Abstract

The fitness effects of new mutations determine key properties of evolutionary processes. Beneficial mutations drive evolution, yet selection is also shaped by the frequency of small-effect deleterious mutations, whose combined effect can burden otherwise adaptive lineages and alter evolutionary trajectories and outcomes in clonally evolving organisms such as viruses, microbes, and tumors. The small effect sizes of these important mutations have made accurate measurements of their rates difficult. In microbes, assessing the effect of mutations on growth can be especially instructive, as this complex phenotype is closely linked to fitness in clonally evolving organisms. Here, we perform high-throughput time-lapse microscopy on cells from mutation-accumulation strains to precisely infer the distribution of mutational effects on growth rate in the budding yeast, *Saccharomyces cerevisiae*. We show that mutational effects on growth rate are overwhelmingly negative, highly skewed towards very small effect sizes, and frequent enough to suggest that deleterious hitchhikers may impose a significant burden on evolving lineages. By using lines that accumulated mutations in either wild-type or slippage repair-defective backgrounds, we further disentangle the effects of two common types of mutations, single-nucleotide substitutions and simple sequence repeat indels, and show that they have distinct effects on yeast growth rate. Although the average effect of a simple sequence repeat mutation is very small (~0.3%), many do alter growth rate, implying that this class of frequent mutations has an important evolutionary impact.

Introduction

Mutations constitute the raw material upon which selection acts. Understanding the properties of new mutations is therefore of central importance to evolutionary biology [1]. For example, the frequency and effect sizes of mutations that increase fitness are key determinants of the rate of evolutionary adaptation [2]. The frequencies of mutations that decrease fitness also impact adaptation, as well as patterns of genetic diversity [3]. In addition, mutational properties are informative of the structure of genetic networks: if a large proportion of mutations affecting a phenotype is non-neutral, then the phenotype can be affected by changes to the function of a large number of genes across the genome, suggesting a high degree of interconnectedness among the gene-regulatory networks operating in the cell. For example, evidence of large numbers of variants affecting complex traits in humans has recently been proposed to support a model of widespread interconnectedness among gene-regulatory networks [4]. The relative contributions of different mutational types (e.g. single-nucleotide substitutions, copy-number variants, repetitive sequence expansions/contractions) to phenotypic differences among organisms is another poorly understood property of mutations. Shedding light on this property is critical not only for understanding a phenotype's propensity to change, but also for selecting appropriate technologies to assay the phenotype's genetic basis [5,6]. Finally, the properties of new mutations are also of interest because of their relevance to human health: *de novo* mutations are thought to constitute a major set of causative variants for many genetic disorders [7], and the rate of small-effect deleterious mutations has been shown to play a significant role in tumor evolution [8].

Mutation-accumulation (MA) lines in model organisms have allowed unbiased exploration of the properties of new mutations. Repeatedly passaging organisms through extreme bottlenecks for many generations allows mutations to accumulate while largely shielded from selection. The phenotypes of these MA lines can then be assayed, revealing the spectrum of mutational effects of new mutations. Studies have used mutation accumulation to probe mutational effects in diverse organisms, but the resulting estimates of typical effect sizes vary widely, even among studies assaying closely related phenotypes in the same species (reviewed in [9,10]). Two culprits likely explain the discrepancies. First, MA studies have historically lacked genotypic information. That is, it was not known how many mutations were present in each strain, let alone how many trait-altering mutations there were. Many studies addressed this issue by assuming a parametric distribution representing a single mutational effect; each MA strain was then modeled as containing a Poisson random number of mutations with an unknown mean. The parameters of the distribution of mutational effects were then jointly fitted with a parameter representing the mean number of mutations present across the MA strains of interest. However, these estimates of mutation rate are difficult to interpret because in most cases the confidence intervals of such estimates have no upper bound (see for example [9,11,12]). This problem is caused in part by the second culprit: noisy phenotype measurements. The identification of small mutational effects depends on the amount of measurement noise. In addition, because estimates of mutational parameters are confounded with each other [11], the lack of a precise mutation rate estimate translates into uncertainty in the estimates of the other mutational parameters, which describe the shape of the effect distribution.

Several recent studies have sequenced MA lines to make independent measurements of mutation rate. The expected numbers of mutations per line for these sequencing-based mutation rates tend to far exceed the expected numbers of non-neutral mutations estimated from phenotypic measurements in MA lines. This observation has led to the conclusion that in most cases, the majority of substitutions are neutral or nearly-neutral with respect to the observed phenotype (reviewed in [10]). However, caution must be taken in transferring mutation rate estimates between different MA experiments. There is ample evidence that mutation rate is highly experiment-dependent even within a species, with substitution rates differing with strain ploidy, genetic background, and even the environmental conditions in which the mutation accumulation occurred [13–16]. Recent work using either direct measurement of accumulated mutation number in phenotyped MA lines in *Chlamydomonas reinhardtii* [17], *Drosophila melanogaster* [18], mice [19], and *Escherichia coli* [20] or measuring mutation number and phenotype in parallel MA experiments in a mismatch repair-deficient strain of *E. coli* [21] has provided more precise estimates of the distribution of mutational effect size in these species. For example, Robert *et al.* 2018 [21] and Böndel *et al.* 2019 [17] both show strong evidence for highly leptokurtic (L-shaped, with most mutations having very small effect sizes) distributions of fitness effects in *E. coli* and *C. reinhardtii*, respectively, and Sane *et al.* 2020 [20] identify significant differences in the rate of beneficial mutations between transitions and transversions in *E. coli*.

