# Sparse Sampling of Signal Innovations

[Theory, algorithms, and performance bounds]

[Thierry Blu,  
Pier-Luigi Dragotti,  
Martin Vetterli,  
Pina Marziliano,  
and Lionel Coulot]

Signal acquisition and reconstruction is at the heart of signal processing, and sampling theorems provide the bridge between the continuous and the discrete-time worlds. The most celebrated and widely used sampling theorem is often attributed to Shannon (and many others, from Whittaker to Kotel'nikov and Nyquist, to name a few) and gives a sufficient condition, namely bandlimitedness, for an exact sampling and interpolation formula. The sampling rate, at twice the maximum frequency present in the signal, is usually called the Nyquist rate. Bandlimitedness, however, is not necessary as is well known but only rarely taken advantage of [1]. In this broader, nonbandlimited view, the question is: when can we acquire a signal using a sampling kernel followed by uniform sampling and perfectly reconstruct it?

The Shannon case is a particular example, where any signal from the subspace of bandlimited signals, denoted by BL, can be acquired through sampling and perfectly

*Digital Object Identifier 10.1109/MSP.2007.914998*

interpolated from the samples. Using the sinc kernel, or ideal low-pass filter, nonbandlimited signals will be projected onto the subspace BL. The question is: can we beat Shannon at this game, namely, acquire signals from outside of BL and still perfectly reconstruct? An obvious case is bandpass sampling and variations thereof. Less obvious are sampling schemes taking advantage of some sort of sparsity in the signal, and this is the central theme of this article. That is, instead of generic bandlimited signals, we consider the sampling of classes of nonbandlimited parametric signals. This allows us to circumvent Nyquist and perfectly sample and reconstruct signals using *sparse* sampling, at a rate characterized by how sparse they are per unit of time. In some sense, we sample at the *rate of innovation* of the signal by complying with Occam's razor principle [known as Lex Parcimoniae or Law of Parsimony: Entia non svnt multiplicanda præter necessitatem, or "Entities should not be multiplied beyond necessity" (from Wikipedia)].

Besides Shannon's sampling theorem, a second basic result that permeates signal processing is certainly Heisenberg's uncertainty principle, which suggests that a singular event in the frequency domain will be necessarily widely spread in the time domain. A superficial interpretation might lead one to believe that a perfect frequency localization requires a very long time observation. That this is not necessary is demonstrated by high resolution spectral analysis methods, which achieve very precise frequency localization using finite observation windows [2], [3]. The way around Heisenberg resides in a parametric approach, where the prior that the signal is a linear combination of sinusoids is put to contribution.

If by now you feel uneasy about slaloming around Nyquist, Shannon, and Heisenberg, do not worry. Estimation of sparse data is a classic problem in signal processing and communications, from estimating sinusoids in noise, to locating errors in digital transmissions. Thus, there is a wide variety of available techniques and algorithms. Also, the best possible performance is given by the Cramér-Rao lower bounds for this parametric estimation problem, and one can thus check how close to optimal a solution actually is.

We are thus ready to pose the basic questions of this article. Assume a sparse signal (be it in continuous or discrete time) observed through a sampling device that is a smoothing kernel followed by regular or uniform sampling. What is the minimum sampling rate (as opposed to Nyquist's rate, which is often infinite in cases of interest) that allows to recover the signal? What classes of sparse signals are possible? What are good observation kernels, and what are efficient and stable recovery algorithms? How does observation noise influence recovery, and what algorithms will approach optimal performance? How will these new techniques impact practical applications, from inverse problems to wideband communications?

**CAN WE BEAT SHANNON AT THIS GAME, NAMELY, ACQUIRE SIGNALS FROM OUTSIDE OF BL AND STILL PERFECTLY RECONSTRUCT?**

And finally, what is the relationship between the presented methods and classic methods as well as the recent advances in compressed sensing and sampling?

**SIGNALS WITH FINITE RATE OF INNOVATION**

Using the sinc kernel (defined as  $\text{sinc}(t) = \sin \pi t / \pi t$ ), a signal  $x(t)$  bandlimited to  $[-B/2, B/2]$  can be expressed as

$$x(t) = \sum_{k \in \mathbb{Z}} x_k \text{sinc}(Bt - k), \quad (1)$$

where  $x_k = \langle B \text{sinc}(Bt - k), x(t) \rangle = x(k/B)$ , as stated by Shannon in his classic 1948 paper [4]. Alternatively, we can say that  $x(t)$  has  $B$  degrees of freedom per second, since  $x(t)$  is exactly defined by a sequence of real numbers  $\{x_k\}_{k \in \mathbb{Z}}$ , spaced  $T = 1/B$  seconds apart. It is natural to call this the *rate of innovation* of the bandlimited process, denoted by  $\rho$ , and equal to  $B$ .

A generalization of the space of bandlimited signals is the space of shift-invariant signals. Given a basis function  $\varphi(t)$  that is orthogonal to its shifts by multiples of  $T$ , or  $\langle \varphi(t - kT), \varphi(t - k'T) \rangle = \delta_{k-k'}$ , the space of functions obtained by replacing sinc with  $\varphi$  in (1) defines a shift-invariant space  $\mathcal{S}$ . For such functions, the rate of innovation is again equal to  $\rho = 1/T$ .

Now, let us turn our attention to a generic sparse source, namely a Poisson process, which is a set of Dirac pulses,  $\sum_{k \in \mathbb{Z}} \delta(t - t_k)$ , where  $t_k - t_{k-1}$  is exponentially distributed with p.d.f.  $\lambda e^{-\lambda t}$ . Here, the innovations are the set of positions  $\{t_k\}_{k \in \mathbb{Z}}$ . Thus, the rate of innovation is the average number of Diracs per unit of time:  $\rho = \lim_{T \rightarrow \infty} C_T / T$ , where  $C_T$  is the number of Diracs in the interval  $[-T/2, T/2]$ . This parallels the notion of *information rate* of a source based on the average entropy per unit of time introduced by Shannon in the same 1948 paper. In the Poisson case with decay rate  $\lambda$ , the average delay between two Diracs is  $1/\lambda$ ; thus, the rate of innovation  $\rho$  is equal to  $\lambda$ . A generalization involves weighted Diracs or

$$x(t) = \sum_{k \in \mathbb{Z}} x_k \delta(t - t_k).$$

By similar arguments,  $\rho = 2\lambda$  in this case, since both positions and weights are degrees of freedom. Note that this class of signals is not a subspace, and its estimation is a non-linear problem.

Now comes the obvious question: is there a sampling theorem for the type of sparse processes just seen? That is, can we acquire such a process by taking about  $\rho$  samples per unit of time, and perfectly reconstruct the original process, just as the Shannon sampling procedure does.

