ABSTRACT

We present a spectral analysis of the e^+e^- annihilation emission from the Galactic Centre region based on the first year of measurements made with the spectrometer SPI of the INTEGRAL mission. We have found that the annihilation spectrum can be modelled by the sum of a narrow and a broad 511 keV line plus an ortho-positronium continuum. The broad line is detected (significance 3.2σ) with a flux of $(0.35 \pm 0.11) \times 10^{-3}$ photons $s^{-1} cm^{-2}$. The measured width of 5.4 ± 1.2 keV *FWHM* is in agreement with the expected broadening of 511 keV photons emitted in the annihilation of positroniums that are formed by the charge exchange process of slowing down positrons with hydrogen atoms. The flux of the narrow line is $(0.72 \pm 0.12) \times 10^{-3}$ photons $s^{-1} cm^{-2}$ and its width is 1.3 ± 0.4 keV *FWHM*. The measured ortho-positronium continuum flux yields a fraction of positronium of $(96.7 \pm 2.2)\%$.

To derive in what phase of the interstellar medium positrons annihilate, we have fitted annihilation models calculated for each phase to the data. We have found that $49_{-23}^{+2}\%$ of the annihilation emission comes from the warm neutral phase and $51_{-2}^{+3}\%$ from the warm ionized phase. While we may not exclude that less than 23% of the emission might come from cold gas, we have constrained the fraction of annihilation emission from molecular clouds and hot gas to be less than 8% and 0.5%, respectively.

We have compared our knowledge of the interstellar medium in the bulge (size, density, and filling factor of each phase) and the propagation of positrons with our results and found that they are in good agreement if the sources are diffusively distributed and if the initial kinetic energy of positrons is lower than a few MeV. Despite its large filling factor, the lack of annihilation emission from the hot gas is due to its low density, which allows positrons to escape this phase.

1. Introduction

In the quest for the origin of positrons, images of the annihilation line emission tell us that positrons annihilate primarily in the bulge of our Galaxy (Knödlseher et al. 2005, and references therein). Assuming that positrons do not propagate far from their sources, the spatial distribution of the annihilation emission should trace the spatial distribution of the sources. Under this hypothesis, the observations of the spectrometer SPI onboard the INTEGRAL observatory show that the sources of the bulk Galactic positrons seem to be associated with the old stellar population (Knödlseher et al. 2005).

In this paper we try to infer, from the spectral characteristics of the annihilation emission measured by SPI, information on the particular processes involved in the interaction of Galactic positrons with the interstellar medium (ISM). This information should provide some clues regarding the origin of Galactic positrons. The identification by spectral analysis of the ISM phase in which positrons annihilate could enable one to retrieve the type of positron sources under particular assumptions

of the distance travelled by positrons as a function of their initial kinetic energy. For instance, if positrons propagate a short distance from their sources, it is then likely that the positron sources belong to or are specifically tied to the medium in which positrons annihilate.

The spectral characteristics of the annihilation emission (shape and intensity of the line, relative intensity of the ortho-positronium continuum) offer valuable information on the physical conditions of the ISM where positrons annihilate (Guessoum et al. 1991; Guessoum et al. 2005). Several reports on observations with Ge spectrometers suggest a width of the line in the 2–3 keV range (Smith et al. 1993; Leventhal et al. 1993; Harris et al. 1998). Using only OSSE data, Kinzer et al. (1996) derived a positronium fraction of 0.97 ± 0.03 . Measurements with the Ge detector TGRS onboard the WIND mission (1995–1997) gives a compatible value of 0.94 ± 0.04 (Harris 1998). From the line width and the positronium fraction measurements, Harris et al. (1998) concluded that a scenario in which annihilation does not occur either in cold molecular

clouds or in the hot phase of the ISM is favored. Using preliminary SPI data of Jean et al. (2003) and TGRS data of Harris et al. (1998), Guessoum et al. (2004) showed that the bulk of the annihilation occurs in warm gas. However, they do not exclude that a significant fraction of the annihilation may occur in hot gas and in interstellar dust. Recently, Churazov et al. (2005) inferred from SPI measurements that the spectral parameters of the emission can be explained by positrons annihilating in a warm gas or in a combination of warm and cold gases.

In the present work, we include in the spectral analysis the classical model of the ISM described by McKee & Ostriker (1977). In this model, the ISM consists of molecular clouds, atomic gas in either a cold or a warm phase, and ionized gas in either a warm or a hot phase. Each phase is characterized by particular physical conditions in abundance, temperature, ionization fraction and density. Since the annihilation process and the Doppler broadening depend on the target properties (H atoms, electrons, velocity...) positrons annihilating in a given phase emit a particular spectrum. For instance, positrons in a cold medium annihilate mostly by forming positronium in flight, whereas the dominant process in a warm ionized medium is radiative recombination with free electrons. The spectral characteristics of the annihilation in the various ISM phases were first studied by Guessoum et al. (1991). They were recently revisited by Guessoum et al. (2005) – hereafter GJG05 – in view of the most recent results on positron interaction cross sections with H, H₂ and He as well as a detailed study on the annihilation in dust grains.

In the next section, we present the SPI observations and the method used to analyse the spectral distribution of the annihilation emission. We take into account the SPI spectral response (continuum Compton, energy resolution and line deformation due to radiation damage). In Sect. 3, we present the results of the spectral analysis. We adopt two different approaches consisting of (a) an adjustment of simple Gaussian and ortho-positronium laws and (b) a fit of the ISM phase fractions using the spectral characteristics of the annihilation in each phase calculated by GJG05. This approach differs from that of Churazov et al. (2005) who fit the temperature and ionized fraction of the gas where annihilation occurs with a measured spectrum based on $\sim 4.5 \times 10^6$ s duration SPI observations of the Galactic Centre region. In Sect. 4, we discuss the implications of these results for the origin and physics of Galactic positrons and in Sect. 5, we summarize the most important new information.

2. Observations and analysis methods

2.1. Observations and data preparation

The data analysed in this work are those of the December 10, 2004 public INTEGRAL data release. The data span the IJD epoch 1073.394–1383.573, where IJD is the Julian Date minus 2 451 544.5 days. In order to reduce systematic uncertainties in the analysis, we exclude observation periods with strong instrumental background fluctuations. These background variations are generally due to solar flares or the exit and entry of the observatory into the Earth's radiation belts. After this cleaning, we obtain a total effective exposure time of 15.2 Ms.

Fig. 1. Spectrum obtained by model fitting (see text). The instrumental background spectrum is shown for comparison.

The exposure is rather uniform in the central regions of our Galaxy from where most of the annihilation signal is observed (see Knödlseder et al. 2005).