Interpretation of mean mutational effect sizes is further complicated by the fact that although precise estimates of single-nucleotide mutation (SNM) rate are now available from MA studies across a wide range of organisms and conditions, other frequent mutation types, especially mutations in simple sequence repeats (SSRs), are more difficult to identify using conventional analyses of next-generation sequencing data [22,23]. However, because of their repetitive nature, these regions are particularly prone to acquiring mutations by forming loops during replication (polymerase slippage events), which lead to contraction or expansion of the repeat locus. Recent advances in genome-wide SSR genotyping (e.g. [24]) have allowed high-throughput studies of the effects of SSR variants, which demonstrated that variation in these difficult-to-genotype mutation types contributes significantly to phenotypic variation in nature: thousands of short SSR loci contribute substantially to the variance attributed to common polymorphisms affecting gene expression across human tissues and cell lines [6,25,26], rare variants and *de novo* mutations in SSRs are associated with Autism Spectrum Disorder [27,28], and expression of genes whose promoters contain these repeats diverges more than SSR-free promoters among closely related yeast species [29]. Evidence that mutations in short repeats may contribute significantly to the spectrum of mutational effects is also emerging in MA studies. For example, it has been suggested that the higher estimate of fitness-altering mutation rate in *Dictyostelium discoideum* when compared to other single-celled organisms may be explained by the large number of SSRs in its genome, and the resulting high frequency of expansion/contraction events occurring at these highly mutable loci [9]. More direct evidence comes from estimating the frequency of SSR mutations in MA experiments in *Daphnia pulex* [30]. Selection against SSR mutations was demonstrated by comparing their prevalence in a MA experiment to a control in which selection was active [30]. However, with the exception of that study, little is known about the relative contribution of SNMs as compared to SSR indels and other mutation types to the full spectrum of mutational effects.

Precise and accurate phenotypic measurements are especially important if mutations of small effect dominate. In microbes, batch culture can be used to generate growth rate measurements averaged across tens of millions of cells within a population. However, such measurements can still have appreciable errors, likely caused by the interactions of small biological and technical variations with the exponential growth process: for example, in one study, yeast growth rate measured by optical density in batch culture varied across replicates with a standard deviation of 3% of the mean [31], limiting the ability to detect small mutational effects to strains with the most extreme effects or largest numbers of mutations. Moreover, in laboratory strains of budding yeast, frequently occurring respiration-deficient, slow-growing ‘*petite*’ cells can stochastically bias average growth rates downwards to extents that are independent of the genetic properties of each individual strain [32,33]. We have developed an alternative to batch culture measurements that uses time-lapse microscopy to perform growth rate measurements simultaneously in tens of thousands of microbial microcolonies [34,35]. Because of the highly replicated nature of the assay, it yields very precise estimates of strains’ mean growth rates [35,36].

Here, we combine sequence information, precise growth rate measurements, and modeling to interrogate the properties of spontaneous mutations in yeast. We are particularly interested in three key questions: how frequent are small-effect deleterious mutations, what proportion of the genome affects growth when mutated, and how do the effects of different classes of small mutations affect growth? To answer these questions, we estimate the effects of spontaneous mutations on growth rate, a complex phenotype closely related to microbial fitness, in two sets of MA lines with different mutation spectra. We first show that our microscopy-based growth rate assay allows us to accurately and precisely estimate the net effect on growth of the mutations in each line, notwithstanding stochastic variation in the proportion of slow-growing *petite* cells across the experimental samples. We next use these individual-level growth data along with substitution rate data from MA lines to fit a distribution of mutational effects. Our results demonstrate that the distribution of spontaneous SNMs is highly skewed towards mutations with extremely small effects on growth rate, and that the vast majority of these mutations decrease growth rate in rich media. Finally, we use an additional, slippage repair-deficient set of MA lines to show that spontaneous indels in SSRs significantly affect growth rate. By applying high-throughput phenotyping and integrating genotype and phenotype data into a single framework for fitting mutational effects, we show that the effects of spontaneous mutations accumulated in MA experiments can be parsed into multiple classes and that SSR mutations make important contributions to trait variation, on the order of a quarter of the combined effect of SNMs. Our results underscore the role that deleterious load from a range of mutational types is likely to play in clonal evolution.

Results

Statistical modeling accounts for across-strain variability in the proportion of respiration-deficient (petite) colonies

Our study seeks to infer the effects of spontaneous mutations on yeast growth rate. However, estimating the growth rates of interest is non-trivial. Laboratory strains of *S. cerevisiae* are prone to the spontaneous formation of *petites*, mutants with impaired mitochondrial function that grow

at a slower rate than their non-petite counterparts [32,33]. Variation in petite numbers across samples can arise from chance events that cause different numbers of petites in the original founder populations for each sample. Such variation would impact the mean growth rate estimated in each strain, resulting in estimates that reflect stochastic inter-strain differences in petite proportions, obscuring the genetic effect of mutations on the rate of growth of non-petite cells.

To determine whether differences in petite proportions across MA line estimates could be impacting growth rate estimates, we first tested whether experimental aliquots of genetically similar strains truly differ in the proportion of petite cells. On petri dishes, petite colonies in *ade2-* strains can be identified by color, as they lack the red color typical of mutants in the end stages of the adenine biosynthesis pathway [37]. We therefore assayed the proportion of petites in a set of 18 MA lines described in [38]. Because these strains differed from each other by only ~2 mutations on average, large variation in the proportion of petites across these strains was not likely to be explained by genetic differences among the strains. The line with the highest proportion of non-red colonies had a large proportion of non-petite (large, rapidly growing) colonies that were not red, indicating a decoupling between colony color and respiratory ability; this line was excluded from further analysis. We found significant variation in the proportion of colonies that were red across the remaining lines ($p \ll 0.001$ by likelihood ratio test, see Methods) (**S1A Fig**).

