEOS-Chem.

A number of mechanisms of varying complexity have been proposed to model OA chemistry (Donahue et al., 2006; Henze and Seinfeld, 2006; Ervens et al., 2011; Spracklen et al., 2011; Murphy et al., 2012; Barsanti et al., 2013; Hermansson et al., 2014). These mechanisms tend to be computationally expensive and have little success in reproducing the observed variability of OA concentrations (Tsigaridis et al., 2014). Here we use a simple linear approach to simulate five components of OA – anthropogenic POA and SOA, open-fire POA and SOA, and biogenic SOA. Anthropogenic and open-fire POA emissions are from the NEI08 and QFED2 inventories described above. For anthropogenic and open-fire SOA, we adopt the Hodzic and Jimenez (2011) empirical parameterization that assumes irreversible condensation of the oxidation products of VOC precursor gases (AVOC and BBVOC, respectively). AVOCs

and BBVOCs are emitted in proportion to CO, with an emission ratio of 0.069 g AVOC (g CO)⁻¹ (Hayes et al., 2015) and 0.013 g BBVOC (g CO)⁻¹ (Cubison et al., 2011). They are both oxidized by OH in the model with a rate constant of $1.25 \times 10^{-11} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$ to generate SOA. This approach produces amounts of SOA and timescales of formation consistent with field measurements at many locations (de Gouw and Jimenez, 2009; Hodzic and Jimenez, 2010; Cubison et al., 2011; Jolleys et al., 2012; Hayes et al., 2015).

We assume biogenic SOA to be produced with a yield of 3 % from isoprene and 5 % from monoterpenes, formed at the point of emission. Laboratory studies have shown that different biogenic SOA formation mechanisms operate depending on the NO concentration, which determines the fate of the organic peroxy radicals (RO₂) produced from VOC oxidation (Kroll et al., 2005, 2006; Chan et al., 2010; Xu et al., 2014). In the high-NO pathway, the RO₂ radicals react with NO, while in the low-NO pathway, they react with HO₂, other RO₂ radicals, or isomerize. During SEAC⁴RS the two pathways were of comparable importance (Travis et al., 2015). We use four separate tracers in the model to track SOA formed from isoprene and monoterpenes via the high- and low-NO pathways. This tracer separation is purely diagnostic as the SOA yields are assumed here to be the same in both pathways. The SOA is apportioned to the high- or low-NO tracer by the fraction of RO₂ reacting with NO at the point and time of emission. A more mechanistic GEOS-Chem simulation of isoprene SOA in SEAC⁴RS including irreversible aqueous-phase formation coupled to gas-phase chemistry is presented by Marais et al. (2015). It finds in particular that the mean isoprene SOA yield in the low-NO pathway is twice that in the high-NO pathway.

GEOS-Chem computes the AOD for each aerosol component *i* by summing the optical depths over all vertical model layers $L = [1, \dots, n]$:

$$\text{AOD} = \sum_i \sum_{L=1}^n \alpha_i(L) M_i(L), \quad (1)$$

where $\alpha_i(L)$ and $M_i(L)$, respectively, are the component mass extinction efficiency ($\text{m}^2 \text{ g}^{-1}$) and partial column mass (g m^{-2}) for level *L*. The α_i values are pre-calculated for selected wavelengths using a standard Mie scattering algorithm. The algorithm assumes specified aerosol dry size distributions and optical properties from the Global Aerosol Data Set (GADS; Koepke et al., 1997), with updates by Drury et al. (2010) on the basis of summer observations from the ICARTT aircraft campaign over the eastern US. The mass extinction efficiencies are then adjusted for hygroscopic growth as a function of the local relative humidity (RH), following Martin et al. (2003). The total AOD is reported here at 550 nm and is the sum of the contributions from all aerosol components. Comparison of dry aerosol size distribution and hygroscopic growth show good general agreement with observations similar to Drury et al. (2010) (Supplement).

Comparison of GEOS-FP ML heights with lidar and ceilometer data from SEAC⁴RS, SOAS, and DISCOVER-AQ indicates a 30–50 % positive bias across the southeast US in daytime (Scarino et al., 2014b; Millet et al., 2015). We decrease the daytime GEOS-FP ML heights by 40 % in our simulation to correct for this bias. During SEAC⁴RS, ML heights were measured by the NASA-Langley High Spectral Resolution Lidar (HSRL; Hair et al., 2008; Scarino et al., 2014a) on the basis of aerosol gradients under clear-sky conditions. After correction, the modeled ML height is typically within 10 % of the HSRL data along the SEAC⁴RS flight tracks, with a mean daytime value (± 1 standard deviation) of 1690 ± 440 m in the HSRL data and 1530 ± 330 m in the model (Zhu et al., 2015). The daytime ML was typically capped by a shallow cloud convective layer (CCL) extending up to about 3 km, capped in turn by a subsidence inversion and the free troposphere above. When giving column statistics we will refer to the ML as below 1.5 km and the CCL as between 1.5 and 3 km.

Our simulation of sulfate and OA differs in a number of ways from previous GEOS-Chem simulations using earlier versions of the model (Park et al., 2004, 2006; Heald et al., 2006; Leibensperger et al., 2012a; Zhang et al., 2012; Ford and Heald, 2013). Benchmark simulations of ²¹⁰Pb aerosol (Liu et al., 2001; http://acmg.seas.harvard.edu/geos/geos_benchmark.html) show that the global mean aerosol lifetime against deposition is 15 % shorter with the GEOS-FP meteorological data used here than with the previously used GEOS-5 data. Correcting the ML height bias over the southeast US in the GEOS-FP data increases our simulated PM_{2.5} concentrations by 15–25 %. Previous GEOS-Chem studies did not include the Criegee biradical mechanism for SO₂ oxidation, which in our simulation increases the mean sulfate concentrations over the southeast US by 50 % and increases the SO₂ / sulfate ratio to better agree with observations (Sect. 4). The default SOA mechanism in GEOS-Chem, based on reversible partitioning of semivolatile products of VOC oxidation (Pye et al., 2010), underestimates OA levels during SEAC⁴RS by a factor of 3 (Marais et al., 2015). The simple SOA parameterization used here effectively assumes irreversible uptake as a mechanism for SOA formation and provides a much improved simulation of OA over the southeast US, as shown below. Marais et al. (2015) present a more mechanistic treatment of isoprene SOA formation in GEOS-Chem, based on irreversible uptake in aqueous aerosols, in their simulation of SEAC⁴RS observations. Their mean SOA yield from isoprene (3.3 %) is comparable to our imposed value of 3 % but accounts for NO_x dependence.