The spectrum is extracted by model fitting, assuming that the sky intensity distribution is a $\Delta l \approx 8^\circ$ and $\Delta b \approx 7^\circ$ FWHM 2D-Gaussian. This distribution is one of the best fitting models derived by Knödlseder et al. (2005) who studied in detail the morphology of the annihilation emission. This spatial distribution does not correspond to the spatial distribution of the Galactic diffuse continuum emission, which is expected to be more extended in longitude and less extended in latitude. Therefore the intensity of the Galactic diffuse continuum emission, calculated in the spectral analysis, is overestimated (see Sect. 3.1). However, this systematic error does not affect the shape of the annihilation spectrum since the Galactic continuum emission is fitted by a power-law and, consequently, this overestimation factor is the same over the whole energy band.

We perform the analysis in 1 keV wide energy bins for a 200 keV wide spectral window covering 400–600 keV. Each energy bin is adjusted to the data for each germanium detector separately, assuming that the count rate is due to the sum of the sky contribution and the instrumental background. The latter is assumed to be the sum of 3 terms: a constant, a component proportional to the rate of saturating GeD events (GEDSAT rate) and a component proportional to the convolution product of the GEDSAT rate with a 352 day exponential decay law (see Eq. (1) in Knödlseder et al. 2005). The last two components are tracers of the short time scale and radioactive build up variation of the instrumental background at 511 keV, respectively.

Figure 1 shows the resulting spectrum. For comparison, and to illustrate the quality of the background subtraction, we also show the detector averaged count rate spectrum. While overall the background subtraction is satisfactory, significant residuals remain at the location of some of the strong background lines. For instance, the 439 keV line, emitted in the decay of the metastable state of the ^{69}Zn isotope is not properly removed. This metastable state has a half-life of ≈ 14 h and consequently the temporal variation of this background line differs from the background model used in the model fitting. This gives rise

Fig. 2. Time series of residuals in number of sigma unit obtained by subtracting the background plus sky models to the data. Two energy bands are shown for comparison: **a)** 435–443 keV and **b)** 526–534 keV. The date are in IJD (see text).

to residuals that may induce systematic errors in the spectral analysis.

Figure 2 presents the residuals of the detector averaged count rate after subtraction of the background and sky models in the 435–443 keV and 526–534 keV bands. The residuals of the first band, which contains the 439 keV line, show large fluctuations leading to a reduced χ^2 of 5.4, while the reduced χ^2 is 1.9 for the 526–534 keV band which is free of strong background lines.

2.2. Spectral analysis methods

In order to avoid influences of instrumental background lines on the spectral analysis, we select the following energy bands, which are relatively free of systematic residuals (see previous subsection): 406–435, 443–467, 480–570, 578–580 and 589–593 keV. They cover $\approx 75\%$ of the extracted energy range. This is sufficient (1) to quantify accurately the flux of the ortho-positronium continuum and (2) to characterize the shape of the annihilation line.

The spectral response of the instrument to a narrow (Dirac like) gamma-ray line is an instrumentally broadened Gaussian plus a Compton continuum. Due to radiation damage, the shape

of the Gaussian is deformed with a low energy tail¹. This warping may affect the determination of the physical line width and has to be taken into account in the analysis. A simple way to model radiation damage is to convolve a Gaussian with a decreasing exponential function of energy (see Eq. (1)). The energy scale ϵ_d of the exponential function quantifies the level of degradation and is called the “degradation parameter” hereafter. The degradation increases with time but is regularly removed by the annealing process (Roques et al. 2003). Analysis of the shapes of adjacent background lines yields an energy resolution at 511 keV of 2.0 keV *FWHM* and a mean degradation parameter $\epsilon_d = 0.3$ keV, in agreement with previous analyses (Roques et al. 2003; Lonjou et al. 2005).

The Compton continuum shape and level at 511 keV is extracted from the IRF (Imaging Response Function) and RMF (Redistribution Matrix File) available in the SPI data processing database. These response matrices were generated by Monte-Carlo simulations (Sturmer et al. 2003). Since the annihilation emission has an extent of $\approx 8^\circ$ *FWHM* and INTEGRAL scans this emission, we average the IRFs in the field-of-view of SPI.

The spectral response function $R(E)$ is:

$$R(E) = G(E, \Gamma_{\text{inst}}) \otimes e^{-E/\epsilon_d} + C(E) \quad (1)$$

where $G(E, \Gamma_{\text{inst}})$ is a Gaussian with a *FWHM* of $\Gamma_{\text{inst}} = 2.0$ keV, \otimes denotes a convolution product and $C(E)$ is the Compton continuum function. We then convolve models of the astrophysical signal, $S(E, p)$, with this spectral response and fit the set of parameters p using the measured spectrum.

We adopt two different approaches to characterize the spectral distribution of the annihilation emission:

In the first approach, the “independent model”, we model the spectrum by four independent components: two Gaussians $G(E, \Gamma_i)$ (to model narrow and broad 511 keV lines of *FWHM* Γ_i), the ortho-positronium continuum $O(E)$ and a power law to account for Galactic diffuse continuum emission. The independent model $S_I(E)$ is described by:

$$S_I(E) = I_n \times G(E, \Gamma_n) + I_b \times G(E, \Gamma_b) + I_{3\gamma} \times O(E) + A_c \left(\frac{E}{511 \text{ keV}} \right)^s \quad (2)$$

where I_n , Γ_n , I_b and Γ_b are the flux and width (*FWHM*) of the narrow and broad lines, respectively. $I_{3\gamma}$ is the flux of the ortho-positronium continuum, which is represented by the Ore & Powell (1949) function $O(E)$. A_c is the amplitude of the Galactic continuum at 511 keV and s is the slope of the power law spectrum.

In the second approach, hereafter called the “ISM model”, we adopt the spectral characteristics (line shape and ortho-positronium continuum relative flux) for the different ISM phases given in the model calculated by GJG05, and with these

¹ High energy protons and neutrons impinging on the detectors displace Ge atoms in the crystal and then increase the number of hole traps. These traps reduce the number of collected holes, leading to an underestimation of the energy released by the photon in the detector.

spectral characteristics, we adjust the phase fractions f_i so as to obtain the best fit to the measured spectrum. The ‘‘ISM model’’ is described by:

$$S_{\text{ISM}}(E) = I_{e^+e^-} \times \sum_{i=1}^5 f_i \times S_i(E, x_{\text{gr}}) + A_c \left(\frac{E}{511 \text{ keV}} \right)^s \quad (3)$$

where $S_i(E, x_{\text{gr}})$ is the normalized spectral distribution (in keV^{-1}) of the annihilation photons in phase i with $i = \{\text{molecular, cold, warm neutral, warm ionized, hot}\}$, $I_{e^+e^-}$ is the annihilation flux ($\text{photons s}^{-1} \text{cm}^{-2}$) and x_{gr} represents the fraction of dust grains ($x_{\text{gr}} = 1$ in the standard grain model of GJG05); x_{gr} allows for uncertainties in dust abundance and positron-grain reaction rates. Annihilation in dust grains is significant only in the hot phase where the standard grain model ($x_{\text{gr}} = 1$) yields a $FWHM$ of ≈ 2 keV, as opposed to a line width of ≈ 11 keV in the absence of grains ($x_{\text{gr}} = 0$). The grain fraction has a negligible effect in the molecular, cold and warm neutral phases, and affects the 511 keV line width in the warm ionized gas by less than 2%. The grain fraction is a free parameter of the fit, and so too are the phase fractions f_i , subject to the requirement that $\sum_{i=1}^5 f_i = 1$.