We next sought to determine whether we could accurately estimate the petite proportion in each strain directly from microcolony growth rate data. Unlike batch culture-based measures of growth rate, which estimate population-average growth rates, the output of the microcolony growth rate measurements we performed is a distribution of individual microcolony growth rates for each sample (**Fig 1A**) [35,39]. We therefore can make estimates of the proportion of petites directly from microcolony growth rate data, while simultaneously estimating the mean growth rate of the non-petite microcolonies. We model the distribution of colony-wise growth rates as a mixture of two Gaussian growth rate distributions, with the parameters of the distribution of petite growth rates estimated from independent petite strains derived from the MA ancestor (see Materials and Methods). We found that microcolony assay-derived petite proportions are highly correlated with colony color-based proportion estimates (Pearson correlation coefficient = 0.83), indicating that microcolony growth rate data can be used directly to partition growth rates of petite and respiring colonies. Microcolony assay-based petite proportion estimates are ~4% lower than the colony color-based estimates (**S1B Fig**). This discrepancy may be a consequence of underestimation of the proportion of petites using growth rate data; alternatively, the discrepancy may arise as a result of a small number of non-petite white-colored colonies (which we have seen in these strains [40]). However, because measurements of mutational effect on growth rate are relative to the ancestral strain, a consistent offset in the estimated proportion of petites would result in consistent bias in mean growth rate estimates of all strains, including the ancestor, resulting in accurate estimates of *relative* growth rates.

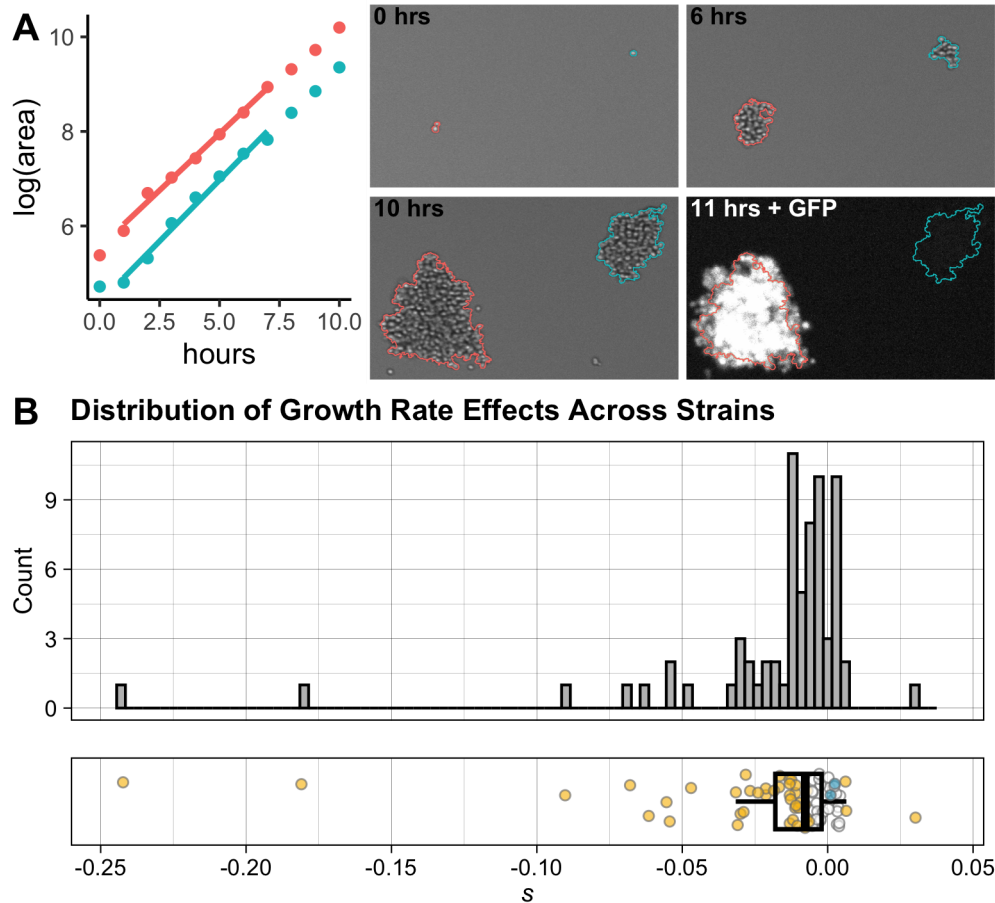

Fig 1. Measuring the cumulative effects of spontaneously accumulated mutations on growth rate across MA strains

(A) The microcolony growth rate assay. Microcolony growth rates are measured in parallel using automated microscopy and image analysis. Fluorescent imaging at the end of the growth period is used to differentiate between the MA strain and the ancestor-derived strain grown in each well as a reference. The brightfield images of three timepoints show automated colony detection for two representative colonies: from a GFP-marked ancestral reference (red) and an MA line (blue), growing side-by-side with different starting sizes and lag times, but at similar rates. A fluorescence image taken after the final timepoint shows the GFP expression in the reference colony. The points on the plot represent $\log(\text{area})$ over a 10 hour time period measured for these colonies, with the best fit used to determine growth rates for each colony (using a 7-timepoint window) shown as a line. (B) Mutation effects (s) in MA lines relative to ancestral reference strain. Points in plot on the bottom are colored yellow if their s value differs significantly from the ancestor at an FDR of 0.05. Blue points represent mutational effects calculated for two control strains derived from independent haploid spores of the ancestral diploid (these are not included in histogram or boxplot calculation). Boxplot shows the 25th and 75th percentiles, and median, of the s value across all MA strains.

Accumulated mutations have primarily negative effects on haploid growth rate

To assess the effects of spontaneous mutations, we first examined the distribution of growth rates of a set of haploid MA lines, each likely harboring a unique set of mutations. These lines are derived from diploid parent strains that accumulated mutations over the course of 2000 generations [31,40,41], accumulating an average of ~8 SNMs each [42] (or ~4 SNMs per haploid strain assayed here). Hall *et al.* reported that 2.5% of these diploid yeast MA strains, and 14% of viable haploid progeny of these strains, had a significant increase in growth rate as compared to the ancestral line [43]. Sequencing revealed that about a fifth of these diploid MA lines harbored aneuploidies [42]; we excluded the progeny of these aneuploid strains from our study to avoid confounding the effects of smaller mutations. We assayed the growth rates of 70 haploid viable MA line progeny (each derived from a single unique diploid parent MA strain) using the microcolony growth assay [34,35,39]. Cells of each MA strain were grown and imaged in independent wells of 96-well plates; each well also contained cells of a reference strain (a GFP-marked haploid line derived from the MA ancestor) to control for well effects on growth (**Fig 1A**). The use of haploid MA lines allows us to assay the effects of any mutations in these lines in the absence of dominance effects.