Several companion papers apply the same GEOS-Chem model configuration as described here to other analyses of the SEAC⁴RS data focused on gas-phase chemistry. These include investigation of the factors controlling ozone in the southeast US (Travis et al., 2015), isoprene chemistry and the formation of organic nitrates (Fisher et al., 2015), validation of satellite HCHO data as constraints on isoprene emissions

(Zhu et al., 2015), and the sensitivity of model concentrations and processes to grid resolution (Yu et al., 2015). These studies include extensive comparisons to the gas-phase observations in SEAC⁴RS. Our focus here will be on the aerosol observations.

3 Surface aerosol concentrations

We begin by evaluating the simulation of PM_{2.5} and its components against ground observations. Total PM_{2.5} is measured gravimetrically at 35 % RH at a large number of EPA monitoring sites (Fig. 3). Filter-based measurements of PM_{2.5} composition are taken every 3 days at surface networks including the EPA CSN (25 sites in the study domain marked in Fig. 2, mostly in urban areas), IMPROVE (15 sites, mostly in rural areas), and SEARCH (5 sites, urban and suburban/rural). These three networks all provide 24-hour average concentrations of the major ions (SNA), carbon species (BC and OC), and dust, though there are differences in protocols (Edgerton et al., 2005; Hidy et al., 2014; Solomon et al., 2014), in particular with respect to OC artifact correction. The IMPROVE and SEARCH OC are both blank-corrected but in different ways (Dillner et al., 2009; Chow et al., 2010), while CSN OC is uncorrected. We apply a constant $0.3 \mu\text{g m}^{-3}$ background correction to the CSN OC data as in Hand et al. (2012a). The resulting CSN OC measurements are within 1 % of SEARCH and 44 % higher than IMPROVE when averaged across the southeast US. When necessary, OA is inferred from the OC filter samples using an OA / OC mass ratio of 2.24 as measured in the boundary layer during SEAC⁴RS by an aerosol mass spectrometer (AMS) onboard the DC-8 aircraft (Sect. 4). We do not discuss sea-salt concentrations as they make a negligible contribution to PM_{2.5} inland ($< 0.1 \mu\text{g m}^{-3}$ averaged across the EPA networks).

Figure 3 shows mean August–September 2013 PM_{2.5} at the EPA sites and compares it to GEOS-Chem values. Concentrations peak over Arkansas, Louisiana, and Mississippi, corresponding to the region of maximum isoprene emission in Fig. 2. The spatial distribution and composition of PM_{2.5} is otherwise fairly homogeneous across the southeast US, reflecting coherent stagnation, mixing, and ventilation of the region (X. Zhang et al., 2012; Pfister et al., 2015). Sulfate accounts on average for 25 % of PM_{2.5}, while OA accounts for 55 %. GEOS-Chem captures the broad features shown in the surface station PM_{2.5} data with little bias ($R = 0.65$, normalized mean bias or NMB = -1.4%). The model hotspot in southern Arkansas is due to OA from a combination of biogenic emissions and agricultural fires. As discussed below, agricultural fires make only a small contribution on a regional scale.

The spatial distributions of sulfate and OC concentrations are shown in Fig. 4. The observed and simulated sulfate maxima are shifted to the northeast relative to total PM_{2.5}, shown

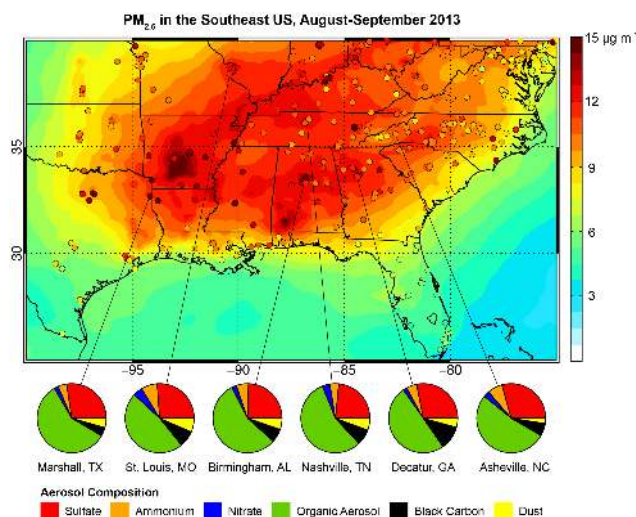

Figure 3. Mean PM_{2.5} in the southeast US in August–September 2013. EPA observations (circles) are compared to GEOS-Chem model values (background). Model values are calculated at 35 % relative humidity as per the Federal Reference Method protocol. Observed mean PM_{2.5} speciation by mass is shown in the pie charts for representative CSN sites. Organic aerosol (OA) mass concentrations are derived from measurements of organic carbon (OC) by assuming an OA / OC mass ratio of 2.24.

in Fig. 3. GEOS-Chem captures a larger fraction of the observed variability at rural sites ($R = 0.78$ for IMPROVE) than at urban/suburban sites ($R = 0.71$ for SEARCH, 0.62 for CSN) as would be expected from the sub-grid scale of urban pollution. A scatter plot of the simulated daily mean surface sulfate concentrations compared to the filter observations from all three networks in August–September 2013 is shown in the Supplement. The model bias (NMB) is +5 % relative to IMPROVE, +10 % relative to SEARCH, and +9 % relative to CSN. Over the southeast US domain defined in Fig. 2, 42 % of sulfate production is from in-cloud production by H₂O₂, 22 % is from gas-phase oxidation by OH, and 36 % is from gas-phase oxidation by SCIs. Previous studies by Pierce et al. (2013) and Boy et al. (2013) found similarly large contributions of SCIs to sulfate production over forested regions in summer. However, there is substantial uncertainty in the SCI kinetics, as discussed above, and it is possible that other oxidants are responsible for the missing sulfate (hence the “Other” label in Fig. 4).