The necessary sampling rate is clearly  $\rho$ , the rate of innovation. To show that it is sufficient can be done in a number of cases of interest. The archetypal sparse signal is the sum of Diracs, observed through a suitable sampling kernel. In this case, sampling theorems at the rate of innovation can be proven. Beyond the question of a representation theorem, we also derive efficient computational procedures, showing the practicality of the approach. Next comes the question of robustness to noise and optimal estimation procedures under these conditions. We propose algorithms to estimate sparse signals in noise that achieve performance close to optimal. This is done by computing Cramér-Rao bounds that indicate the best performance of an unbiased estimation of the innovation parameters. Note that when the signal-to-noise ratio (SNR) is poor, the algorithms are iterative and thus trade computational complexity for estimation performance.

To easily navigate through the article, the reader will find the most frequent notations in Table 1 that will be used in the sequel.

### SAMPLING SIGNALS AT THEIR RATE OF INNOVATION

We consider a  $\tau$ -periodic stream of  $K$  Diracs with amplitudes  $x_k$  located at times  $t_k \in [0, \tau[$ :

$$x(t) = \sum_{k=1}^K \sum_{k' \in \mathbb{Z}} x_k \delta(t - t_k - k'\tau). \quad (2)$$

We assume that the signal  $x(t)$  is convolved with a sinc window of bandwidth  $B$ , where  $B\tau$  is an *odd integer* and is uniformly sampled with sampling period  $T = \tau/N$ . (We will use this hypothesis throughout the article to simplify the expressions and because it allows convergence of the  $\tau$ -periodized sum of sinc kernels.) We therefore want to retrieve the innovations  $x_k$  and  $t_k$  from the  $n = 1, 2, \dots, N$  measurements

$$y_n = \langle x(t), \text{sinc}(B(nT - t)) \rangle = \sum_{k=1}^K x_k \varphi(nT - t_k), \quad (3)$$

$$\text{where } \varphi(t) = \sum_{k' \in \mathbb{Z}} \text{sinc}(B(t - k'\tau)) = \frac{\sin(\pi Bt)}{B\tau \sin(\pi t/\tau)} \quad (4)$$

is the  $\tau$ -periodic sinc function or Dirichlet kernel. Clearly,  $x(t)$  has a rate of innovation  $\rho = 2K/\tau$ , and we aim to devise a sampling scheme that is able to retrieve the innovations of  $x(t)$  by operating at a sampling rate that is as close as possible to  $\rho$ .

Since  $x(t)$  is periodic, we can use the Fourier series to represent it. By expressing the Fourier series coefficients of  $x(t)$  we thus have

$$x(t) = \sum_{m \in \mathbb{Z}} \hat{x}_m e^{j2\pi mt/\tau}, \quad \text{where} \\ \hat{x}_m = \frac{1}{\tau} \sum_{k=1}^K x_k \underbrace{e^{-j2\pi mt_k/\tau}}_{u_k^m}. \quad (5)$$

We observe that the signal  $x(t)$  is completely determined by the knowledge of the  $K$  amplitudes  $x_k$  and the  $K$  locations  $t_k$ , or equivalently,  $u_k$ . By considering  $2K$  contiguous values of  $\hat{x}_m$  in (5), we can build a system of  $2K$  equations in  $2K$  unknowns that is linear in the weights  $x_k$  but is highly nonlinear in the locations  $t_k$  and therefore cannot be solved using classical linear algebra. Such a system, however, admits a unique solution when the Diracs locations are distinct, which is obtained by using a method known in spectral estimation as *Prony's method* [2], [3], [5], [6], and which we choose to call the *annihilating filter* method for the reason clarified below. Call  $\{h_k\}_{k=0,1,\dots,K}$  the filter coefficients with  $z$ -transform

$$H(z) = \sum_{k=0}^K h_k z^{-k} = \prod_{k=1}^K (1 - u_k z^{-1}). \quad (6)$$

[TABLE 1] FREQUENTLY USED NOTATIONS.

SYMBOL	MEANING
$x(t), \tau, \hat{x}_m$	$\tau$ -PERIODIC FINITE RATE OF INNOVATION SIGNAL AND ITS FOURIER COEFFICIENTS
$K, t_k, x_k$ , and $\rho$	INNOVATION PARAMETERS: $x(t) = \sum_{k=1}^K x_k \delta(t - t_k)$ FOR $t \in [0, \tau[$ AND RATE OF INNOVATION OF THE SIGNAL: $\rho = 2K/\tau$
$\varphi(t), B$	"ANTI_ALIASING" FILTER, PRIOR TO SAMPLING: TYPICALLY, $\varphi(t) = \text{sinc } Bt$ NOTE: $B \times \tau$ IS RESTRICTED TO BE AN ODD INTEGER
$y_n, \hat{y}_m, N, T$	(NOISY) SAMPLES $\{y_n\}_{n=1,2,\dots,N}$ OF $(\varphi * x)(t)$ AT MULTIPLES OF $T = \tau/N$ [SEE (14)] AND THEIR DFT COEFFICIENTS $\hat{y}_m$
$A, L$	RECTANGULAR ANNIHILATION MATRIX WITH $L + 1$ COLUMNS [SEE (12)]
$H(z), h_k$ AND $H$	ANNIHILATING FILTER: $z$ -TRANSFORM, IMPULSE RESPONSE AND VECTOR REPRESENTATION

That is, the roots of  $H(z)$  correspond to the locations  $u_k = e^{-j2\pi t_k/\tau}$ . It clearly follows that

$$h_m * \hat{x}_m = \sum_{k=0}^K h_k \hat{x}_{m-k} = \sum_{k=0}^K \sum_{k'=1}^K \frac{x_{k'}}{\tau} h_k u_{k'}^{m-k} \\ = \sum_{k'=1}^K \frac{x_{k'}}{\tau} u_{k'}^m \underbrace{\sum_{k=0}^K h_k u_{k'}^{-k}}_{H(u_{k'})=0} = 0. \quad (7)$$

The filter  $h_m$  is thus called annihilating filter since it annihilates the discrete signal  $\hat{x}_m$ . The zeros of this filter uniquely define the locations  $t_k$  of the Diracs. Since  $h_0 = 1$ , the filter coefficients  $h_m$  are found from (7) by involving at least  $2K$  consecutive values of  $\hat{x}_m$ , leading to a linear system of equations; e.g., if

we have  $\hat{x}_m$  for  $m = -K, -K + 1, \dots, K - 1$ , this system can be written in *square Toeplitz* matrix form as follows:

$$\begin{bmatrix} \hat{x}_{-1} & \hat{x}_{-2} & \cdots & \hat{x}_{-K} \\ \hat{x}_0 & \hat{x}_{-1} & \cdots & \hat{x}_{-K+1} \\ \vdots & \vdots & \ddots & \vdots \\ \hat{x}_{K-2} & \hat{x}_{K-3} & \cdots & \hat{x}_{K-1} \end{bmatrix} \begin{bmatrix} h_1 \\ h_2 \\ \vdots \\ h_K \end{bmatrix} = - \begin{bmatrix} \hat{x}_0 \\ \hat{x}_1 \\ \vdots \\ \hat{x}_{K-1} \end{bmatrix}. \quad (8)$$