We are interested in the distribution of the changes in growth rate among MA-derived haploid strains relative to the growth rate of the ancestral strain. We measure these differences as the selection coefficient, s , which is positive when mutations are beneficial (increase growth rate) and negative when they are deleterious:

Equation 1

$$s_{MA} = \frac{g_{MA}}{g_{anc}} - 1$$

where s_{MA} is the selection coefficient representing the combined effect of the mutations in a given MA line on growth rate, and g_{MA} and g_{anc} are the growth rates of the MA and ancestral strains, respectively. We estimate the proportion of petites in each strain by fitting a mixture of Gaussians as described above (and in Materials and Methods), and estimating g_{MA} and g_{anc} as the respective means of the non-petite colony growth rates for the MA and ancestral strains.

Before examining the distribution of MA-line selection coefficients, we first tested the effect of partitioning petite and non-petite growth rates. As expected, modeling colony growth rates in each strain as a mixture of two Gaussians that allows for a subpopulation of petites produces a significantly better fit to the data ($p \ll 0.001$ by likelihood ratio test; see Methods) than simply fitting a single Gaussian distribution to the colony growth rates of each MA line (**S1B Fig**). In addition, the strains subjected to growth rate assays included two non-GFP marked control strains, derived from independent haploid spores of the ancestral diploid; these served as independent controls in the experiment, as their growth rates should be the same as that of the ancestral reference strain. As expected, the confidence interval for the selection coefficient s estimated for each of these strains overlaps 0, indicating that they do not significantly differ in growth rate from the ancestral strain. However, these strains do differ in the proportion of petite

colonies as estimated by our modeling. As a result, if mutational effects are estimated without accounting for petites, these ancestral control strains are incorrectly estimated to have a significant mutational effect relative to the GFP-marked ancestral control (**S1C Fig**). Together, these results support the importance of using modeling to separate the effects of stochastically variable petite proportions across strains from the genetic effects of spontaneous mutations on growth rate.

The distribution of MA-line mutational effects (**Fig 1B, S1 Table**) reveals that the majority of strains contain at least one mutation that alters growth rate, and that mutations tend to be deleterious. At a false discovery rate (FDR) of 0.05, ~4% of strains have a significant increase in non-petite growth rate (positive s value), and 56% have a significant decrease in non-petite growth rate (negative s value) relative to the ancestral strain. The growth-rate differences tend to be small. 37% of strains have an s value between -0.01 and -0.05 (1%-5% decrease relative to the ancestral growth rate), and only 10% of strains have an s value below -0.05 (growth rate decrease below 5%); an additional 9% of strains have significant decreases but with an s value above -0.01 . Only a single strain has an s value of >0.01 .

Modeling reveals distinct distributions of the effects of SNMs and unidentified mutations

We next sought to determine the properties of the distribution of individual mutational effects (DME) whose combined effects were observed in **Fig 1B**. To model the DME, we expanded on the approach proposed by Keightley [11]; in short, individual mutational effects are modeled as drawn from a reflected gamma distribution, with sides weighted to represent the different proportions of mutations with positive vs negative effects on the phenotype of interest. The gamma distribution is advantageous because it captures a range of distribution shapes, from highly peaked to exponential, with only two parameters: here, we use the mean (m) and shape (k) of the distribution. To account for the fact that mutations may be biased in the direction of their effects, the two sides of the reflected gamma distribution are weighted based on q , a parameter representing the proportion of mutations causing a positive effect on the observed phenotype (see <http://shiny.bio.nyu.edu/ms4131/MAModel/> to interactively explore how changes to parameters affect the distribution of mutational effects in MA lines). We treat individual mutations as additive: the net mutational effect in each strain (s_{MA} from **Equation 1**) is the sum of the mutational effects of individual mutations found in that strain. Unlike earlier work, where the number of mutations per strain was not known, here we leverage sequence information to constrain the model. The mean number of non-neutral mutations per strain, U , is modeled as half the average number of mutations in the MA strains' diploid parents [42], corrected with a fitted parameter (p_0) estimating the total proportion of mutations that are neutral with respect to growth rate (**Equation 13**) (note that U has also been used to denote the deleterious rate specifically [44], which here would be $(1-q)U$). The distribution of observed mutational effects in the MA strains, s_{MA} , is therefore modeled as a multifold convolution of the distribution of individual mutational effects.

Although we expected that constraining the model by the known number of mutations per diploid-parent strain would improve fitting, we also considered that there may be a substantial number of mutations missed in the initial sequencing of the MA lines whose haploid derivatives

are phenotyped here. In particular, the analysis in [42] disregarded any repetitive regions, including SSRs, which have a higher mutation rate than the surrounding genome [45]. As a result, the true number of mutations in the MA lines may be the sum of the number of known mutations (almost all SNMs) reported in [42], and of an additional set of ‘unidentified’ mutations, which would include indels in SSR regions. Therefore, in addition to the ‘*SNMs only*’ model described above, we considered three approaches to modeling the distribution of the effects of ‘unidentified’ mutations: the ‘*single DME*’ model, in which both substitution effects and unidentified mutation effects are modeled as being drawn from a single distribution of mutational effects; the ‘*two-gamma*’ model, in which the effects of unidentified mutations are modeled as being drawn from a separate reflected gamma distribution; and a ‘*Gaussian*’ model, in which substitution effects are modeled as a reflected gamma distribution and the combined effects of unidentified mutations in each strain are modeled as a Gaussian distribution. Below, we lay out the properties and justifications for each of these models in more detail, and then present the results of fitting these models to our data.