The observed OC distribution shows a decreasing gradient from southwest to northeast that maps onto the distribution of isoprene emissions shown in Fig. 2. The IMPROVE OC is generally low compared to CSN and SEARCH, as has been noted previously (Ford and Heald, 2013; Attwood et al., 2014). GEOS-Chem reproduces the broad features of the observed OC distribution with moderate skill in capturing the variability ($R = 0.64$ for IMPROVE, 0.62 for SEARCH, 0.61 for CSN). Model OC is biased high with a NMB of +66 %

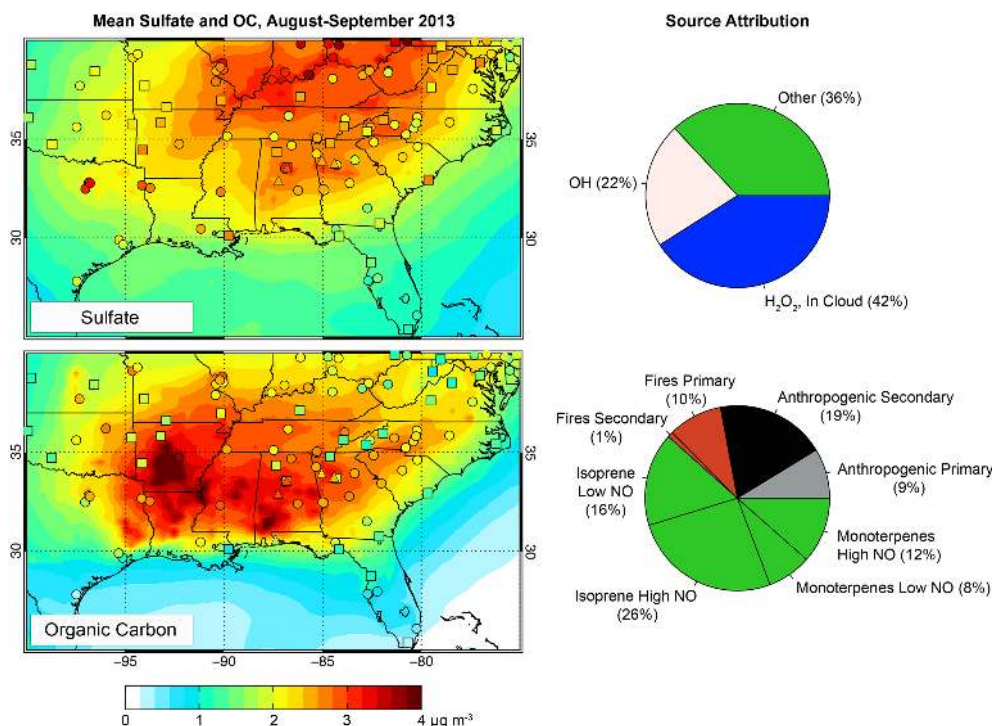

Figure 4. Mean sulfate (top) and OC (bottom) surface air concentrations in the southeast US in August–September 2013. Network observations from CSN (circles), IMPROVE (squares), and SEARCH (triangles) are compared to GEOS-Chem model values (background). OC measurements are artifact-corrected as described in the text. Source attribution for sulfate and OC is shown on the right as averages for the southeast US domain defined in Fig. 2. For sulfate, source attribution is by SO_2 oxidant. For OC, source attribution is primary or secondary, by source type, and by NO regime.

for IMPROVE, +29 % for SEARCH, and +14 % for CSN. The range of NMBs for the different networks could reflect differences in measurement protocols described above – IMPROVE OC is lower than SEARCH by 27 % for collocated measurements made at Birmingham, Alabama (Supplement). We discuss this further in the next section in the context of the aircraft data.

Source attribution of OC in the model (Fig. 4) suggests a dominance of biogenic sources. Isoprene alone contributes 42 % of the regional OC burden. This is in contrast with previous work by Barsanti et al. (2013), who fitted chamber observations to a model mechanism and found monoterpenes to be as or more important than isoprene as a source of OC in the southeast US (particularly under low-NO conditions). SEAC⁴RS observations support a significant role of isoprene as a source of OA (W. W. Hu et al., 2015; Campuzano-Jost et al., 2014; Liao et al., 2015).

Anthropogenic sources in the model contribute 28 % to regional OC, roughly evenly distributed across the region. Open fires contribute 11 %, mainly from agricultural fires in Arkansas and Missouri. Influence from western US fires is significant in the free troposphere (see Sect. 4) but not at the surface.

When all of the components are taken together, we find that 81 % of the surface OC in the southeast US is sec-

ondary in origin. This is well above the 30–69 % range of previous literature estimates for the region (Lim and Turpin, 2002; Yu et al., 2004; Kleindienst et al., 2007; Blanchard et al., 2008) and likely reflects the decreasing trend in anthropogenic emissions (Fig. 1) and possibly a low bias in some estimation methods (Docherty et al., 2008). Assuming fossil fractions of 50 and 70 % for anthropogenic primary and secondary OC, respectively (Zotter et al., 2014; Hayes et al., 2015), we estimate that 18 % of the total OC burden is derived from fossil fuel use. This is consistent with an 18 % fossil fraction from radiocarbon measurements made on filter samples collected in Alabama during SOAS (Edgerton and the SOAS science team, 2014).

4 Aerosol vertical profile

We now examine the aerosol vertical distribution measured by the NASA DC-8 aircraft and simulated by GEOS-Chem along the flight tracks on 18 flights over the southeast US (Fig. 2). Aerosol mass composition was measured by the High-Resolution Aerodyne AMS for SNA and OA (Canagaratna et al., 2007) and by the NOAA humidified dual single-particle soot photometer for BC (HD-SP2; Schwarz et al., 2015). Dust concentrations were measured from filter

Figure 5. Median vertical profiles of aerosol concentrations over the southeast US (Fig. 2) during the SEAC⁴RS aircraft campaign (August–September 2013). Observed and simulated profiles of sulfate (left), OA (center), and dust (right) in 1 km bins are shown with the corresponding median surface network observations. OC from the surface networks is converted to OA using an OA / OC ratio of 2.24. The contributions of anthropogenic SOA, biogenic SOA, and open-fire POA to total simulated OA are also shown. The individual observations are shown in gray and the horizontal bars denote the 25th and 75th percentiles of the observations. Concentrations are in $\mu\text{g m}^{-3}$, converted to STP conditions for the aircraft data and under local conditions for the surface data. The choice of scale truncates some very large individual observations.

samples (Dibb et al., 2003), but the ML values are $\sim 10\times$ higher than measured by surface networks or simulated in GEOS-Chem, as previously found by Drury et al. (2010) during ICARTT. Instead we estimate dust concentrations from Particle Analysis by Laser Mass Spectrometer (PALMS) measurements (Thomson et al., 2000; Murphy et al., 2006). The PALMS data provide the size-resolved number fraction of dust-containing particles, which is multiplied by the measured aerosol volume size distribution from the LAS instrument (Thornhill et al., 2008; Chen et al., 2011) and an assumed density of 2.5 g cm^{-3} . The size distribution is truncated to $\text{PM}_{2.5}$ by applying the transmission curve for the $2.5\text{ }\mu\text{m}$ aerosol impactor used by the ground networks.