If the  $x_k$ s do not vanish, this  $K \times K$  system of equations has a unique solution because any  $h_m$  satisfying it is also such that  $H(u_k) = 0$  for  $k = 1, 2, \dots, K$ . Given the filter coefficients  $h_m$ , the locations  $t_k$  are retrieved from the zeros  $u_k$  of the  $z$ -transform in (6). The weights  $x_k$  are then obtained by considering, for instance,  $K$  consecutive Fourier-series coefficients as given in (5). By writing the expression of these  $K$  coefficients in vector form, we obtain a Vandermonde system of equations that yields a unique solution for the weights  $x_k$  since the  $u_k$ s are distinct. Notice that we need in total no more than  $2K$  consecutive coefficients  $\hat{x}_m$  to solve both the Toeplitz system (8) and the Vandermonde system. This confirms our original intuition that the knowledge of only  $2K$  Fourier-series coefficients is sufficient to retrieve  $x(t)$ .

We are now close to solving our original sampling question; the only remaining issue is to find a way to relate the Fourier-series coefficients  $\hat{x}_m$  to the actual measurements  $y_n$ . Assume  $N \geq B\tau$  then, for  $n = 1, 2, \dots, N$ , we have that

$$y_n = \langle x(t), \text{sinc}(Bt - n) \rangle = \sum_{|m| \leq \lfloor B\tau/2 \rfloor} T \hat{x}_m e^{j2\pi mn/N}. \quad (9)$$

Up to a factor  $NT = \tau$ , this is simply the inverse discrete Fourier transform (DFT) of a discrete signal bandlimited to  $[-\lfloor B\tau/2 \rfloor, \lfloor B\tau/2 \rfloor]$  and which coincides with  $\hat{x}_m$  in this bandwidth. As a consequence, the discrete Fourier coefficients of  $y_n$  provide  $B\tau$  consecutive coefficients of the Fourier series of  $x(t)$  according to

$$\begin{aligned} \hat{y}_m &= \sum_{n=1}^N y_n e^{-j2\pi mn/N} \\ &= \begin{cases} \tau \hat{x}_m & \text{if } |m| \leq \lfloor B\tau/2 \rfloor \\ 0 & \text{for other } m \in [-N/2, N/2]. \end{cases} \quad (10) \end{aligned}$$

Let us now analyze the complete retrieval scheme more precisely and draw some conclusions. First of all, since we need at least  $2K$  consecutive coefficients  $\hat{x}_m$  to use the annihilating filter method, this means that  $B\tau \geq 2K$ . Thus, the bandwidth of the sinc kernel,  $B$ , is always larger than  $2K/\tau = \rho$ , the rate of innovation. However, since  $B\tau$  is odd, the minimum number of samples per period is actually one sample larger,

$N \geq B_{\min}\tau = 2K + 1$ , which is the next best thing to critical sampling. Moreover, the reconstruction algorithm is fast and does not involve any iterative procedures. Typically, the only step that depends on the number of samples,  $N$ , is the computation of the DFT coefficients of the samples  $y_n$ , which can of course be implemented in  $O(N \log_2 N)$  elementary operations using the fast Fourier transform algorithm. All the other steps of the algorithm (in particular, polynomial rooting) depend on  $K$  only, i.e., on the rate of innovation  $\rho$ .

### MORE ON ANNIHILATION

A closer look at (7) indicates that *any* nontrivial filter  $\{h_k\}_{k=0,1,\dots,L}$  where  $L \geq K$  that has  $u_k = e^{-j2\pi t_k/\tau}$  as zeros will annihilate the Fourier series coefficients of  $x(t)$ . The converse is true: any filter with transfer function  $H(z)$  that annihilates the  $\hat{x}_m$  is automatically such that  $H(u_k) = 0$  for  $k = 1, 2, \dots, K$ . Taking (10) into account, this means that for such filters

$$\sum_{k=0}^L h_k \hat{y}_{m-k} = 0, \quad \text{for all } |m| \leq \lfloor B\tau/2 \rfloor. \quad (11)$$

These linear equations can be expressed using a matrix formalism: let  $A$  be the Toeplitz matrix

$$A = \begin{matrix} & \overbrace{\begin{bmatrix} \hat{y}_{-M+L} & \hat{y}_{-M+L-1} & \cdots & \hat{y}_{-M} \\ \hat{y}_{-M+L+1} & \hat{y}_{-M+L} & \cdots & \hat{y}_{-M+1} \\ \vdots & \ddots & \ddots & \vdots \\ \vdots & \ddots & \ddots & \vdots \\ \vdots & \ddots & \ddots & \vdots \\ \hat{y}_M & \hat{y}_{M-1} & \cdots & \hat{y}_{M-L} \end{bmatrix}}^{L+1 \text{ columns}} \\ \left. \begin{matrix} 2M-L+1 \text{ rows} \\ \\ \\ \\ \\ \end{matrix} \right\} & \end{matrix} \quad \text{where } M = \lfloor B\tau/2 \rfloor, \quad (12)$$

and  $H = [h_0, h_1, \dots, h_L]^T$  the vector containing the coefficients of the annihilating filter, then (11) is equivalent to

$$AH = 0, \quad (13)$$

which can be seen as a rectangular extension of (8). Note that, unlike (6),  $H$  is not restricted to satisfy  $h_0 = 1$ . Now, if we choose  $L > K$ , there are  $L - K + 1$  independent polynomials of degree  $L$  with zeros at  $\{u_k\}_{k=1,2,\dots,K}$ , which means that there are  $L - K + 1$  independent vectors  $H$  which satisfy (13). As a consequence, the rank of the matrix  $A$  does never exceed  $K$ . This provides a simple way to determine  $K$  when it is not known a priori: find the smallest  $L$  such that the matrix  $A$  built according to (12) is singular, then  $K = L - 1$ .

**BESIDES SHANNON'S SAMPLING THEOREM, A SECOND BASIC RESULT THAT PERMEATES SIGNAL PROCESSING IS CERTAINLY HEISENBERG'S UNCERTAINTY PRINCIPLE.**

The annihilation property (11) satisfied by the DFT coefficients  $\hat{y}_m$  is narrowly linked to the periodized sinc-Dirichlet window used prior to sampling. Importantly, this approach can be generalized to other kernels such as the (nonperiodized) sinc, the Gaussian windows [7], and more recently any window that satisfies a Strang-Fix like condition [8].