If there is no fundamental difference in the distribution of effects of ‘unidentified’ mutations and the distribution of SNM effects, it should be possible to model their effects by releasing the constraint on the average number of mutations per strain (essentially the model proposed by Keightley [11], with no constraint on the value of U); the difference between the estimate of U in this model and the estimate of non-neutral mutations estimated by our SNM-only model would provide an estimate for the typical number of unidentified mutations per strain. We fit this model to our data in the ‘*single DME*’ model.

The other two approaches for modeling unidentified mutational effects are rooted in the possibility that SNMs and unidentified mutations have distinct distributions of phenotypic effects, and that our phenotyping data are precise enough to be able to distinguish these two distributions. In this case, the effects of SNMs are described as above in the ‘*SNM-only*’ model, but the DME for unidentified mutations is modeled separately in one of two ways. First, it is possible to model the effects of these mutations as a reflected gamma distribution with an unknown number of mutations (the ‘*two-gamma*’ model). This is the same model described above for SNMs, with the proportion of positive vs negative mutational effects, the shape and mean of the gamma distribution, and (unlike for SNMs) the average number of unidentified mutations with an effect on growth rate all fitted by the model. However, we hypothesized that the parameter estimates from this model would not be very informative due to the confounding between mutation number and mutation effect size/distribution shape when the total number of mutations is unknown, especially because the effects being modeled by this distribution represent an unknown portion of the total observed effects and the rate of non-neutral mutations must be high enough to be consistent with most strains’ differing in growth rate from the ancestral strain.

Considering the lack of information about the number of unidentified mutations in each MA strain, we can instead seek to understand the typical *combined per-strain* contribution of these mutations. To do so, we modeled the combined effects of unidentified mutations in each line as being drawn from a Gaussian distribution with mean μ_{unid} and standard deviation σ_{unid} (‘*Gaussian*’ model). In this model, the σ_{unid} term fits variance not explained by experimental noise or by the distribution of mutational effects fit to SNMs. Although this model is not

informative regarding the parameters of the distribution of single unidentified mutations, it provides useful information regarding the distribution of the cumulative effects of the unidentified mutations on the growth of each MA strain.

In all three cases, the observed growth rate of each MA line is the result of the sum of the effects of its SNMs (whose average number per line is known), its unidentified mutations (whose number is unknown), and experimental noise.

We initially fit all three models, as well as the ‘*SNM-only*’ model that includes only the effects of sequenced substitution mutations, to the mutational effects estimated for each strain (see Materials and Methods for maximum-likelihood estimation procedure, **S1 Table** for the data that was used as input into the models, and **S2 Table** for model results). The Akaike Information Criterion (AIC) score was lowest for the ‘*Gaussian*’ model, suggesting that this model fits the data best, and that the fit of the ‘*two-gamma*’ model was not sufficiently improved to warrant the addition of the extra parameters. We also found that, as expected, it was impossible to interpret the mutational parameter estimates in the ‘*two-gamma*’ model, which has large confidence intervals; this is likely the result of confounding effects among all parameter values when attempting to fit a distribution of individual mutational effects with an unknown total mutation number. Importantly, the significantly improved fit of the ‘*Gaussian*’ model over both the ‘*SNM-only*’ and ‘*single-DME*’ models indicates that our phenotypic data were precise enough to identify the effects of both SNMs and unidentified mutations.

Although our approach of fitting the distribution of mutational effects based on summary statistics of the mutational effects observed in each strain is computationally efficient, it treats uncertainty in the mutational effect estimates for the different strains as uncorrelated; however, in practice, these estimates depend on a number of shared parameters, such as the estimate for the means and standard deviations in growth rate of the reference strain and of petite yeast microcolonies. These dependencies mean the parameter space is likely more constrained than it appears when fitting the model to uncorrelated mutational effect estimates: for example, an overestimate of the mean growth rate of the reference strain would lead to a consistent overestimate of the s value across all slow-growing MA strains. The correlated uncertainty in strain estimates should propagate to the estimates of DME parameters (in this example, likely leading to an overestimate of the mean effect size of a single mutation). Failing to account for the correlated structure of strain estimates can lead to incorrect estimates of uncertainty on DME parameters and of the relative goodness of fits of different models. We therefore repeated the fit to the distribution of mutational effects model using the microcolony growth rate data directly. We limited this analysis to the ‘*SNM-only*’ model and the ‘*Gaussian*’ model, which had the best fit to the summary statistic-based data. Parameter estimates and confidence intervals were very similar to those estimated in the summary statistic-based fit, with slightly less uncertainty in the parameter estimates of the ‘*SNM-only*’ model when using the microcolony data directly (**Table 1, S2 Table**). Consistent with our previous finding, the ‘*Gaussian*’ model, which modeled SNMs and unidentified mutations as having two independent DMEs, provided the best fit to the data ($\Delta\text{AIC} = -10.8$, LRT-based $p = 0.00002$ as compared to the ‘*SNM-only*’ model) (**Table 1, Fig 2A, S2 Fig**).

Model	Parameter		ln(L)	AIC	ΔAIC
SNMs only	k_{SNM} (shape parameter of gamma distribution for SNMs)	1.4×10^{-1} ($7.8 \times 10^{-2} - 4.9 \times 10^{-1}$)	384760.6	-769359.3	--
	m_{SNM} (absolute value of gamma distribution mean for SNMs)	5.0×10^{-3} ($3.4 \times 10^{-3} - 1.4 \times 10^{-2}$)			
	q_{SNM} (proportion of SNMs with positive effect on growth)	10.5% (2.5% – 24%)			
	$p_{0\ SNM}$ (proportion of SNMs with no effect on growth)	0.1% (0% – 63.1%)			
SNMs + unid, ‘Gaussian’	k_{SNM} (shape parameter of gamma distribution for SNMs)	5.5×10^{-2} ($2.0 \times 10^{-2} - 1.8$)	384768.1	-769370.1	-10.8
	m_{SNM} (absolute value of gamma distribution mean for SNMs)	4.1×10^{-3} ($2.0 \times 10^{-3} - 5.5 \times 10^{-2}$)			
	q_{SNM} (proportion of SNMs with positive effect on growth)	6% (0.9% – 26.6%)			
	$p_{0\ SNM}$ (proportion of SNMs with no effect on growth)	5.9% (0% – 94%)			
	μ_{unid} (mean combined effect size of all unidentified mutations within a strain)	-3.3×10^{-3} ($-7.0 \times 10^{-3} - 7.7 \times 10^{-4}$)			
	σ_{unid} (standard deviation of combined effect sizes of all unidentified mutations across strains)	5.5×10^{-3} ($2.7 \times 10^{-3} - 8.6 \times 10^{-3}$)			