In both cases, the spectral distribution of the Galactic continuum emission is assumed to be a power law with amplitude A_c at 511 keV and a fixed slope of $s = -1.75$ as derived by OSSE measurements in this energy range (Kinzer et al. 1999; Kinzer et al. 2001). The energy band analysed is not large enough and the SPI exposure not sufficient to constrain the slope accurately from the data themselves. We also fix the line position at 511 keV since we observe a relatively symmetric distribution of the emission around the Galactic Centre and do not expect a Doppler shift due to Galactic rotation in this region. Moreover, Churazov et al. (2005) did not measure a significant shift of the line centroid.

The models (Eqs. (2) and (3)) are convolved with the SPI spectral response, $R(E)$ (Eq. (1)). The parameters p of each model are fitted by minimizing the χ^2 . The individual errors on the best fit parameters are obtained by calculating their confidence intervals for which $\Delta\chi^2 < 1$ (1σ uncertainty) with $\Delta\chi^2 = \chi^2(p) - \chi_{\text{opt}}^2$ and χ_{opt}^2 the minimum value of $\chi^2(p)$.

3. Results

3.1. Independent model

When fitting the line with a single Gaussian, we obtain a χ^2 of 193.7 for 150 degrees of freedom, a line width of (2.2 ± 0.1) keV, a 511 keV line flux of $(1.01 \pm 0.02) \times 10^{-3}$ photons $\text{s}^{-1} \text{cm}^{-2}$ and an ortho-positronium flux of $(4.3 \pm 0.3) \times 10^{-3}$ photons $\text{s}^{-1} \text{cm}^{-2}$. We clearly see a significant excess of counts in the wings of the narrow line, suggesting the presence of a broad line (see Fig. 3). This broad line is presumably due to the annihilation of the para-positronium state formed in flight. We then include the broad line in the analysis and use the model presented in Eq. (2).

In this model, the parameters to be adjusted are the widths of the narrow and broad lines, their intensities, the ortho-positronium continuum flux and the level of the Galactic diffuse continuum. Figure 4 shows the result of the fit. We obtain

Fig. 3. Fit of the spectrum measured by SPI with contributions from a Gaussian line, an ortho-positronium continuum and a power-law Galactic continuum. A single Gaussian does not give a good fit to the flux measured in the wings of the line.

Fig. 4. Fit of the spectrum measured by SPI with narrow and broad Gaussian lines, an ortho-positronium continuum and a power-law Galactic continuum (constant slope of -1.75). Note that the asymmetric shape of the lines is due to the convolution of the Gaussian with the spectral response of SPI (Compton continuum and degradation).

a χ^2 value of 171.3 for 148 degrees of freedom. The χ^2 value is improved by 22.4 with respect to the χ^2 value obtained when we fit the line with a single Gaussian.

The measured parameters are listed in Table 1. The detection significance of the broad line is 3.2σ . Its $FWHM$ (5.36 ± 1.22 keV) is in agreement with the width of the annihilation line of positronium formed in flight in H (5.8 keV; see GJG05). The total line (narrow+broad) flux is $I_{2\gamma} = (1.07 \pm 0.03) \times 10^{-3}$ photons $\text{s}^{-1} \text{cm}^{-2}$, in agreement with the flux derived by Knödlseeder et al. (2005) for the 2D Gaussian shaped emission profile. The measured ortho-positronium flux yields a ratio $I_{3\gamma}/I_{2\gamma}$ of 3.95 ± 0.32 and consequently a positronium fraction of $f_{\text{Ps}} = 0.967 \pm 0.022$, also in agreement with previous measurements (Kinzer et al. 1999; Harris et al. 1998; Churazov et al. 2005). The statistical uncertainties of $I_{2\gamma}$ and $I_{3\gamma}/I_{2\gamma}$ are not

Table 1. Best-fit values of the free parameters ($\chi^2 = 171.3$ for 148 degrees of freedom). I_n , Γ_n , I_b and Γ_b are the flux and width (*FWHM*) of the narrow and broad lines, respectively. $I_{3\gamma}$ is the flux of the ortho-positronium continuum and A_c is the amplitude of the Galactic continuum at 511 keV. The first set of error bars refers to the 1σ statistical errors and the second set to the systematic errors.

Parameters	Measured values
I_n ($10^{-3} \text{ s}^{-1} \text{ cm}^{-2}$)	$0.72 \pm 0.12 \pm 0.02$
Γ_n (keV)	$1.32 \pm 0.35 \pm 0.05$
I_b ($10^{-3} \text{ s}^{-1} \text{ cm}^{-2}$)	$0.35 \pm 0.11 \pm 0.02$
Γ_b (keV)	$5.36 \pm 1.22 \pm 0.06$
$I_{3\gamma}$ ($10^{-3} \text{ s}^{-1} \text{ cm}^{-2}$)	$4.23 \pm 0.32 \pm 0.03$
A_c ($10^{-6} \text{ s}^{-1} \text{ cm}^{-2} \text{ keV}^{-1}$)	$7.17 \pm 0.80 \pm 0.06$

obtained by combining quadratically the uncertainties of $I_{3\gamma}$, I_n and I_b as listed in Table 1, since these parameters are not independent. Instead we fit the parameters of the function:

$$S_l(E) = I_{2\gamma} \times [f_n G(E, \Gamma_n) + (1 - f_n) G(E, \Gamma_b) + R_{3\gamma/2\gamma} O(E)] + A_c \left(\frac{E}{511 \text{ keV}} \right)^s \quad (4)$$

where $R_{3\gamma/2\gamma} = I_{3\gamma}/I_{2\gamma}$ and f_n is the fraction of 511 keV flux in the narrow line. The width of the narrow line (1.32 ± 0.35 keV) can be explained by thermalized positrons annihilating either in the warm neutral medium (1.16 keV) or in the warm ionized medium (0.98 keV). We also searched for a component with a 11 keV *FWHM* as expected from positrons annihilating in a hot (10^6 K) interstellar grain-free gas. We obtain only an upper limit of $0.36 \times 10^{-3} \text{ photons s}^{-1} \text{ cm}^{-2}$ (2σ) for such a component, whereupon we conclude that annihilation in a hot plasma contributes less than $\approx 7\%$ to the total annihilation flux.