### FRI SIGNALS WITH NOISE

“Noise,” or more generally model mismatch are unfortunately omnipresent in data acquisition, making the solution presented in the previous section only ideal. Schematically, perturbations to the finite rate of innovation (FRI) model may arise both in the analog domain during, e.g., a transmission procedure, and in the digital domain after sampling (see Figure 1)—in this respect, quantization is a source of corruption as well. There is then no other option but to increase the sampling rate in order to achieve robustness against noise.

Thus, we consider the signal resulting from the convolution of the  $\tau$ -periodic FRI signal (2) and a sinc-window of bandwidth  $B$ , where  $B\tau$  is an *odd* integer. Due to noise corruption, (3) becomes

$$y_n = \sum_{k=1}^K x_k \varphi(nT - t_k) + \varepsilon_n \quad \text{for } n = 1, 2, \dots, N, \quad (14)$$

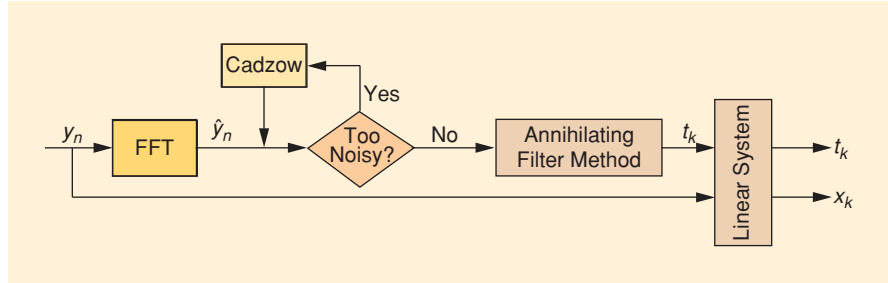

where  $T = \tau/N$  and  $\varphi(t)$  is the Dirichlet kernel (4). Given that the rate of innovation of the signal is  $\rho$ , we will consider  $N > \rho\tau$  samples to fight the perturbation  $\varepsilon_n$ , making the data redundant by a factor of  $N/(\rho\tau)$ . At this point, we do not make specific assumptions—in particular, of statistical nature—on  $\varepsilon_n$ . What kind of algorithms can be applied to efficiently exploit this extra redundancy and what is their performance?

A related problem has already been encountered decades ago by researchers in spectral analysis where the problem of finding sinusoids in noise is classic [9]. Thus we will not try to propose new approaches regarding the algorithms. One of the difficulties is that there is as yet no unanimously agreed optimal algorithm for retrieving sinusoids in noise, although there has been numerous evaluations of the different methods (see, e.g., [10]). For this reason, our choice falls on the the simplest approach, the total least-squares approximation (implemented using a singular value decomposition (SVD), an approach initiated by Pisarenko in [11]), possibly enhanced by an initial “denoising” (more exactly, model matching) step provided by what we call Cadzow’s iterated algorithm [12]. The full algorithm, depicted in Figure 2, is also detailed in its two main components in “Annihilating Filter: Total Least-Squares Method” and “Cadzow’s Iterative Denoising.”

By computing the theoretical minimal uncertainties known as Cramér-Rao bounds on the innovation parameters, we will see that these algorithms exhibit a quasi-optimal behavior down

[FIG1] Block diagram representation of the sampling of an FRI signal, with indications of potential noise perturbations in the analog, and in the digital part.

[FIG2] Schematic view of the FRI retrieval algorithm. The data are considered “too noisy” until they satisfy (11) almost exactly.

to noise levels of the order of 5 dB (depending on the number of samples). In particular, these bounds tell us how to choose the bandwidth of the sampling filter.

### TOTAL LEAST-SQUARES APPROACH

In the presence of noise, the annihilation equation (13) is not satisfied exactly, yet it is still reasonable to expect that the minimization of the Euclidian norm  $\|AH\|^2$  under the constraint that  $\|H\|^2 = 1$  may yield an interesting estimate of  $H$ . Of particular interest is the solution for  $L = K$ —annihilating filter of minimal size—because the  $K$  zeros of the resulting filter provide a unique estimation of the  $K$  locations  $t_k$ . It is known that this minimization can be solved by performing an SVD of  $A$  as

#### ANNIHILATING FILTER: TOTAL LEAST-SQUARES METHOD

An algorithm for retrieving the innovations  $x_k$  and  $t_k$  from the noisy samples of (14).

- 1) Compute the  $N$ -DFT coefficients of the samples  $\hat{y}_m = \sum_{n=1}^N y_n e^{-j2\pi nm/N}$ .
- 2) Choose  $L = K$  and build the rectangular *Toeplitz* matrix  $A$  according to (12).
- 3) Perform the *SVD* of  $A$  and choose the eigenvector  $[h_0, h_1, \dots, h_K]^T$  corresponding to the *smallest* eigenvalue—i.e., the annihilating filter coefficients.
- 4) Compute the roots  $e^{-j2\pi t_k/\tau}$  of the  $z$ -transform  $H(z) = \sum_{k=0}^K h_k z^{-k}$  and deduce  $\{t_k\}_{k=1, \dots, K}$ .
- 5) Compute the least mean square solution  $x_k$  of the  $N$  equations  $\{y_n - \sum_k x_k \varphi(nT - t_k)\}_{n=1, 2, \dots, N}$ .

When the measures  $y_n$  are very noisy, it is necessary to first *denoise* them by performing a few iterations of Cadzow’s algorithm (see “Cadzow’s Iterative Denoising”), before applying the above procedure.

### CADZOW'S ITERATIVE DENOISING

Algorithm for “denoising” the samples  $y_n$  of “Annihilating Filter: Total Least-Squares Method.”

- 1) Compute the  $N$ -DFT coefficients of the samples  $\hat{y}_m = \sum_{n=1}^N y_n e^{-j2\pi nm/N}$ .
- 2) Choose an integer  $L$  in  $[K, B\tau/2]$  and build the rectangular *Toeplitz* matrix  $A$  according to (12).
- 3) Perform the *SVD* of  $A = USV^T$  where  $U$  is a  $(2M - L + 1) \times (L + 1)$  unitary matrix,  $S$  is a diagonal  $(L + 1) \times (L + 1)$  matrix, and  $V$  is a  $(L + 1) \times (L + 1)$  unitary matrix.
- 4) Build the diagonal matrix  $S'$  from  $S$  by keeping only the  $K$

most significant diagonal elements, and deduce the total least-squares approximation of  $A$  by  $A' = US'V^T$ .