Table 1
Properties of DMEs identified by alternative models on full data

A model that accounts for unidentified mutations by fitting a Gaussian distribution representing the effects of these mutations across strains performs better than a model that only accounts for SNMs. Parameter values for each model shown with 95% Confidence Intervals; ΔAIC is calculated relative to the “SNMs only” model.

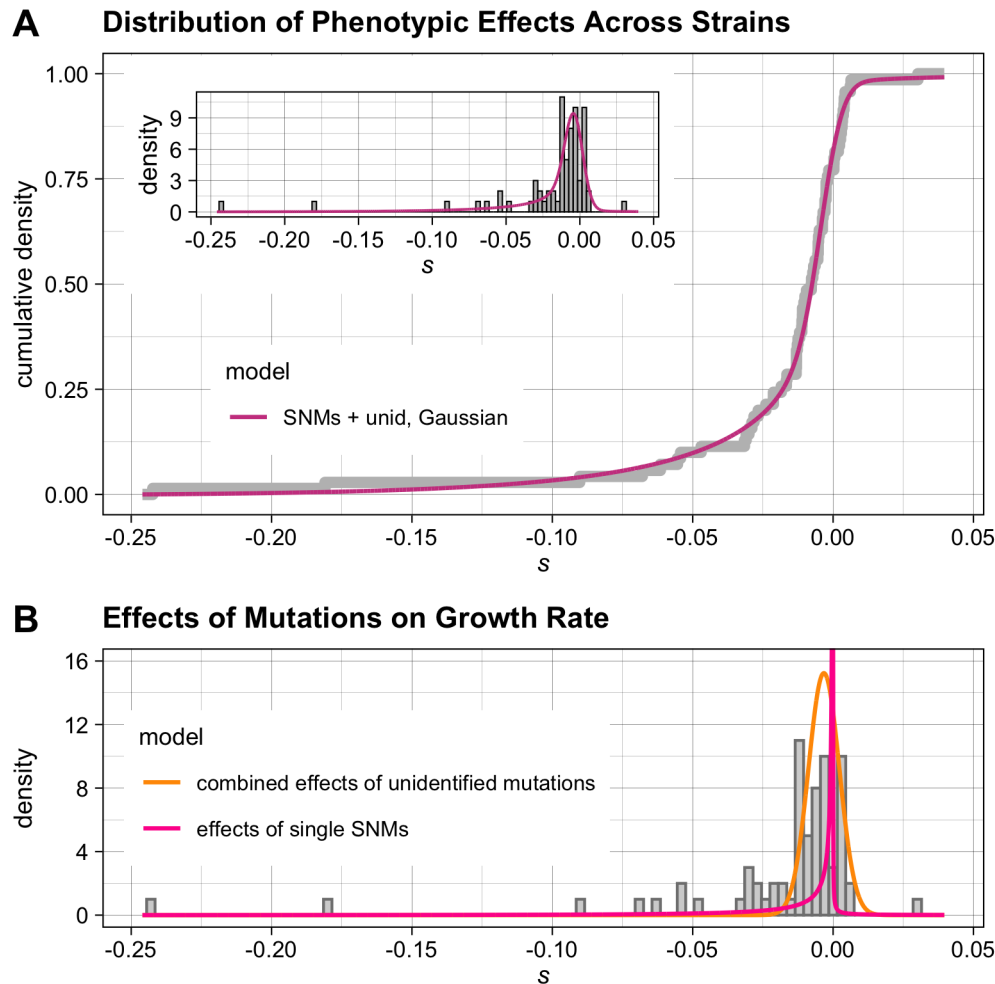

Fig 2. The distributions of mutational effects estimated by a model with independent distributions for sequenced and unidentified mutations

(A) The cumulative density function of the fit of the ‘*Gaussian*’ model (which models SNM effects as a reflected gamma distribution and the sum of all unidentified mutations in a strain as a Normal distribution) to all individual MA strain mutational effects s . Inset: histogram of mutational effects, with probability density function of the model overlaid. To account for the effect of experimental noise on the estimates of s , the model density function is shown convolved with a Gaussian noise kernel with a variance that is the mean of the error variances of each strain’s mutational effect estimate. (B) The distributions corresponding to the maximum likelihood estimates of individual effects of SNMs (pink line) and combined effects of unidentified mutations per strain (orange line) plotted over the distribution of MA strain mutational effects.

We find that the vast majority of non-neutral SNMs are deleterious. We further find that the inferred distribution of SNM effects is highly skewed towards mutations with an effect size approaching 0 (**Fig 2B**). As a result, there is large uncertainty regarding the proportion of SNMs that are completely neutral with respect to growth rate; however, at a selection coefficient cutoff

of 10^{-6} (larger than the reciprocal of effective population size for wild yeast populations, which has been estimated to be on the order of 3.4×10^6 [46]) our best-fit model indicates that 3% of all substitutions have a significant positive effect on growth rate, and 39% have a significant negative effect on growth rate. Our model estimates that the mean effect of unidentified mutations across the MA lines is likely to be moderately deleterious, and that the typical combined effect of all the unidentified mutations in an MA line is comparable to the effect of a single SNM.