Figure 5 shows the median sulfate, OA, and dust vertical profiles over the southeast US. Also shown are the median concentrations from the surface networks over the study domain shown in Fig. 2. The difference between the surface and aircraft data that can be attributed to differences in sampling (time and duration) is quantified by the difference in GEOS-Chem output when the model is sampled with the surface data vs. when the model is sampled with the aircraft data. For sulfate, the model underestimates the aircraft observations by 20% below 5 km but overestimates the surface observations by 5–10% as discussed in Sect. 3. The general shape of the vertical profile is well simulated (with a low bias from 3 to 4 km) and this applies also to SO_2 and to the SO_2 / sulfate ratio (Supplement). The sulfate concentrations are highest near the surface and drop rapidly with altitude, but there is significant mass loading in the lower free troposphere. 23% of the observed sulfate column mass lies in the free troposphere above 3 km and this is well simulated by the model

(23%). Analysis of SENEX and SEAC⁴RS vertical profiles by Wagner et al. (2015) suggests that most of this free tropospheric sulfate is ventilated from the PBL rather than being produced within the free troposphere from ventilated SO_2 . GEOS-Chem shows moderate skill in explaining the variability in the aircraft sulfate data ($R = 0.81$ for all observations in the southeast US, $R = 0.68$ below 3 km, $R = 0.49$ above 3 km).

Similarly to sulfate, OA measured from aircraft peaks at the surface and decreases rapidly with height (Fig. 5). The aircraft OA mass concentration below 1 km is 25–50% higher than measured at the surface networks. IMPROVE is substantially lower than the other networks, as has been noted above and in previous studies (Ford and Heald, 2013; Attwood et al., 2014), and may be due to instrumental issues particular to that network. The discrepancy between the AMS observations and CSN/SEARCH can largely be explained by differences in sampling, as shown by the model. The GEOS-Chem simulation matches closely the aircraft observations. The vertical distribution of OA is similar to that of sulfate, with 20% of the total column being above 3 km both in the model and in the observations. The GEOS-Chem source attribution, also shown in Fig. 5, indicates that open fires contribute $\sim 50\%$ of OA in the free troposphere. This fire influence is seen in the observations as occasional plumes of OA up to 6–7 km altitude (individual gray dots in Fig. 5). Fire plumes can be problematic for interpreting the AOD / PM relationship for individual scenes but much less so in a temporal average as the mean influence on the column is small. Simulating fire influence successfully in the model does require buoyant injection of western US wildfire emissions in

Figure 6. Median vertical profiles of aerosol composition over the southeast US during SEAC⁴RS (August–September 2013). Observations from the DC-8 aircraft (left) are compared to GEOS-Chem values sampled at the aircraft times and locations (center). Also shown is the observed and simulated fraction of the total aerosol mass column below a given height (right). The southeast US domain is as defined in Fig. 2.

the free troposphere, as noted in previous studies (Turquety et al., 2007; Fischer et al., 2014).

Comparison of GEOS-Chem to the individual OA observations along the aircraft flight tracks shows good simulation of the variability ($R = 0.82$ for all observations, $R = 0.74$ below 3 km, $R = 0.42$ above 3 km). This is despite (or maybe because of) our use of a very simple parameterization for the OA source. Further GEOS-Chem comparison to SEAC⁴RS and SOAS observations is presented by Marais et al. (2015) using a more mechanistic analysis of SOA. The successful GEOS-Chem simulation of the OA vertical profile argues against a large CCL source from aqueous-phase cloud processing. This is supported by the work of Wagner et al. (2015), who found little OA enhancement in air masses processed by cumulus wet convection.

Dust made only a minor contribution to total aerosol mass in the southeast US during SEAC⁴RS, accounting for less than 10 % of observed surface PM_{2.5} (Fig. 3). The PBL dust concentrations measured by PALMS are roughly consistent with the surface data but the model is much lower (Fig. 5). This reflects a southward bias in the model transport of Saharan dust (Fairlie et al., 2007), but is of little consequence for the simulation of PM_{2.5} or the AOD / PM relationship over the southeast US. Figure 5 shows few free tropospheric plumes in the SEAC⁴RS observations, consistent with the dust climatology compiled from CALIOP data by Liu et al. (2008).

Figure 6 compiles the median observed and simulated vertical profiles of aerosol concentrations and composition during SEAC⁴RS. OA and sulfate dominate at all altitudes. Ammonium is associated with sulfate as discussed in the next Section. OA accounts for most of PM_{2.5} below 1 km, with a mass fraction $F_{\text{OA}} = [\text{OA}] / [\text{PM}_{2.5}]$ of 0.62 g g^{-1} (0.65 in GEOS-Chem). This is consistent with the surface SEARCH

data ($F_{\text{OA}} = 0.56 \text{ g g}^{-1}$). Figure 1 shows a lower F_{OA} in the IMPROVE surface observations, increasing from 0.34 g g^{-1} in 2003 to 0.44 g g^{-1} in 2013, reflecting instrumentation bias as discussed above. The aircraft data show that most of the aerosol mass is OA at all altitudes. The aerosol column is mostly in the PBL (60 % in the ML, ~ 25 % in the CCL), but ~ 15 % is in the free troposphere with 10 % above 5 km (Fig. 6, right panel). GEOS-Chem reproduces the observed shape of the vertical distribution of total aerosol mass, and this is an important result for application of the model to derive the AOD–PM relationship.

5 Extent of neutralization of sulfate aerosol

The extent of neutralization of sulfate aerosol by ammonia, computed from the fraction $f = [\text{NH}_4^+] / (2[\text{SO}_4^{2-}] + [\text{NO}_3^-])$, where concentrations are molar, has important implications for the aerosol phase and hygroscopicity, for the formation of aerosol nitrate (Martin et al., 2004; Wang et al., 2008), and for the formation of SOA (Froyd et al., 2010; Eddingsaas et al., 2010; McNeill et al., 2012; Budisulistiorini et al., 2013; Liao et al., 2015). Figure 6 shows ammonium to be the third most important aerosol component by mass in the southeast US in summer after OA and sulfate. Summertime particle-phase ammonium concentrations have declined at approximately the same rate as sulfate from 2003 to 2013 (Fig. 1 and Blanchard et al., 2013). However, we find no significant trend over that time in ammonium wet deposition fluxes over the southeast US (NADP, 2015), in contrast to a ~ 50 % decline in sulfate wet deposition. This implies that ammonia emissions have not decreased but the partitioning into the aerosol has.