5) Build a denoised approximation  $\hat{y}'_n$  of  $\hat{y}_n$  by averaging the diagonals of the matrix  $A'$ .

6) Iterate step 2 until, e.g., the  $(K + 1)$ <sup>th</sup> largest diagonal element of  $S$  is smaller than the  $K$ <sup>th</sup> largest diagonal element by some pre-requisite factor.

The number of iterations needed is usually small (less than ten). Note that, experimentally, the best choice for  $L$  in step 2 is  $L = M$ .

defined by (12)—more exactly: an eigenvalue decomposition of the matrix  $A^T A$ —and choosing for  $H$  the eigenvector corresponding to the smallest eigenvalue. More specifically, if  $A = USV^T$

where  $U$  is a  $(B\tau - K) \times (K + 1)$  unitary matrix,  $S$  is a  $(K + 1) \times (K + 1)$  diagonal matrix with decreasing positive elements, and  $V$  is a  $(K + 1) \times (K + 1)$  unitary matrix, then  $H$  is the last column of  $V$ . Once the  $t_k$  are retrieved, the  $x_k$  follow from a least mean square minimization of the difference between the samples  $y_n$  and the FRI model (14).

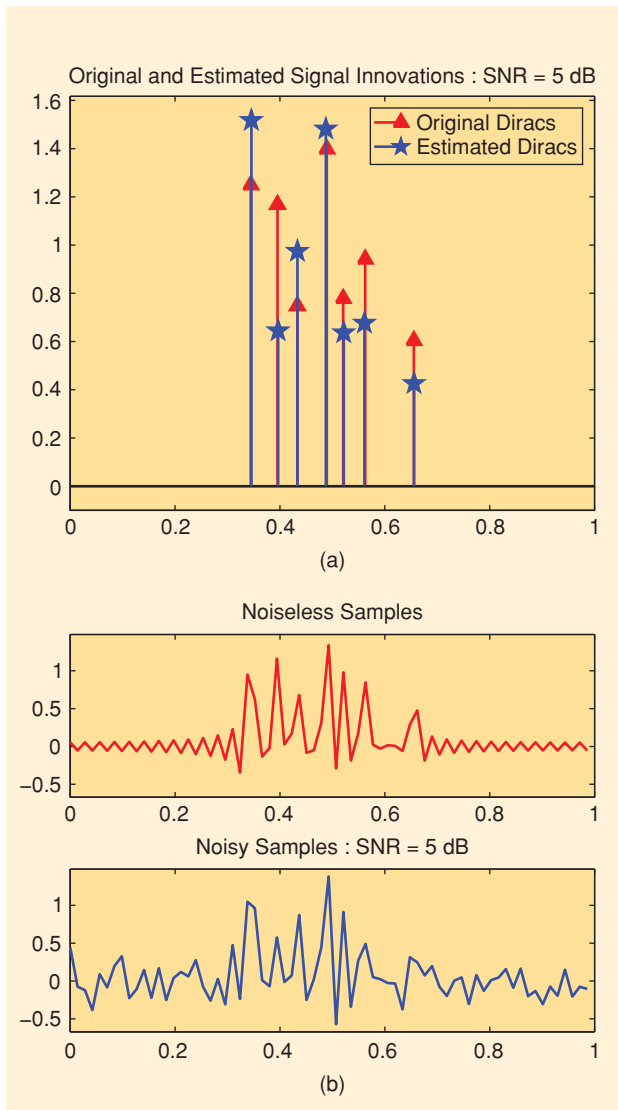

This approach, summarized in “Annihilating Filter: Total Least-Squares Method,” is closely related to Pisarenko’s method [11]. Although its cost is much larger than the simple solution presented earlier, it is still essentially linear with  $N$  (excluding the cost of the initial DFT).

#### EXTRA DENOISING: CADZOW

The previous algorithm works quite well for moderate values of the noise—a level that depends on the number of Diracs. However, for a small SNR, the results may become unreliable and it is advisable to apply a robust procedure that “projects” the noisy samples onto the sampled FRI model of (14). This iterative procedure was already suggested by Tufts and Kumaresan in [13] and analyzed in [12].

As noticed earlier, the noiseless matrix  $A$  in (12) is of rank  $K$  whenever  $L \geq K$ . The idea consists thus in performing the *SVD* of  $A$ , say  $A = USV^T$ , and forcing to zero the  $L + 1 - K$  smallest diagonal coefficients of the matrix  $S$  to yield  $S'$ . The resulting matrix  $A' = US'V^T$  is not *Toeplitz* anymore but its best *Toeplitz* approximation is obtained by averaging the diagonals of  $A'$ . This leads to a new “denoised” sequence  $\hat{y}'_n$  that matches the noiseless FRI sample model better than the original  $\hat{y}_n$ ’s. A few of these iterations lead to samples that can be expressed almost exactly as bandlimited samples of an FRI signal. Our observation is that this FRI signal is all the closest to the noiseless one as  $A$  is closer to a square matrix, i.e.,  $L = \lfloor B\tau/2 \rfloor$ .

The computational cost of this algorithm, summarized in “Cadzow’s Iterative Denoising,” is higher than the annihilating filter method since it requires performing the *SVD* of a square matrix of large size, typically half the number of samples. However, using modern computers we can expect to perform the *SVD* of a square matrix with a few hundred columns in less than a second. We show in Figure 3 an example of FRI signal reconstruction having seven Diracs whose 71 samples are buried in a noise with 5 dB SNR power (redundancy  $\approx 5$ ); the