Spontaneous simple sequence repeat mutations significantly affect growth rate in yeast

Our modeling results strongly suggest that SNMs alone do not account for the full range of phenotypic effects observed in the yeast MA lines tested; likely candidates for the source of these mutational effects are SSR loci. To directly test whether mutations in these loci significantly affect growth rate, we measured growth in a set of MA lines mutant for the *MSH3* gene involved in slippage repair [38]. These strains accumulated mutations over the course of 200 generations, and contain an average of 1.8 SSR mutations each, the majority of which are deletions of a single repeat unit.

We first selected *msh3Δ* mutant MA lines for which we could confidently report the absence of any substitutions outside SSR regions, and where any phenotypic change could therefore be attributed to ‘unidentified’ mutations. After 200 generations of MA, only 15 high-coverage sequenced strains reported in [38] had no known substitutions. Samples of the strains had been frozen every 20 generations throughout the mutation accumulation. We therefore genotyped a subset of strains that had high sequencing coverage, but harbored known substitutions, at the 100-generation point. This analysis resulted in an additional four 100-generation *msh3Δ* MA strains with high coverage and no known substitutions. We selected 18 200- or 100-generation MA strains without known substitutions for growth-rate analysis (**S3 Table**). It is possible that our chosen strains contain an SNM that was missed. However, based on the previously calculated non-SSR substitution rate in these strains (0.004 substitutions/strain/generation) [38], as well as the proportion of each strain’s genome that was either in a repetitive sequence or not sequenced at 10x coverage, we calculate that the total expected number of unidentified non-SSR substitutions across all the phenotyped strains is only ~0.6 mutations. As a result, any significant deviations from the ancestral growth rate in these strains are most likely attributable to the effects of SSR mutations.

Our phenotyping of *msh3Δ* MA lines shows that they include many lines with significant deviations from the ancestor in non-petite growth rate (**Fig 3, S3 Table**). 17% of strains have a significant increase in growth rate, and 44% have a significant decrease in growth rate relative to the ancestral *msh3Δ* strain. Strains with significant mutational effects are found both among the strains that accumulated mutations for 100 generations (3 of 4 strains) and among strains that accumulated mutations for 200 generations (8 of 14 strains). The mean mutational effect across all strains was a decrease in *s* of approximately 0.0024 per 100 generations. Considering the fact that there are ~1.8 simple sequence repeat mutations per 200-generation *msh3Δ* MA strain [38], this change corresponds to a ~0.3% mean decrease in growth rate per SSR mutation. Importantly, the low average number of mutations in each strain, combined with the high proportion of strains

with a detected mutational effect on growth rate, suggests that many SSR mutations (at least one third of them) are not neutral.

Fig 3. Mutational effects of simple sequence repeat mutations

Mutation effects (s) of *msh3Δ* MA lines relative to their *msh3Δ* ancestor. Points in plot on the bottom are colored yellow if their s value differs significantly from the ancestor at an FDR of 0.05.

Discussion

The distribution of mutational effects determines key properties of a trait's evolution. We sought to understand three critical aspects of the characteristics of new mutations: the frequency of deleterious mutations that cannot be effectively purged from adaptive lineages during clonal evolution; the proportion of the genome that affects growth when mutated, which may be a proxy for the interconnectedness of genetic networks in the cell; and the contributions of different mutation types to growth effects, an important consideration for future approaches to studying evolutionarily relevant genetic diversity. We used MA lines of the budding yeast *Saccharomyces cerevisiae* to estimate the distribution of the effects of spontaneous mutations on growth, a complex phenotype that contributes substantially to microbial fitness. By combining precise measurements of growth phenotypes with genotypic information, we found that SNMs do not account for all the observed mutational effects, and that an additional set of mutations outside of this commonly investigated mutational class, indels in SSR loci, makes a significant (but smaller) contribution to mutational effects on growth rate. We also found that the distribution of spontaneous substitution effects in yeast is highly skewed towards extremely small effects, consistent with other recent estimates of mutational effects performed across a range of organisms (e.g. [17,21]).

Our work provides multiple lines of evidence that a class of frequent mutations besides single-nucleotide substitutions has significant effects on growth phenotypes in yeast. Our modeling of 2000-generation phenotypic effects suggests that the unidentified mutations whose

effects we are detecting have typical combined effect sizes per strain similar to the average effect size of a single substitution. The exact estimate of the contribution of these mutations may be affected by the choice of the parametric distribution of mutational effects used in the model. However, this result matches closely with the mean effect of non-substitution mutations measured directly in the 200-generation *msh3Δ* slippage-repair-deficient mutation accumulation.

Mutations in SSRs are the most likely candidate for the identity of the non-substitution mutations underlying the inferred and observed growth rate effects in the 2000-generation and *msh3Δ* MA experiments, respectively. Our previous estimates suggest that in the 200-generation *msh3Δ* MA experiment, SSRs are mutated at a rate of ~ 0.9 loci per genome per 100 generations [38]. These mutations are likely relatively frequent in wild type strains as well: although estimates of the SSR spontaneous mutation rate vary widely, our work suggests that it may be up to half of the rate observed in the *msh3Δ* background [38]. However, SSRs were masked in the original sequencing analysis of the 2000-generation MA lines used here [42], as is commonly done due to the difficulty of accurately identifying SSR mutations using conventional variant-calling approaches [24]. Although other mutation types, such as large chromosomal rearrangements and aneuploidies, are likely to have strong phenotypic effects, strains with potential aneuploidies were excluded from our analysis, and segmental duplications are very rare: rates in diploid yeast are on the order of $\sim 1 \times 10^{-5}$ duplications per cell division [14,42], suggesting that they are unlikely to have occurred in even one of the 200-generation *msh3Δ* MA strains assayed here. Therefore, the most likely explanation for the high number of significant changes in growth rate observed among these strains is that they are the result of fitness consequences of SSR mutations. In combination with documented effects of SSR mutations and variants on gene expression in yeast [29] and humans [6,25–28], and the finding that SSR length is selectively constrained in laboratory populations of *Daphnia* [30], our study underscores the importance of looking beyond genic substitutions in studies aimed at understanding the phenotypic effects of mutations.