The Galactic continuum intensity at 511 keV (A_c) is slightly larger than the $\approx 4\text{--}6 \times 10^{-6} \text{ photons s}^{-1} \text{ cm}^{-2} \text{ keV}^{-1}$ obtained by Kinzer et al. (1999) with OSSE measurements. However, these authors extracted this spectral component assuming a uniform distribution along the Galactic plane with a latitude width of 5° *FWHM*, while we assume a latitude width of 7° *FWHM*. This can explain the factor $\approx 7/5$ discrepancy between the two estimations.

In order to estimate systematic errors, we first performed the analysis with the uncertainty of the spectrum bins increased by a factor such that the reduced χ^2 is equal to 1. This factor is found to be ≈ 1.075 , yielding 7.5% systematic errors. Secondly, we quantified the effect on the results of possible uncertainties in the fixed parameters (degradation parameter, slope of the continuum). The uncertainty in the degradation parameter affects neither the continuum intensities nor the total 511 keV flux. Performing the analysis with $\epsilon_d = 0.2$ keV and 0.4 keV yields differences of less than 1.5% of the statistical errors in these parameter values. Nevertheless, the narrow and broad line widths (and fluxes) change by 14% (and 13%) and 4.5% (and 13%) of their statistical uncertainties, respectively. We adopt these values as systematic errors for the parameters of the lines. Kinzer et al. (1999) did not provide uncertainties in the slope of the Galactic Centre continuum spectrum measured

Fig. 5. Best fit of the spectrum measured by SPI with the warm components of the ISM and the Galactic continuum. Contributions from the molecular, cold and hot components are not needed to explain the data.

by OSSE. Kinzer et al. (2001) used a slope of -1.65 to adjust the Galactic continuum model to the OSSE data. Considering the results presented in Table 3 of Kinzer et al. (1999), we can reasonably assume an uncertainty of ± 0.1 in the slope. This yields a systematic error of $\approx 10\%$ in the intensity of the ortho-positronium continuum in our analysis, the other parameters being not significantly affected by this change (less than $\approx 1\%$ of the statistical errors). The corresponding systematic uncertainty in the fraction of positronium is then $\pm 0.3\%$.

We also constructed another spectrum by model fitting (see Sect. 2.1) but excluding regions of observations for which the Crab nebula and Cyg X-1 are in the field-of-view of SPI, in order to check whether these sources produce a bias in the analysis results. The statistical error bars of the spectrum are larger due to the smaller amount of data in this dataset. The analysis of this spectrum provides results that are statistically consistent with those presented in Table 1.

3.2. ISM model

The parameters of this model are the phase fractions (f_i), the grain fraction (x_{gr}), the annihilation flux ($I_{e^+e^-}$) and the amplitude of the Galactic diffuse continuum at 511 keV (A_c ; see Eq. (3)). Figure 5 shows the best-fit model and Table 2 the corresponding parameters. The 1σ statistical uncertainties in the phase fractions were calculated separately by searching for the 68.3% confidence interval of a phase fraction allowing the other parameters to vary but keeping the constraints $\sum_i f_i = 1$. The total annihilation flux and the continuum amplitude at 511 keV obtained by this analysis are consistent with the independent model analysis. The spectral characteristics of the measured annihilation emission can be explained by positrons annihilating only in the warm ISM. Our best fit for the cold phase fraction is 0, however the upper-limit for this value is 23%, so we cannot yet reject a significant contribution from this phase. The contribution of positrons in molecular clouds

Table 2. Measured ISM phase fractions obtained with $\epsilon_d = 0.3$ keV ($\chi^2 = 176.4$ for 148 degrees of freedom). The resulting positronium fraction is $0.935^{+0.003}_{-0.016}$. The first set of error bars refers to the 1σ statistical errors and the second set to the systematic errors.

Parameters	Measured values
f_m (Molecular)	$0.00^{+0.08+0.02}_{-0.00-0.00}$
f_c (Cold)	$0.00^{+0.23+0.04}_{-0.00-0.00}$
f_{wn} (Warm Neutral)	$0.49^{+0.02+0.02}_{-0.23-0.04}$
f_{wi} (Warm Ionized)	$0.51^{+0.03+0.02}_{-0.02-0.02}$
f_h (Hot)	$0.00^{+0.005+0.00}_{-0.00-0.00}$
x_{gr} (Grain fraction)	$0.00^{+1.20+0.20}_{-0.00-0.00}$

and hot gas is negligible since we obtain upper-limits of 8% and 0.5%, respectively.

The total positronium fraction ($f_{Ps} = 93.5^{+0.3}_{-1.6}\%$) is calculated according to the intrinsic positronium fraction of each phase predicted by the GJG05 model, weighted by the phase fraction f_i . The positronium fraction in each phase is the sum of the contributions of positroniums formed in flight and in thermal conditions (via charge exchange and radiative recombination). These contributions were calculated using the probabilities of charge exchange in flight and the annihilation rates tabulated in GJG05. It should be noted that in this analysis, the fraction of ortho-positronium continuum is tied to the phase fractions.

Applying the method described in Sect. 3.1, we find 9% of systematic errors with this analysis, leading to the systematic uncertainties presented in Table 2 for the molecular and cold phase fractions, while we obtained $^{+0.00}_{-0.04}$ of systematic uncertainty for the warm neutral phase fraction. However, when the fit of the phase fraction is performed with a degradation parameter (ϵ_d) of 0.2 keV (0.4 keV), the optimal fractions are 51% (47%) and 49% (53%) for the warm neutral and warm ionized phases, respectively, the other fractions do not change and the fraction of positronium is 0.938 (0.933). The uncertainty in the slope of the continuum power-law model does not affect the results of the fit. Then to be conservative, the systematic errors for the warm neutral and ionized phase fractions are taken to be $^{+0.02}_{-0.04}$ and ± 0.02 respectively, and $\pm 0.3\%$ for the positronium fraction.

We now present the salient characteristics of the different spectral forms of the annihilation radiation that emerges from the different phases of the ISM; this will serve as a guide in the determination of the relative contributions of the different phases. The annihilation spectra for the different ISM phases can be characterized by the sum of three components: a narrow line due to the annihilation of thermalized positrons (except in the hot phase where the line is broad: a width of 11 keV), a broad line emitted by the annihilation of positronium formed in flight, and an ortho-positronium continuum.