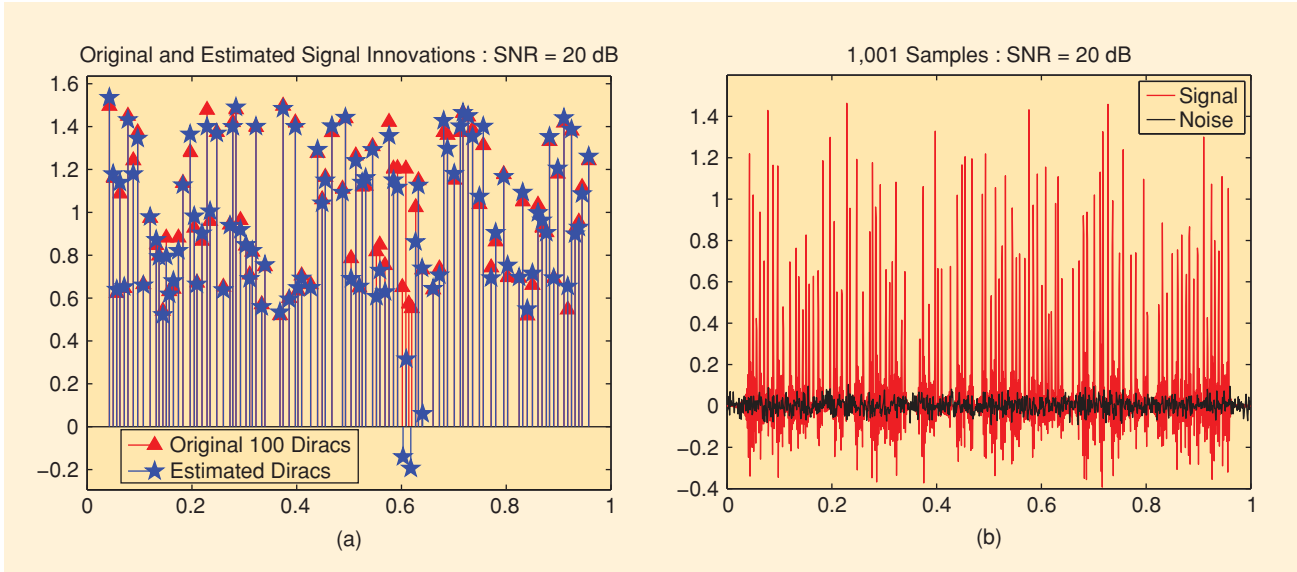

**[FIG3]** Retrieval of an FRI signal with (a) seven Diracs from (b) 71 noisy (SNR = 5 dB) samples.

total computation time is 0.9 s on a PowerMacintosh G5 at 1.8 GHz. Another more striking example is shown in Figure 4 where we use 1,001 noisy (SNR = 20 dB) samples to reconstruct 100 Diracs (redundancy  $\approx 5$ ): the total computation time is 61 s. Although it is not easy to check on a crowded graph, all the Dirac locations have been retrieved very precisely, while a few amplitudes are wrong. The fact that the Diracs are sufficiently far apart ( $\geq 2/N$ ) ensures the stability of the retrieval of the Dirac locations.

### CRAMÉR-RAO BOUNDS

The sensitivity of the FRI model to noise can be evaluated theoretically by choosing a statistical model for this perturbation. The result is that any unbiased algorithm able to retrieve the innovations of the FRI signal from its noisy samples exhibits a covariance matrix that is lower bounded by Cramér-Rao Bounds (see “Cramér-Rao Lower Bounds”). As can be seen in Figure 5, the retrieval of an FRI signal made of two Diracs is almost optimal for SNR levels above 5 dB since the uncertainty on these

[FIG4] Retrieval of an FRI signal with (a) 100 Diracs from (b) 1,001 noisy (SNR = 20 dB) samples.

### CRAMÉR-RAO LOWER BOUNDS

We are considering noisy real measurements  $Y = [y_1, y_2, \dots, y_N]$  of the form

$$y_n = \sum_{k=1}^K x_k \varphi(nT - t_k) + \varepsilon_n$$

where  $\varepsilon_n$  is a zero-mean *Gaussian* noise of covariance  $R$ ; usually the noise is assumed to be stationary:  $[R]_{n,n'} = r_{n-n'}$  where  $r_n = \mathcal{E}\{\varepsilon_{n+n'}\varepsilon_n\}$ . Then any unbiased estimate  $\Theta(Y)$  of the unknown parameters  $[x_1, x_2, \dots, x_K]^T$  and  $[t_1, t_2, \dots, t_K]^T$  has a covariance matrix that is lower bounded by the inverse of the Fisher information matrix (adaptation of [21, (6)])

$$\text{cov}\{\Theta\} \geq (\Phi^T R^{-1} \Phi)^{-1},$$

$$\text{where } \Phi = \begin{bmatrix} \varphi(T - t_1) & \dots & \varphi(T - t_K) & -x_1 \varphi'(T - t_1) & \dots & -x_K \varphi'(T - t_K) \\ \varphi(2T - t_1) & \dots & \varphi(2T - t_K) & -x_1 \varphi'(2T - t_1) & \dots & -x_K \varphi'(2T - t_K) \\ \vdots & & \vdots & \vdots & & \vdots \\ \varphi(NT - t_1) & \dots & \varphi(NT - t_K) & -x_1 \varphi'(NT - t_1) & \dots & -x_K \varphi'(NT - t_K) \end{bmatrix}.$$

Note that this expression holds quite in general: it does not require that  $\varphi(t)$  be periodic or bandlimited, and the noise does not need to be stationary.

*One-Dirac periodized sinc case*—If we make the hypothesis that  $\varepsilon_n$  is  $N$ -periodic and  $\varphi(t)$  is the Dirichlet kernel (4), then the  $2 \times 2$  Fisher matrix becomes diagonal. The minimal uncertainties on the location of one Dirac,  $\Delta t_1$ , and on its amplitude,  $\Delta x_1$ , are then given by:

$$\frac{\Delta t_1}{\tau} \geq \frac{B\tau}{2\pi|x_1|\sqrt{N}} \left( \sum_{|m| \leq \lfloor B\tau/2 \rfloor} \frac{m^2}{\hat{r}_m} \right)^{-1/2} \quad \text{and} \quad \Delta x_1 \geq \frac{B\tau}{\sqrt{N}} \left( \sum_{|m| \leq \lfloor B\tau/2 \rfloor} \frac{1}{\hat{r}_m} \right)^{-1/2}.$$

locations reaches the (unbiased) theoretical minimum given by Cramér-Rao bounds. Such a property has already been observed for high-resolution spectral algorithms (and notably those using a maximum likelihood approach) by Tufts and Kumaresan [13].

It is particularly instructive to make the explicit computation for signals that have exactly two innovations per period  $\tau$  and where the samples are corrupted with a white Gaussian noise. The results, which involve the same arguments as in [14], are given in “Uncertainty Relation for the One-Dirac Case” and essentially state that the uncertainty on the location of the Dirac is proportional to

**UNBIASED RETRIEVAL OF THE INNOVATIONS OF THE FRI SIGNAL FROM ITS NOISY SAMPLES EXHIBITS A COVARIANCE MATRIX LOWER BOUNDED BY CRAMÉR-RAO BOUNDS**

$1/\sqrt{NB\tau}$  when the sampling noise is dominant (white noise case), and to  $1/(B\tau)$  when the transmission noise is dominant ( $\varphi(t)$ -filtered white noise). In both cases, it appears that it is better to maximize the bandwidth  $B$  of the sinc-kernel in order to minimize the uncertainty on the location of the Dirac. A closer inspection of the white noise case shows that the improved time resolution is obtained at the cost of a loss of amplitude accuracy by a  $\sqrt{B\tau}$  factor.