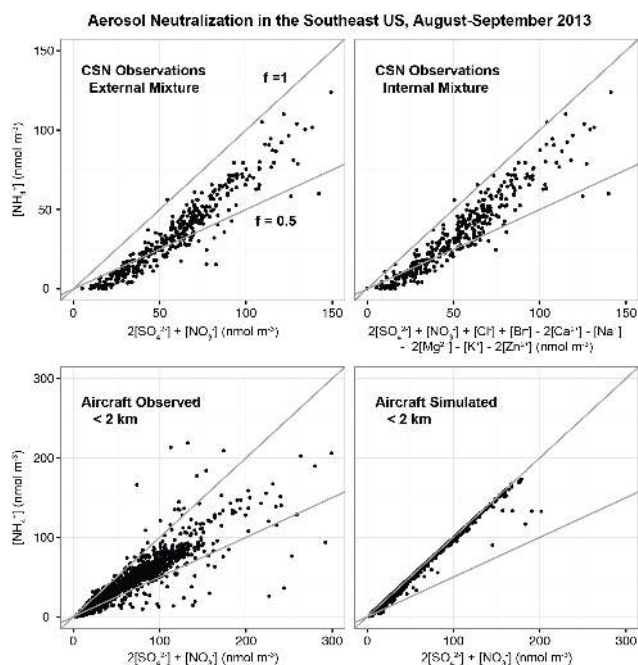

Figure 7. Extent of neutralization of sulfate aerosol in the southeast US (August–September 2013). The extent of neutralization for an external sulfate-nitrate-ammonium (SNA) mixture is given by the $f = [\text{NH}_4^+]/(2[\text{SO}_4^{2-}] + [\text{NO}_3^-])$ molar ratio, and this can be adjusted for an internal mixture by considering additional ions. The top panels show observations from the CSN network, assuming an external (left) or internal (right) mixture; there is little difference between the two because the concentrations of additional ions are usually small. The bottom panels show the SEAC⁴RS aircraft observations below 2 km and the corresponding GEOS-Chem values. Also shown are the lines corresponding to different extents of neutralization ($f = 0.5$ for ammonium bisulfate and $f = 1$ for ammonium sulfate).

One would expect ammonium aerosol trends to follow those of sulfate if the aerosol is fully neutralized ($f = 1$), so that partitioning of ammonia into the aerosol phase is limited by the supply of sulfate. However, this is not the case in the observations. Figure 7 shows the extent of neutralization in the observations and the model, assuming that the SNA aerosol is externally mixed from other ionic aerosol components such as dust. The model aerosol is fully neutralized ($f = 1$) but the observed aerosol is not, with a median extent of neutralization of $0.55 \text{ mol mol}^{-1}$ in the CSN data and $0.68 \text{ mol mol}^{-1}$ in the AMS data below 2 km. This is comparable to $f = 0.49 \text{ mol mol}^{-1}$ observed at the SOAS Centreville site earlier in the summer. The CSN data include full ionic analysis and we examined whether internal mixing of SNA aerosol with other ions could affect the extent of neutralization. The top right panel of Fig. 7 shows that it does not, reflecting the low concentrations of these other ions. The AMS reports total sulfate. While organosulfates have a low pKa and would interact with ammonium as a single charged

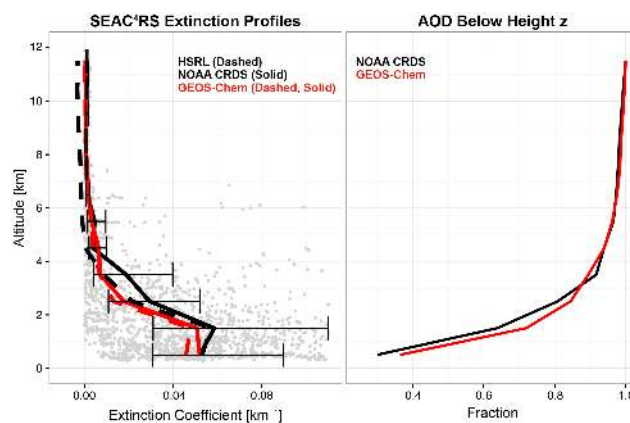

Figure 8. Median vertical profiles of aerosol extinction coefficients (532 nm) over the southeast US during SEAC⁴RS. The left panel shows independent observations from the NASA HSRL and NOAA CRDS instruments, with GEOS-Chem sampled at the times and locations of the available instrument data. The individual CRDS observations are shown in gray and the horizontal bars denote the 25th and 75th percentiles of the CRDS observations for each 1 km bin. The choice of scale truncates some very large individual observations. The right panel shows the observed (CRDS) and simulated fraction of the total AOD below a given height. The southeast US domain is as defined in Fig. 2.

ion, they were typically a small fraction of total sulfate (Liao et al., 2015).

A possible explanation is that ammonia uptake by aerosol with $f < 1$ may be inhibited by organic particle material. This has been demonstrated in a laboratory study by Liggi et al. (2011), who show that the time constant for ammonia to be taken up by sulfate aerosol with incomplete extent of neutralization increases with the ratio of condensing organic gases to sulfate and may be hours to days.

The complete extent of neutralization of sulfate aerosol in the model, in contrast to the observations, leads to bias in the simulated aerosol phase and hygroscopicity for relating AOD to PM. Calculations by Wang et al. (2008) for ammonium-sulfate particles of different compositions show a 10–20% sensitivity of the mass extinction efficiency to the extent of neutralization, with the effect changing sign depending on composition and RH. An additional effect of $f = 1$ in the model would be to allow formation of ammonium nitrate aerosol, but nitrate aerosol is negligibly small in the model as it is in the observations (Fig. 6). At the high temperatures over the southeast US in the summer, we find in the model that the product of HNO_3 and NH_3 partial pressures is generally below the equilibrium constant for formation of nitrate aerosol. By contrast, surface network observations in winter show nitrate to be a large component of surface $\text{PM}_{2.5}$ (Fig. 1; Hand et al., 2012b; Ford and Heald, 2013), reflecting both lower temperatures and the lower levels of sulfate.