Table 3 summarizes the spectral characteristics of the annihilation emission in the different phases. The widths of the 511 keV line listed in this table were extracted from Table 3 of GJG05. The relative intensities of the different components (R_i)

Table 3. Spectral characteristics of the annihilation radiation in the different phases. Γ_n and Γ_b are the width ($FHWM$) of the narrow and broad annihilation line, respectively. R_n , R_b and $R_{3\gamma}$ are the relative flux of the narrow line, broad line and ortho-positronium, respectively. f_{Ps} is the fraction of positronium. Values of R_i and f_{Ps} in the different phases were calculated using the fraction of positronium formed in flight and the annihilation rates tabulated in GJG05. The measured spectral characteristics are shown for comparison. They were calculated using the best-fit values of the free parameters of the “Independent model” (Table 1) and the “ISM model” (Table 2).

Phase	Γ_n (keV)	Γ_b (keV)	R_n (%)	R_b (%)	$R_{3\gamma}$ (%)	f_{Ps} (%)
Molecular	1.71	6.4	8.4	16.7	74.9	88.8
Cold	1.56	5.8	4.3	17.4	78.3	94.1

and the fraction of positronium (f_{Ps}) for each phase were calculated using the fractions of positronium formed in flight in each case and the annihilation rates tabulated in GJG05 (see Tables 2 and 4 therein), assuming $x_{gr} = 0$. Since annihilation in dust grains is significant only in the hot phase (see Sect. 2.2), we also calculated the spectral characteristics (Γ_i , R_i and f_{Ps}) of the annihilation emission from this phase with $x_{gr} = 1$. The spectral characteristics obtained by the best-fit models are also shown for comparison. They were calculated using the results presented in Tables 1 and 2 of the present paper. By comparing the relative intensities R_i of the annihilation features in each phase with the measured ones, we can conclude that the annihilation emission from a single phase cannot explain the measured spectral characteristics. A combination of annihilation emission from several phases is needed.

In the warm ionized phase, $\approx 87.4\%$ of positrons annihilate after thermalization, forming positroniums by radiative recombination with free electrons, while the remaining positrons annihilate directly with free electrons. In both annihilation processes, the width of the 511 keV line (0.98 keV) can explain the narrow line component of the measured spectrum (Figs. 4 and 5). There is no formation of positronium in flight in this phase since the totality of H is ionized, thus no broad line is emitted. In the warm neutral phase, 94% of positrons form positroniums in flight; one-fourth of them annihilate producing a 511 keV line emission with the 5.8 keV width required to explain the broad line component observed in the SPI data. The remaining $\approx 6\%$ of positrons thermalize and have sufficient kinetic energy to form positroniums by charge exchange with H atoms – one-fourth of these positroniums annihilate producing a narrow ($\Gamma_n = 1.16$ keV) but weak ($R_n \sim 1.2\%$) 511 keV line. Consequently, the total positronium fraction in the warm neutral phase is $\approx 99.9\%$.

Combining 49% of annihilation in the warm neutral phase with 51% of annihilation in the warm ionized phase as derived by the best-fit of the phase fractions yields $\approx 94\%$ total positronium fraction and the measured relative fluxes R_i . The broad line component with the required width can also be due to the annihilation of positroniums formed in flight in cold gas. However, most of the thermalized positrons annihilate directly with H in this phase (the temperature is too low in the cold gas to allow the formation of positronium by charge exchange), and therefore the total fraction of positronium is only due to the positroniums formed in flight ($\approx 94\%$). Consequently, annihilation emission from the cold gas alone, or even combined with the annihilation emission from the warm ionized phase cannot (1) reproduce the measured positronium fraction and (2) explain the shape of the annihilation spectrum. However, a mix of annihilation emission from the cold gas and the warm neutral phase both combined with $\approx 51\%$ of annihilation emission from the warm ionized phase can reproduce the measured spectrum. This explains the uncertainty values on the cold and warm neutral phase fractions obtained by the best fit (see Table 2). Similar conclusions hold for the contribution of the annihilation emission from the molecular medium, which in addition is characterized by (1) narrow and broad 511 keV line widths that are both slightly larger than the cold phase's, and (2) a positronium fraction lower than those of the cold gas and the warm phase (see Table 3). These differences significantly reduce the possible contribution of the molecular medium to the best-fit model. For the hot phase, the widths of the calculated annihilation line, with or without grains, are too broad and the positronium fraction too low for this phase to contribute substantially in the model.

4. Discussion

Our analysis suggests that Galactic positrons annihilate primarily in the warm phases of the ISM. A similar conclusion was reported in previous analyses (Harris et al. 1998; Churazov et al. 2005). Since positron annihilation takes primarily place in the Galactic bulge region (Knödseder et al. 2005), we now compare the current knowledge about the ISM in this area (i.e., within ~ 600 pc radius of the Galactic Centre, corresponding to an approximative bulge size of 8° FWHM) with our results.

4.1. Gas content in the Galactic bulge

The gas content in the Galactic center region is not well known. The gas content of the Galactic bulge as well as its influence on the morphological and spectral characteristics of annihilation emission are under study and will be presented in a future paper (Gillard et al. in preparation). Launhardt et al. (2002) analysed IRAS and COBE data and showed that the nuclear bulge (region inside a Galactocentric radius of ≈ 230 pc with a scale height of ≈ 45 pc) contains $7 \times 10^7 M_\odot$ of hydrogen gas (the mass of $2 \times 10^7 M_\odot$ quoted in their paper has to be corrected by a factor 3.5; Launhardt, private communication).

Launhardt et al. (2002) also argued that roughly 90% of the interstellar mass in this region is trapped in small high-density ($\sim 10^4 \text{ cm}^{-3}$) molecular clouds with a volume filling

factor of a few %, while the remaining $\sim 10\%$ is homogeneously distributed and constitutes the intercloud medium with an average density $\sim 10 \text{ cm}^{-3}$ and probably a high ionization fraction. From radio observations, Mezger & Paul (1979) deduced a mass of HII gas in this region of $1.4 \times 10^6 M_\odot$ with an electron density $n_e \sim 10 \text{ cm}^{-3}$ and an electron temperature $T_e \sim 5000$ K. Observations of the 21 cm line yield a HI mass of $3.1 \times 10^6 M_\odot$ in this region (Rohlfs & Braunsfurth 1982). The mass of H_2 in the nuclear bulge is estimated by subtracting this HI mass and the HII mass derived from the model of Lazio & Cordes (2003)² from the total mass of hydrogen gas measured by Launhardt et al. (2002).