When  $K \geq 2$ , the Cramér-Rao formula for one Dirac still holds approximately when the locations are sufficiently far apart. Empirically, if the minimal difference (modulo  $\tau$ ) between two of the Dirac locations is larger than, say,  $2/N$ , then the maximal (Cramér-Rao) uncertainty on the retrieval of these locations is obtained using the formula given in “Uncertainty Relation for the One-Dirac Case.”

**DISCUSSION**

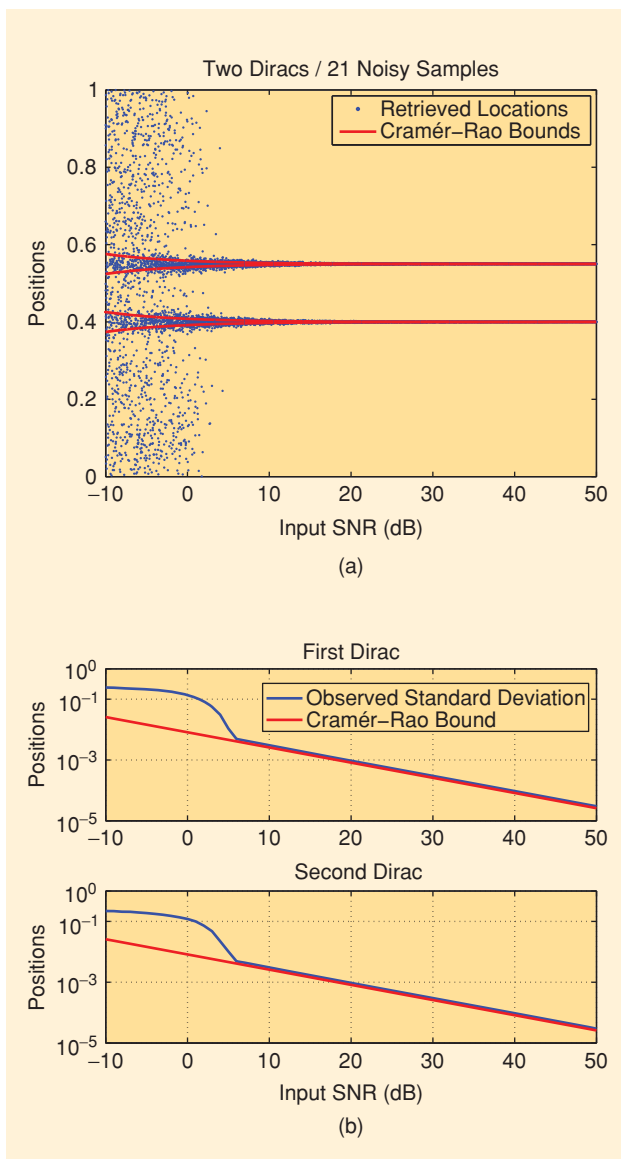

**APPLICATIONS**

Let us turn to applications of the methods developed so far. The key feature to look for is sparsity together with a good model of the acquisition process and of the noise present in the system. For a real application, this means a thorough understanding of the setup and of the physics involved (remember that we assume a continuous-time problem, and we do not start from a set of samples or a finite vector).

One main application to use the theory presented in this article is ultra-wide band (UWB) communications. This communication method uses pulse position modulation (PPM) with very wideband pulses (up to several gigahertz of bandwidth). Designing a digital receiver using conventional sampling theory would require analog-to-digital conversion (ADC) running at over 5 GHz, which would be very expensive and power consumption intensive. A simple model of an UWB pulse is a Dirac convolved with a wideband, zero mean pulse. At the receiver, the signal is the convolution of the original pulse with the channel impulse response, which includes many reflections, and all this buried in high levels of noise. Initial work on UWB using an FRI framework was presented in [15]. The technology described in the present article is currently being transferred to Qualcomm Inc.

The other applications that we would like to mention, namely electroencephalography (EEG) and optical coherence tomography (OCT), use other kernels than the Dirichlet window, and as such require a slight adaptation to what has been presented here.

EEG measurements during neuronal events like epileptic seizures can be modeled reasonably well by an FRI excitation to a Poisson equation, and it turns out that these measurements satisfy an annihilation property [16]. Obviously, accurate localization of the activation loci is important for the surgical treatment of such impairment.

**[FIG5] Retrieval of the locations of a FRI signal. (a) Scatterplot of the locations; (b) standard deviation (averages over 10,000 realizations) compared to Cramér-Rao lower bounds.**

In OCT, the measured signal can be expressed as a convolution between the (low-)coherence function of the sensing laser beam (typically, a Gabor function which satisfies an annihilation property) and an FRI signal whose innovations are the locations of refractive index changes and their range, within the object imaged [17]. Depending on the noise level and the model adequacy, the annihilation technique allows to reach a resolution that is potentially well-below the “physical” resolution implied by the coherence length of the laser beam.

**ONE MAIN APPLICATION TO USE THE THEORY PRESENTED IN THIS ARTICLE IS ULTRA-WIDE BAND (UWB) COMMUNICATIONS.**

### RELATION WITH COMPRESSED SENSING

One may wonder whether the approach described here could be addressed using compressed sensing tools developed in [18] and [19]. Obviously, FRI signals can be seen as “sparse” in the time domain. However, differently from the compressed sensing framework, this domain is not discrete: the innovation times may assume arbitrary real values. Yet, assuming that these innovations fall on some discrete grid  $\{\theta_{n'}\}_{n'=0,1,\dots,(N'-1)}$  known a priori, one may try to address our FRI interpolation problem as

$$\min_{x'_0, x'_1, \dots, x'_{N'-1}} \sum_{n'=0}^{N'-1} |x'_{n'}| \quad \text{under the constraint} \quad \sum_{n=1}^N y_n - \sum_{n'=0}^{N'-1} x'_{n'} \varphi(nT - \theta_{n'}) \Big|^2 \leq N\sigma^2, \quad (15)$$

where  $\sigma^2$  is an estimate of the noise power.

In the absence of noise, it has been shown that this minimization provides the parameters of the innovation, with “overwhelming” probability [19] using  $O(K \log N')$  measurements. Yet this method is not as direct as the annihilating filter method that does not require any iteration. Moreover, the compressed-sensing approach does not reach the critical sampling rate, unlike the method proposed here which almost achieves this goal ( $2K + 1$  samples for  $2K$  innovations). On the other hand, compressed sensing is not limited to uniform measurements of the form (14) and could potentially accommodate arbitrary sampling kernels—and not only the few ones that satisfy an annihilation property. This flexibility is certainly an attractive feature of compressed sensing.