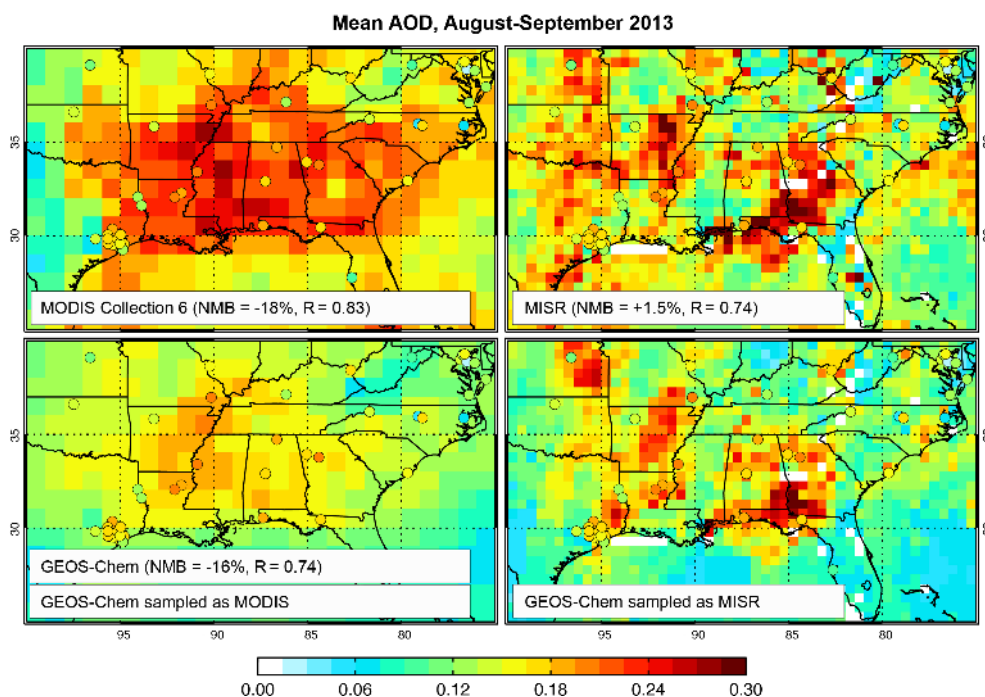

Figure 9. Mean aerosol optical depths (AODs) over the southeast US during SEAC⁴RS (August–September 2013). AERONET data are shown as circles and are the same in all panels. The top panels show MODIS and MISR satellite observations with comparison statistics to AERONET (correlation coefficients, numerical mean biases or NMBs of collocated observations in time and space). The bottom panels show GEOS-Chem model values sampled at the same locations and times as the satellite retrievals. The noise in the MISR panels reflects infrequent sampling (9-day return time, compared to 1-day for MODIS). The negative NMB for the MODIS data reflects occasional retrievals of negative AOD.

6 Aerosol extinction and optical depth

We turn next to light extinction measurements onboard the DC-8 to better understand the relationship between the vertical profiles of aerosol mass (Sect. 4) and AOD. Aerosol extinction coefficients were measured on the SEAC⁴RS aircraft remotely above and below the aircraft by the NASA HSRL and at the altitude of the aircraft by the in situ NOAA cavity ringdown spectrometer (CRDS; Langridge et al., 2011). Figure 8 compares the two measurements, both at 532 nm, with GEOS-Chem. Though the two instruments sampled different regions of the atmosphere at any given time, the mission median profiles are similar. The exception is between 2 and 4 km, where the HSRL extinction coefficient is lower. The shapes of the vertical extinction profiles are consistent with aerosol mass (Fig. 6). The fraction of total column aerosol extinction below 3 km is 93 % for the HSRL data (91 % in GEOS-Chem when sampled at the observation times) and 85 % for the CRDS data (85 % in GEOS-Chem). Almost all of the column extinction is below 5 km (94 % for the CRDS and 93 % for GEOS-Chem). Integrated up to the ceiling of the DC-8 aircraft, the median AODs from HSRL and the CRDS are 0.14 and 0.17, respectively (0.12 and 0.15 for GEOS-Chem).

Figure 9 shows maps of the mean AOD over the southeast US in August–September 2013 as measured by AERONET, MISR, MODIS on the Aqua satellite, and simulated by GEOS-Chem. The model is sampled at the local satellite overpass times (1030 for MISR and 1330 for MODIS). We use the Version 31 Level 3 product from MISR (gridded averages at $0.5^\circ \times 0.5^\circ$ resolution) and the Collection 6 Level 3 product from MODIS (gridded averages at $1^\circ \times 1^\circ$ resolution). We exclude MODIS observations with cloud fraction greater than 0.5 or AOD greater than 1.5 to account for cloud contamination and sensor saturation as in Ford and Heald (2013). We use the Level 2 cloud-filtered daytime average AERONET observations, which can be viewed as a reference measurement.

Comparison of daily collocated MODIS and MISR retrievals with AERONET observations shows high correlation and little bias (statistics inset in Fig. 9). These statistics were calculated only when there are collocated and corresponding data for both AERONET and the satellite retrieval, whereas Fig. 9 shows the spatial average of all available data during August–September 2013. MODIS shows a broad maximum over the southeast US that corresponds well with observed PM_{2.5} in Fig. 3. There is greater heterogeneity in the MISR average due to sparse sampling. GEOS-Chem captures the spatial pattern of the regional AOD enhancement when

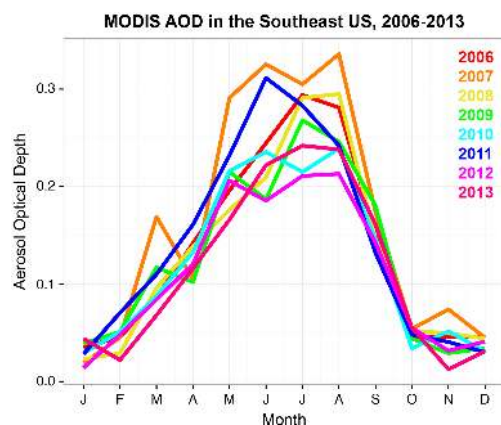

Figure 10. Seasonal variation of MODIS AOD over the southeast US for 2006–2013. The southeast US domain is as defined in Fig. 2.

sampled with the different retrievals and underestimates the magnitude by 16 % (NMB relative to AERONET), consistent with the underestimate of the aircraft aerosol extinction data (including the NASA Ames 4STAR sun photometer, Supplement). The model underestimates AOD (NMB) by 28 %, relative to MODIS and by 8 %, relative to MISR.

7 The aerosol seasonal cycle

As pointed out in the introduction, there has been considerable interest in interpreting the aerosol seasonal cycle over the southeast US and the difference in seasonal amplitude between AOD and surface $\text{PM}_{2.5}$ (Goldstein et al., 2009; Ford and Heald, 2013). Figure 10 shows MODIS monthly average AOD over the southeast US for 2006–2013. The observed AOD in 2013 shows a seasonal cycle consistent with previous years. There has been a general decline in the seasonal amplitude over 2006–2013 driven by a negative summertime trend, with 2011 being anomalous due to high fire activity. The same long-term decrease and 2011 anomaly are seen in the surface $\text{PM}_{2.5}$ data (Fig. 1). Examination of Fig. 10 reveals that the entirety of the seasonal decrease from summer to winter takes place as a sharp transition in the August–October window, in all years.