The rest of the gas in the Galactic bulge is contained in the asymmetric Galactic bar. Its shape can be approximated by an ellipsoid with semi-major axis ~ 1.75 kpc and semi-minor axes ~ 0.6 kpc (Bissantz et al. 2003). The interstellar gas is not uniformly distributed across the bar, which makes its mass difficult to estimate. Mezger et al. (1996) derived a mass of HI gas $\sim 4 \times 10^7 M_\odot$ in the bar from far infra-red and C^{18}O line observations. We can reasonably assume that the HI gas mass is equally distributed between cold and warm neutral gases, as in the Galactic disk (Ferrière 1998). Based on ^{13}CO observations (Combes 1991) and a recent value of the abundance ratio $^{13}\text{CO}/\text{H}_2$ (Martin et al. 2004) we estimate a mass of H_2 gas $\sim 2 \times 10^7 M_\odot$ in the bar.

For the warm and hot ionized phases we consider the volume inside 600 pc for which the Galactic free-electron density model of Lazio & Cordes (2003) yields an HII gas mass of $\sim 2 \times 10^6 M_\odot$. We assume that 90% of this mass is in the warm ionized phase and 10% in the hot phase, similar to the proportion found in the Galactic disk (Ferrière 1998).

From this mass model and the rough geometrical distribution of the gas in the Galactic bulge region, we derive the space-average densities $\langle n_i \rangle$ of the five interstellar phases. Since gravity is stronger in the Galactic bulge than near the Sun, we expect the gas to be more compressed there than locally. We then estimate the true density n_i of each phase in the bulge by multiplying its true density $n_{i,\odot}$ measured near the Sun³, by a common ‘‘compression factor’’ f_c , whose value is set by the requirement that $\sum_i \Phi_i = 1$, where $\Phi_i = \langle n_i \rangle / n_i$ is the volume filling factor of phase i . This requirement leads to $f_c = \sum_i \langle n_i \rangle / n_{i,\odot} \approx 3.6$, and hence to the densities and filling factors listed in Table 4. The true density obtained for the molecular gas with this method is in agreement with the observations of Launhardt et al. (2002), Martin et al. (2004) and Stark et al. (2004).

If positrons are generated uniformly in the Galactic bulge and annihilate in situ (i.e. without propagation) then, in stationary conditions, the phase fraction f_i of each phase must be equal to its filling factor Φ_i . In this case, one would expect the hot medium to be the dominant component. However, in a

² The mass of HII derived from the model of Lazio & Cordes (2003) is in agreement with the measurements performed by Mezger & Paul (1979).

³ with $n_{i,\odot} = 1000, 40, 0.4, 0.21$ and $3.4 \times 10^{-3} \text{ cm}^{-3}$ in the molecular, cold, warm neutral, warm ionized and hot phase respectively (Ferrière 1998).

Table 4. Estimates for the Galactic bulge parameters and resulting consequence on the lifetime and diffusion of 1 MeV positrons (see text). $\langle n \rangle$ and n are the space-averaged and true densities, respectively. Φ is the volume filling factor. $l/2$ is the typical half-size of the phase. K_{ql} is the energy threshold above which the quasilinear diffusion is valid. Δt_{ql} and d_{ql} are the time taken and the distance travelled by positrons in quasilinear diffusion regime. Δt_{coll} and d_{coll} are the time taken and the maximum distance travelled by positrons in the collisional diffusion regime. d_{ann} is the maximum distance travelled by thermalized positrons. τ_{ann} is the lifetime of thermalized positrons. d_{max} is the total distance travelled by positrons ($d_{\text{max}} = d_{\text{ql}} + d_{\text{coll}} + d_{\text{ann}}$). The lifetime for thermalized positrons in the hot phase was calculated assuming a normal abundance of interstellar grains ($x_{\text{gr}} = 1$).

0.01 cm^{-3} density hot medium, 1 MeV positrons thermalize in $\sim 4 \times 10^6$ years and then annihilate on a timescale $\sim 10^8$ years if there are no interstellar grains in this phase; in the standard grain model the annihilation timescale is $\sim 10^7$ years (GJG05). With such long timescales it is likely that positrons escape the hot medium (before they can annihilate), either by propagation or following an encounter with a supernova shock wave (timescales ~ 0.5 –1 Myr; Cox 1990). Positrons escaping the hot medium then have a high probability of entering a warm phase due to the large filling factor of this phase (cf. Table 4). If such positrons annihilate in the warm phases, then the phase fractions between the warm neutral and warm ionized phase should be close to the relative values of their filling factors. In order to verify whether positrons escape a given ISM phase or not, it is necessary to estimate the distance they travel within this phase and compare it with the typical half-size of the phase.

4.2. Propagation of positrons

The distance travelled by positrons depends on their initial velocity and their energy loss rate, which is a function of the density and the ionization fraction of the ambient medium. The timescale for 1 MeV positrons to thermalize in a warm medium is $\tau_w \approx 10^5$ years. Positrons then annihilate with a timescale $\approx 3.4 \times 10^4$ years in the 0.8 cm^{-3} density warm ionized phase.

In the 1.5 cm^{-3} density warm neutral gas, positrons that do not form a positronium in flight by charge exchange with H, take $\approx 1.3 \times 10^4$ years to annihilate. Typical sizes of warm and hot regions are $l_w \sim l_h \sim 100$ pc. Roughly speaking, positrons will escape the hot phase if the distance travelled by diffusion in a time $\tau_h \sim 10^7$ years (slowing down time plus annihilation time in the standard grain model) is greater than the typical half-size of hot region, $l_h/2 \sim 50$ pc, i.e., if the diffusion coefficient D is greater than $D_{\text{min}} = \frac{l_h^2}{24\tau_h} \sim 1.3 \times 10^{25} \text{ cm}^2 \text{ s}^{-1}$. On the other hand, positrons that enter the warm phases will annihilate if the distance travelled by diffusion in a time $\tau_w \sim 10^5$ years is less than $l_w/2 \sim 50$ pc, i.e., if D is smaller than $D_{\text{max}} = \frac{l_w^2}{24\tau_w} \sim 1.3 \times 10^{27} \text{ cm}^2 \text{ s}^{-1}$. These limits have to be compared with the quasilinear diffusion coefficient (Melrose 1980) which can be expressed as:

$$D_{\text{ql}}(E) = D_B \left(\frac{r_L}{\lambda_{\text{max}}} \right)^{1-\delta} \eta^{-1} \quad (5)$$

with $D_B = \frac{1}{3} r_L v$ the Bohm diffusion coefficient, r_L the positron gyroradius, v the positron velocity, λ_{max} the maximum scale of the turbulence, $\delta = 5/3$ for a Kolmogorov turbulent spectrum, and $\eta = \delta B^2 / \langle B \rangle^2$ the relative perturbation in magnetic field pressure which is often approximated to 1, since the turbulent component of the ISM magnetic field has been estimated to be of the same order of magnitude as the regular magnetic field.