In the presence of noise, the beneficial contribution of the  $\ell^1$  norm is less obvious since the quadratic program (15) does not provide an exactly  $K$ -sparse solution anymore, although  $\ell^1/\ell^2$  stable recovery of the  $x'_k$ , is statistically guaranteed [20]. Moreover, unlike the method we are proposing here which is able to reach the Cramér-Rao lower bounds (computed in “Cramér-Rao Lower Bounds”), there is no evidence that the  $\ell^1$  strategy may share this optimal behavior. In particular, it is of interest to note that, in practice, the

compressed sensing strategy involves *random measurement* selection, whereas arguments obtained from Cramér-Rao bounds computation, namely, on the optimal bandwidth of the sinc-kernel, indicate that, on the contrary, it might be worth optimizing the sensing matrix.

### CONCLUSIONS

Sparse sampling of continuous-time sparse signals has been addressed. In particular, it was shown that sampling at the rate of innovation is possible, in some sense applying Occam’s razor to the sampling of sparse signals. The noisy case has been analyzed and solved, proposing methods reaching the optimal performance given by the Cramér-Rao bounds. Finally, a number of applications have been discussed where sparsity can be taken advantage of. The comprehensive coverage given in this article should lead to further research in sparse sampling, as well as new applications.

### UNCERTAINTY RELATION FOR THE ONE-DIRAC CASE

We consider the FRI problem of finding  $[x_1, t_1]$  from the  $N$  noisy measurements  $[y_1, y_2, \dots, y_N]$

$$y_n = \mu_n + \varepsilon_n \quad \text{with} \quad \mu_n = x_1 \varphi(n\tau/N - t_1)$$

where  $\varphi(t)$  is the  $\tau$ -periodic,  $B$ -bandlimited Dirichlet kernel and  $\varepsilon_n$  is a stationary Gaussian noise. Any unbiased algorithm that estimates  $t_1$  and  $x_1$  will do so up to an error quantified by their standard deviation  $\Delta t_1$  and  $\Delta x_1$ , lower bounded by Cramér-Rao formulas (see “Cramér-Rao Lower Bounds”). Denoting the noise power by  $\sigma^2$  and the peak SNR by  $\text{PSNR} = |x_1|^2/\sigma^2$ , two cases are especially interesting:

- The noise is white, i.e., its power spectrum density is constant and equals  $\sigma^2$ . Then we find

$$\frac{\Delta t_1}{\tau} \geq \frac{1}{\pi} \sqrt{\frac{3B\tau}{N(B^2\tau^2 - 1)}} \cdot \text{PSNR}^{-1/2} \quad \text{and} \quad \frac{\Delta x_1}{|x_1|} \geq \sqrt{\frac{B\tau}{N}} \cdot \text{PSNR}^{-1/2}.$$

- The noise is a white noise filtered by  $\varphi(t)$ , then we find

$$\frac{\Delta t_1}{\tau} \geq \frac{1}{\pi} \sqrt{\frac{3}{B^2\tau^2 - 1}} \cdot \text{PSNR}^{-1/2} \quad \text{and} \quad \frac{\Delta x_1}{|x_1|} \geq \text{PSNR}^{-1/2}.$$

In both configurations, we conclude that, in order to *minimize the uncertainty* on  $t_1$ , it is better to *maximize the bandwidth* of the Dirichlet kernel, i.e., choose  $B$  such that  $B\tau = N$  if  $N$  is odd, or such that  $B\tau = N - 1$  if  $N$  is even. Since  $B\tau \leq N$  we always have the following uncertainty relation

$$N \cdot \text{PSNR}^{1/2} \cdot \frac{\Delta t_1}{\tau} \geq \frac{\sqrt{3}}{\pi},$$

involving the number of measurements,  $N$ , the end noise level and the uncertainty on the position.

## AUTHORS

**Thierry Blu** (thierry.blu@m4x.org) received the “Diplôme d’ingénieur” from École Polytechnique, France, in 1986 and the Ph.D. from Télécom Paris, in 1996. His main field of research is approximation/interpolation/sampling theory and wavelets. He was with the Biomedical Imaging Group at the Swiss Federal Institute of Technology, Lausanne, and is now with the Department of Electronic Engineering, the Chinese University of Hong Kong. He received two best paper awards from the IEEE Signal Processing Society (2003 and 2006).

**Pier-Luigi Dragotti** (p.dragotti@imperial.ac.uk) is a senior lecturer (associate professor) in the Electrical and Electronic Engineering Department at Imperial College London. He received the laurea degree in electrical engineering from the University Federico II, Naples, Italy, in 1997 and the master’s and Ph.D. degrees from the École Polytechnique Federale de Lausanne, in 1998 and 2002, respectively. He was a visiting student at Stanford University and a summer researcher in the Mathematics of Communications Department at Bell Labs, Lucent Technologies. His research interests include wavelet theory, sampling and approximation theory, image and video processing, and compression. He is an associate editor of *IEEE Transactions on Image Processing*.

**Martin Vetterli** (martin.vetterli@epfl.ch) received his engineering degree from Eidgenoessische Technische Hochschule-Zuerich, his M.S. from Stanford University, and his Doctorate from École Polytechnique Federale de Lausanne (EPFL). He was with Columbia University, New York, and the University of California at Berkeley before joining EPFL. He works on signal processing and communications, e.g., wavelet theory and applications, joint source-channel coding, sensor networks for environmental monitoring. He received the best paper awards of IEEE Signal Processing Society (1991, 1996, and 2006). He is the coauthor of the book *Wavelets and Subband Coding* (Prentice-Hall, 1995) and the forthcoming textbook *Fourier and Wavelets: Theory, Algorithms and Applications*.

**Pina Marziliano** (epina@ntu.edu.sg) received the B.Sc. in applied mathematics and the M.Sc. in computer science from the Université de Montréal, Canada, in 1994 and 1996, respectively. In 2001, she completed the Ph.D. from the École Polytechnique Fédérale de Lausanne, Switzerland. She joined Genimedia in 2002. Since 2003, she has been an assistant professor in the School of Electrical and Electronic Engineering at the Nanyang Technological University in Singapore. She received IEEE Signal Processing Society 2006 Best Paper Award. Her research interests include sampling theory and applications in communications and biomedical engineering, watermarking, and perceptual quality metrics for multimedia.

**Lionel Coulot** (lionel.coulot@epfl.ch) received the B.Sc. and the M.Sc. degrees in 2005 and 2007, respectively, in communication systems from the Swiss Federal Institute of Technology, Lausanne, where he is currently a Ph.D. candidate. He spent one year on exchange at Carnegie Mellon University and was an intern at Microsoft Research Asia, Beijing, PRC. His research interests include image and signal processing as well as auction and game theory.