We analyzed the causes of this August–October transition using the GEOS-Chem simulation of the SEAC⁴RS period. Figure 11a shows the time series of daily median AOD from AERONET, GEOS-Chem sampled at the times and locations of the AERONET observations, and MODIS over the southeast US. The difference between AERONET and MODIS can be explained by differences in sampling (they otherwise correspond well with each other, see Sect. 6). Observations through early September show large oscillations with a 7–10-day period driven by frontal passages. These are well reproduced by the model. The observed AODs then fall sharply in mid-September and again, this is well reproduced by GEOS-

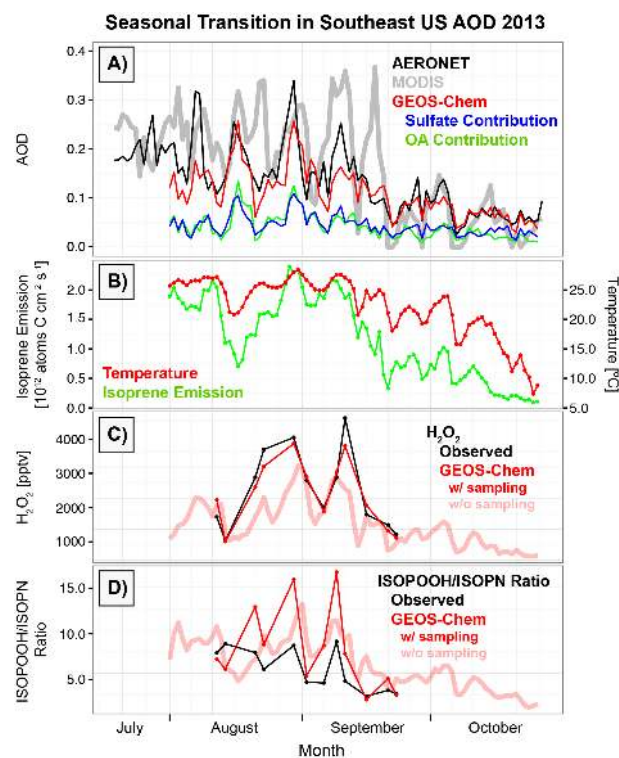

Figure 11. Seasonal transition of aerosol optical depth (AOD) and related variables over the southeast US in August–October 2013. (a) AODs measured by MODIS and AERONET, and GEOS-Chem values sampled at AERONET times and locations with simulated contributions from sulfate and OA. (b) 24-hour average MEGAN2.1 isoprene emissions and GEOS-FP surface air temperatures. (c) H_2O_2 concentrations measured from the aircraft below 1 km altitude and simulated by GEOS-Chem sampled at the times and locations of the observations. Each data point represents the median value over the southeast US for an individual flight. GEOS-Chem H_2O_2 concentrations averaged over the entire region (i.e., without sampling along the flight tracks) are shown separately and extend into October. (d) Same as (c) but for the molar ratio of isoprene peroxides (ISOPOOH) to isoprene nitrates (ISOPN). The southeast US domain is as defined in Fig. 2.

Chem. The successful simulation of the August–October seasonal transition implies that we can use the model to understand the causes of this transition. Figure 11 also shows the sulfate and OA contributions to GEOS-Chem AOD. Sulfate aerosol contributes as much to column light extinction as OA, despite lower concentrations, due to its higher mass extinction efficiency. Both the sulfate and OA contributions to AOD fall during the seasonal transition.

We find that the sharp drops in sulfate and OA concentrations over August–October are due to two factors. The first is a decline in isoprene and monoterpene emissions due to cooler surface temperatures and leaf senescence (Fig. 11b). The second is a transition in the photochemical regime as UV radiation sharply declines (Kleinman, 1991; Jacob et al.,

1995), depleting OH and H₂O₂ (panel c) and hence sulfate formation.

The seasonal transition in photochemical regime also involves a shift from a low-NO to a high-NO chemical regime (Kleinman, 1991; Jacob et al., 1995). This would affect the SOA yield (Marais et al., 2015), though this is not represented in the current GEOS-Chem simulation. Figure 11d shows the ratio of isoprene hydroperoxides (ISOPOOH) to isoprene nitrate (ISOPN) concentrations measured in the PBL during SEAC⁴RS by the Caltech CIMS (Crouse et al., 2006; St. Clair et al., 2010) and simulated by GEOS-Chem. ISOPOOH is formed under low-NO conditions, while ISOPN is formed under high-NO conditions. Both observations and the model show a decline in the ISOPOOH / ISOPN concentration ratio over the course of SEAC⁴RS, with the model showing extended decline into October. If the SOA yield is higher under low-NO conditions (Kroll et al., 2005, 2006; Xu et al., 2014) then this would also contribute to the seasonal decline in OA.

We have thus explained the seasonality of AOD as driven by aerosol sources. Previous studies have pointed out that surface PM_{2.5} in the southeast US has much weaker seasonality than AOD, and observed PM_{2.5} in 2013 had no significant seasonality (Fig. 12, top panel). This difference in the amplitude of the seasonal cycle between PM_{2.5} and AOD is simulated to some extent by GEOS-Chem, as shown in Fig. 12. It is driven in GEOS-Chem by the seasonal variation in ML height (middle panel of Fig. 12), dampening the seasonal cycle of PM_{2.5} by reducing ventilation in winter. The AOD in GEOS-Chem is lower than observed in summer and higher in winter, so that the seasonality is weaker than observed (a factor of 2 compared to an observed factor of 3–4). The summer underestimate is consistent with the aircraft observations, as discussed previously. The winter overestimate could reflect seasonal error in model aerosol sources or optical properties. These model biases aside, one would expect the seasonal variation of boundary layer mixing to dampen the seasonal variation of surface PM_{2.5} relative to AOD, as is found in the observations and in the model.