The magnetic field strength in the Galactic Centre region was estimated to be $\sim 10 \mu\text{G}$ (Sofue et al. 1987; La Rosa et al. 2005). The maximum scale λ_{max} was estimated to be ~ 100 pc from measurements of ISM turbulence (Armstrong et al. 1995). Then for 1 MeV positrons in the Galactic bulge, $D_{\text{ql}} \sim 3 \times 10^{26} \text{ cm}^2 \text{ s}^{-1}$. This coefficient is well above D_{min} and below D_{max} and leads support to our hypothesis that positrons indeed escape the hot phase and subsequently annihilate in the warm phases.

However, quasilinear diffusion is valid only when positrons are in resonance with Alfvén waves. This condition is satisfied when:

$$\gamma\beta > \frac{m_p v_A}{m_e c} = 12.85 \times 10^{-3} \frac{B_{\mu\text{G}}}{\sqrt{n_{\text{cm}^{-3}}}} \quad (6)$$

with γ the Lorentz factor, $\beta = \frac{v}{c}$, m_p the proton mass, m_e the positron mass and v_A the Alfvén speed.

When the kinetic energy of positrons drops below a given threshold K_{ql} , quasilinear diffusion theory breaks down and the diffusion regime changes. K_{ql} is calculated for each phase using Eq. (6) together with $B = 10 \mu\text{G}$ and the densities given in Table 4. The slowing down times Δt_{ql} for 1 MeV positrons to reach K_{ql} are listed in Table 4 as well as the associated distances d_{ql} which are obtained by:

$$d_{\text{ql}} = \sqrt{\int_{K_{\text{ql}}}^{1 \text{ MeV}} 6D_{\text{ql}}(E) \left(\frac{dE}{dt} \right)^{-1} dE}. \quad (7)$$

The distances d_{ql} are lower than or of the same order as the typical half-sizes of the corresponding phases (see Table 4) except for the hot gas.

The diffusion regime of positrons with kinetic energies below K_{ql} is uncertain (interstellar winds, resonance with other plasma waves...) and is currently under study (Marcowith et al., in preparation). However we can estimate an *upper-limit* to the distance d_{coll} travelled by these positrons assuming that they propagate in a *collisional* regime. In this case, the distance is given by:

$$d_{\text{coll}} = \sqrt{\int_{E_{\text{lim}}}^{K_{\text{ql}}} 6D_{\text{coll}}(E) \left(\frac{dE}{dt}\right)^{-1} dE}, \quad (8)$$

where E_{lim} is the lowest kinetic energy for which positrons are able to form a positronium in flight by charge exchange in the molecular, cold and warm neutral phases or are thermalized ($E_{\text{lim}} = \frac{3}{2}kT$) in the warm ionized and hot phases (charge exchange does not happen in these phases since all the hydrogen is ionized). $\frac{dE}{dt}$ is the energy-loss rate. Accounting for the streaming of positrons in the ISM, at a characteristic velocity $\sim v_A$, we write the diffusion coefficient $D_{\text{coll}}(E) = v_A \times \lambda_{\text{coll}}(E)$ where $\lambda_{\text{coll}}(E)$ is the distance over which interactions gradually deflect positrons with kinetic energy E by 90° . λ_{coll} was calculated according to Lang (1974) for a fully ionized plasma and using the approach of Emslie (1978) for neutral hydrogen. When positrons are thermalized, the distance d_{ann} they travel before annihilation is given by:

$$d_{\text{ann}} = \sqrt{6D_{\text{coll}}\tau_{\text{ann}}} \quad (9)$$

where τ_{ann} is the annihilation lifetime of thermalized positrons. The resulting values of $d_{\text{max}} = d_{\text{ql}} + d_{\text{coll}} + d_{\text{ann}}$ (see Table 4) confirm that 1 MeV positrons injected in the hot phase should escape it, while those injected in other phases should annihilate in them. Since positrons leaving the hot phase most likely enter the warm phases (due to their large filling factors) we expect that positron annihilation occurs mostly in the warm phases.

It has to be noted that several authors (see Morris & Serabyn 1996, and references therein) estimate magnetic field values of ~ 1 mG in the Galactic centre region. This is 2 orders of magnitude larger than the value ($10 \mu\text{G}$) used in our study. If we assume that this value is effective everywhere in the Galactic bulge, then this increases v_A by 2 orders of magnitude and rules out quasilinear diffusion in the warm and hot phases for 1 MeV positrons (see Eq. (6)). Consequently, we can only derive upper limits to the distances travelled by positrons in these phases, by assuming that they propagate in a collisional regime. Here again, a detailed investigation of the diffusion of positrons in a non-quasilinear regime is required to derive relevant distances of propagation.

4.3. Initial kinetic energy of positrons

The above estimates on the transport of positrons are based on the assumption that their initial kinetic energy is 1 MeV, which is a typical value for positrons emitted by radioactive nuclei. The actual mean energy of positrons from ^{56}Co , one of the proposed candidates for the source of Galactic positrons, is 0.6 MeV. Figure 6 shows the maximum distance $d_{\text{max}} = d_{\text{ql}} + d_{\text{coll}} + d_{\text{ann}}$ travelled by positrons before annihilating as a

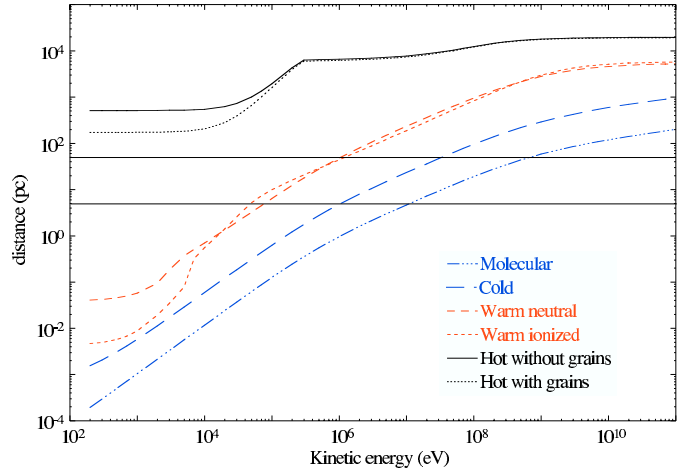

Fig. 6. Maximum distance travelled by positrons as a function of their kinetic energy. Typical half-sizes of warm and hot regions (~ 50 pc) and typical sizes of cold and molecular regions (~ 5 pc) are shown for comparison.

function of their initial kinetic energy in a $10 \mu\text{G}$ magnetic field. The conclusions derived above, assuming 1 MeV positrons, obviously hold for positrons with $E < 1$ MeV even for the hot phase. Positrons with initial kinetic energy above ~ 1 MeV would escape the warm and hot phases and would then have a chance to annihilate in molecular clouds provided they do not escape the Galactic bulge. However, the 1 MeV limit should not be considered as very constraining, since it was derived using rough estimates for the size of each phase (see Table 4). Moreover, we have to keep in mind that the calculated distances d_{max} quantify the spatial extent of the distribution of annihilating positrons around the source. Then the fraction of positrons produced in a warm phase with initial energy of e.g. 2 MeV that escape this warm phase to annihilate in cold or molecular clouds, would probably be sufficiently low to be in agreement with the phase fractions derived by the spectral analysis, since most of these positrons would annihilate in the warm phase.