8 Conclusions

We have used a large ensemble of surface, aircraft, and satellite observations during the SEAC⁴RS field campaign over the southeast US in August–September 2013 to better understand (1) the sources of sulfate and organic aerosol (OA) in the region; (2) the relationship between the aerosol optical depth (AOD) measured from space and the fine particulate matter concentration (PM_{2.5}) measured at the surface; and (3) the seasonal aerosol cycle and the apparent inconsistency between satellite and surface measurements. Our work used the GEOS-Chem global chemical transport model (CTM) with 0.25° × 0.3125° (~ 25 × 25 km²) horizontal resolution

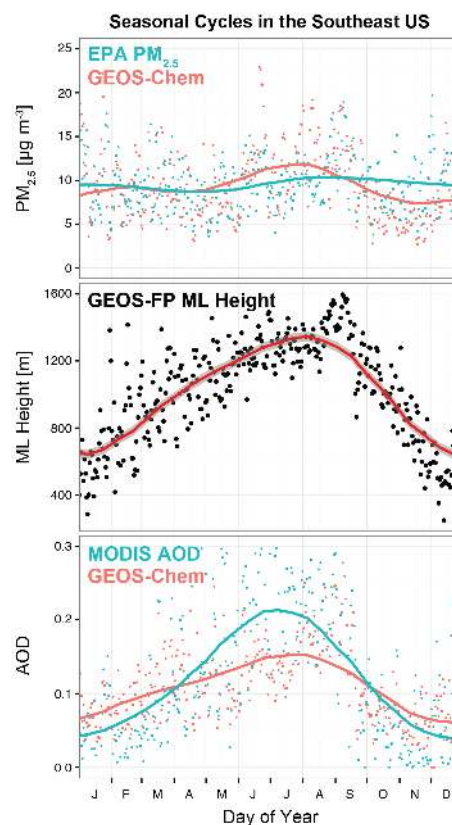

Figure 12. Seasonal aerosol cycle in the southeast US in 2013. Top: daily mean EPA and GEOS-Chem PM_{2.5}. Middle: daily maximum mixed layer height from GEOS-FP with 40 % downward correction applied year-round as in GEOS-Chem (see Sect. 2). Bottom: daily mean AOD from MODIS and GEOS-Chem. GEOS-Chem results in this figure are from the coarse-resolution (4° × 5°) global simulation for 2013. Smoothed curves are calculated using a low-pass filter. All values are averaged over the southeast US as defined in Fig. 2.

over North America as an integrative platform to compare and interpret the ensemble of observations.

PM_{2.5} surface observations are fairly homogenous across the southeast US, reflecting regional coherence in stagnation, mixing, and ventilation. Sulfate and OA account for the bulk of PM_{2.5}. GEOS-Chem simulates sulfate without bias but this requires uncertain consideration of SO₂ oxidation by stabilized Criegee intermediates to account for 30 % of sulfate production in the southeast US. We reproduce the major features of OA observations with a simple parameterization, assuming irreversible condensation of low-volatility VOC oxidation products. Marais et al. (2015) show that the default SOA mechanism in GEOS-Chem, based on reversible partitioning of semivolatile products of VOC oxidation (Pye et al., 2010), underestimates isoprene SOA formation by a factor of 3 in the SEAC⁴RS observations. Our OA simulation bias is +14 % relative to CSN sites and +66 % relative to IMPROVE sites but the IMPROVE data may be too low. OA

in the model originates from biogenic isoprene (40 %) and monoterpenes (20 %), anthropogenic sources (30 %), and open fires (10 %). Marais et al. (2015) present an improved GEOS-Chem simulation of isoprene SOA in SEAC⁴RS using an aqueous-phase mechanism with irreversible uptake coupled to the gas-phase isoprene oxidation cascade and separating the contributions from the high-NO and low-NO pathways. This mechanism provides in particular a successful simulation of observations for the OA–formaldehyde relationship and for the concentration of SOA formed from isoprene epoxides.

Aircraft vertical profiles show that 60 % of the aerosol column mass is in the mixed layer (ML), 25 % is in the convective cloud layer (CCL), and 15 % is in the free troposphere (FT). This is well reproduced in GEOS-Chem. OA accounts for 65 % of the aerosol column mass in the observations and in the model. The successful simulation of OA vertical profiles argues against a large OA source in the free troposphere other than PBL ventilation. Occasional fire and dust plumes were observed in the free troposphere but have little impact on temporal averages.

The extent of neutralization of sulfate aerosol over the southeast US ($f = [\text{NH}_4^+]/(2[\text{SO}_4^{2-}] + [\text{NO}_3^-])$) is observed to be in the range 0.49–0.68 mol mol⁻¹ for the different data sets, despite an excess of ammonia being present. This is inconsistent with thermodynamic equilibrium and with the observation of a 2003–2013 decline in ammonium aerosol concentrations paralleling that of sulfate. We hypothesize that the departure from equilibrium is correlated with OA, as supported by laboratory findings by Liggio et al. (2011) that organic particle material may impede ammonia uptake by sulfate aerosol. This may have important implications for aerosol hygroscopicity and chemistry.

The vertical profile of aerosol light extinction measured from the aircraft follows closely that of aerosol mass. GEOS-Chem has a ~16 % low bias in aerosol extinction compared to these observations and simulates the vertical profile correctly. Sulfate accounts for as much of the column light extinction as OA, despite lower mass concentrations. Evaluation of collocated MODIS and MISR AOD retrievals with AERONET shows excellent agreement. GEOS-Chem is 16 % too low compared to AERONET and 7–28 % too low compared to MODIS and MISR, consistent with its bias relative to the aircraft extinction data. We thus find reasonable agreement between AODs measured from space and from the surface, aircraft aerosol extinction and mass profiles, and surface PM_{2.5} measurements, the largest discrepancy being between different measurements of OA.

We find that the previously reported summer-to-winter decrease in MODIS AOD data over the southeast US is driven by a sharp August-to-October transition, in all years. This seasonal transition is well captured by GEOS-Chem where it is caused by declines in both sulfate and OA. Biogenic emissions of isoprene and monoterpenes shut down during this

time period due to lower temperatures and leaf senescence, and rapidly declining UV radiation suppresses SO₂ oxidation by OH and H₂O₂. The seasonal decline of UV radiation also suppresses the low-NO pathway of isoprene oxidation, which may be associated with larger OA yields than the high-NO pathway.

Previous studies have pointed out an apparent inconsistency between the large seasonal variation of AOD measured from space and the much weaker seasonal variation of PM_{2.5} measured at the surface (Goldstein et al., 2009; Ford and Heald, 2013). We find that this can be explained at least in part by the seasonal trend in boundary layer ventilation, offsetting the effect of decreased wintertime PM sources on the surface concentrations. Overall our results show that measured AODs from space are consistent with measurements of PM_{2.5} air quality in the southeast US. This implies that satellite measurements can reliably be used to infer PM_{2.5} if a good CTM representation of PBL mixing and ventilation is available.