In our discussion, we have assumed that positrons are generated uniformly in the Galactic bulge. This assumption is valid in the case of numerous positron sources, including light dark matter annihilating into electron-positron pairs (Boehm et al. 2003). However, such positrons should have an initial kinetic energy lower than a few MeV to explain the measured spectrum. Other possible uniformly distributed sources in the Galactic bulge are type Ia supernovae, novae and low mass X-ray binaries, all of which belong to the old stellar population. However, these sources produce their own warm and hot phases by heating the surrounding ISM, so that they do not inject positrons in cold atomic and molecular regions.

Low energy (< 1 MeV) positrons produced in the warm phase probably stay in this phase and annihilate at a distance $\lesssim 50$ pc from the sources. When such positrons are produced in the hot medium, they are likely to leave this medium and enter the warm phase within which they will annihilate. Then, assuming that the typical size of the hot phase does not exceed ~ 200 pc and that positrons are produced at the edge of this

phase, then the maximum distance covered by such positrons is $\lesssim 250$ pc from the source. Therefore a single source releasing positrons in a warm or hot region (e.g. a gamma-ray burst as suggested by Parizot et al. 2005) might have difficulty accounting for the observed spatial extent of the annihilation emission, which covers a radius ~ 600 pc around the Galactic centre.

5. Conclusions

The positron-electron annihilation emission spectrum can be explained by narrow and broad 511 keV lines plus an ortho-positronium continuum. The detection significance of the broad line is $\approx 3.2\sigma$. The broad line width of (5.4 ± 1.2) keV *FWHM* is in agreement with the value calculated by GJG05 for positronium formed in flight by charge exchange with H (≈ 5.8 keV). This value is also in agreement with the width (≈ 5.3 keV) calculated by Churazov et al. (2005). The narrow line width is (1.3 ± 0.4) keV *FWHM*. This width is consistent with the ≈ 1 keV width of positrons annihilating by radiative recombination in the warm ionized medium.

Galactic positrons seem to annihilate mostly in the warm phases of the ISM. These results are in agreement with conclusions of Harris et al. (1998) and Churazov et al. (2005). We estimate that $\approx 50\%$ of the annihilation emission comes from the warm neutral phase and $\approx 50\%$ from the warm ionized phase. The contribution of molecular clouds and the hot phase are less than 8% and 0.5%, respectively. We cannot exclude from our spectral analysis that a significant fraction ($< 23\%$) of the emission comes from cold gas. However in view of the gas content of the Galactic bulge, this fraction is expected to be negligible.

A preliminary study of the interstellar gas content and positron propagation in the Galactic bulge shows that the phase fractions derived from the spectral analysis are in agreement with the relative filling factors of the warm and low temperature gases. The lack of detection of annihilation in molecular and cold atomic gases could be explained by their low filling factors. The spectral analysis suggests comparable amounts of annihilation in the warm neutral and warm ionized phases of the ISM. This is in good agreement with our expectation if the positron sources are uniformly distributed and if the initial kinetic energy of positrons is lower than a few MeV, otherwise they may escape the warm phase of the ISM and annihilate in molecular or cold atomic regions.

Despite its large filling factor, positrons do not annihilate in the hot gas because its density is low enough to allow them to escape. Using quasilinear diffusion theory and assuming a magnetic field $\sim 10 \mu\text{G}$ in the Galactic bulge, we estimate that, down to low kinetic energies, positrons are generally confined in warm and cold regions. In the hot phase, they should be less confined and assuming that they are released in a collisional regime when their kinetic energy drops below ~ 270 keV, they have sufficient kinetic energy to escape it. However, the diffusion regime of positrons with keV energies in a hot low-density plasma is not yet known. More detailed studies on the Galactic bulge gas content and on the diffusive regime of positrons as a function of their energy and the magnetic field strength are under way and will be presented in forthcoming papers.

According to the rough gas model described in Sect. 4, we expect the warm ionized component to dominate the annihilation emission in the nuclear bulge, while the warm neutral component should dominate in the Galactic bar. Additional exposure will make it possible to perform spectra in different regions of the Galactic Centre and confirm this prediction.

Our understanding of Galactic positron physics can be improved by imaging and spectroscopic explorations of Galactic regions other than the central regions, particularly by measurements of the annihilation emission from the Galactic disk, which appears to be explainable by ^{26}Al decay (Knödseder et al. 2005). While our understanding of positron annihilation in the Galactic Centre region is limited by the poor knowledge of both the sources and initial kinetic energy of positrons and the gas content in the Galactic bulge, the task would be easier for the disk emission, since: (1) we know that positrons from ^{26}Al are released in the molecular ring region since COMPTEL onboard CGRO measured the spatial distribution of the 1.8 MeV gamma-ray line emitted during the radioactive decay of this isotope; (2) the average energy of such positrons has been measured to be 450 keV; (3) the distribution and characteristics of the gas in the molecular ring region are known with better accuracy than in the Galactic bulge. Consequently, the measured spatial distribution of the annihilation emission from the disk would teach us how far from the sources positrons annihilate and this will lead to estimates of their diffusion coefficient. The spectral characteristics of the disk emission would tell us in what phases of the ISM positrons annihilate. Since much ^{26}Al is located in the molecular ring region, we expect to measure a strong 6.4 keV *FWHM* line component due to the annihilation of positronium formed in flight in H_2 (see Fig. 5 of GJG05). On the other hand, the significance of the annihilation emission from the disk is still weak ($3\text{--}4\sigma$) after one year of the INTEGRAL mission. Additional exposure is needed to allow the spectral analysis to provide constraining results.

Acknowledgements. We are grateful to R.J. Murphy for useful discussions on the energy loss rate of positrons in the ISM. We thank the anonymous referee for suggestions that have improved the quality of this paper.