An important question addressed by our study concerns the frequency of mutations affecting complex traits and fitness (these traits' genomic target size). If a large proportion of mutations alter a trait value, it suggests that cellular networks are highly interconnected, because changes to genes in many pathways affect the trait [4]. Fitness is rightly seen as the ultimate interconnected trait [47], and the number of mutations affecting growth rate likely serves as a close lower bound of the number affecting fitness itself. However, estimates of the target size for fitness differ substantially. For example, Lynch *et al.* [48] estimate that 0.1–1.8% of all mutations have 'discernible' fitness effects in *S. cerevisiae*. This low estimate, however, is at odds with our results. Although the overall rate of substitutions in the MA strains assayed here was independently estimated from sequencing data, the number of those mutations that had an effect on the phenotype in question was fit as a parameter in our model: the proportion of SNMs that are neutral ($s = 0$). This parameter can be interpreted in terms of the genomic target size for our phenotype of interest: mutations in $(1 - p_0)$ of the genome result in effects on growth rate in rich media. Our maximum-likelihood estimate of p_0 is 6%, which implies that the majority of SNMs are non-neutral. In addition, estimates based on the maximum-likelihood parameter values of the DME suggest that $>40\%$ of SNMs would be visible to selection in the wild, where yeast

population sizes are on the order of 3×10^6 [46]; the effective population sizes are even larger in typical laboratory evolution experiments, in which N_e of $>10^8$ are common (e.g. [49,50]).

The uncertainty in the estimate of the genomic target size is important to consider with respect to the shape of the DME. Recent studies of mutational effects in *C. reinhardtii* and *E. coli* that also utilized mutation-number information found, as we did, that the DME is skewed toward very small effects [17,21]. It is therefore important to determine whether these very small effects are real or are based on faulty inference from noisy data. Unlike other parameters we estimated, the estimate of p_0 has a very large uncertainty that allows both possibilities: although the maximum-likelihood estimate of 6% suggests that very few SNMs are completely neutral, its 95% confidence interval ranges from 0 to 94% of SNMs. Any amount of measurement noise makes it difficult for a model to differentiate very small-effect mutations from zero-effect mutations. Nonetheless, other considerations lead to the conclusion that neutrality is limited. Despite the uncertainty in the proportion neutrality among individual mutations, we find that a large proportion of MA strains (~60%) deviate significantly from their ancestor in growth rate, although most contain only ~4 SNMs, providing evidence that non-neutral mutations must be relatively frequent. Furthermore, our work suggests that a large number of mutations in SSRs have a significant effect on fitness: despite the fact that the average SSR mutation number in the *msh3Δ* MA strains assayed here is ~1.5 (with ~20% of strains expected to have no mutations at all), ~60% of these strains have detectable changes in growth rate relative to their ancestor. Overall, our results indicate that mutations affecting fitness are very common, both among SNMs and additional unidentified mutations.

We also demonstrate that the vast majority (73%–99%) of non-neutral spontaneous substitutions affecting growth rate in rich media are deleterious. This result is consistent with most previous studies of the distribution of mutational effects on fitness phenotypes [9,17,31,51]. In our experiments, growth rate was assayed in rich media in which laboratory yeast are commonly propagated. The high proportion of deleterious mutations suggests that the strain used is already well-adapted to these growth conditions.

A key goal of mutation accumulation studies is that the distribution of mutational effects gleaned from these experiments would shed light on constraints affecting the speed and direction of evolution. The low frequency of mutations increasing fitness identified in such experiments—including the present one—often precludes a detailed analysis of the properties of mutations that may be selected for in the course of evolution. Nonetheless, the distribution of mutations with deleterious effects on fitness is informative. During clonal evolution—long bouts of which occur in many microorganisms, as well as during tumor development—deleterious mutations have a direct effect on evolutionary trajectories due to the prevalence of mutational hitchhiking. When beneficial mutations are rare, they often appear in individuals harboring a number of deleterious mutations. As a result, the 'fittest' individuals after a bout of clonal evolution often contain numerous deleterious mutations. Studies of cancer evolution show that these hitchhikers can have a significant effect on evolutionary trajectories, and may explain phenomena such as spontaneous cancer remission and tumor heterogeneity [8,52].

Our study can help untangle conflicting evidence regarding the prevalence of deleterious-mutation hitchhiking. A study comparing sexual and asexual evolution in yeast found that evolved asexual lines had significantly lower fitness than sexual lines, an effect attributed to hitchhiking deleterious mutations [53]. In contrast, a study that exhaustively measured the effects of hitchhiking mutations in a set of yeast lines evolved asexually found that only ~3% of these had significantly deleterious effects, with only a single mutation of 116 assayed decreasing fitness by >1%, while ~80% were neutral [54]. Our work can bridge the gap between these results, because it underscores the fact that most mutations are likely deleterious but with very small effects that are below the detection limit of commonly used growth assays. The DME estimated here implies that only 7.5% of all mutations can be expected to have individual effects with an $s < -0.01$ (1% decrease in growth rate), and about half of these would have deleterious effects strong enough to counteract the typical beneficial mutation identified by Buskirk *et al.*, making them targets of selection. However, we would expect another 88% of mutations to have deleterious effects smaller than 0.01 (similar to the 80% reported as neutral), and although the effects of these mutations would not be individually detectable in most assays, their combined effects would significantly decrease the fitnesses of the clones carrying them, consistent with the findings by McDonald *et al* [53]. Thus, robust estimates of the distribution of mutational effects can provide key parameters for interpreting and potentially predicting the results of evolutionary processes.

Materials and Methods

Strains

All strains used in this study are derived from MA lines described in [31,41] and [38]. Briefly, the original lines were created from a haploid strain of genotype *ade2, lys2-801, his3-Δ200, leu2-3.112, ura3-52, ho* that was transformed with a plasmid expressing HO to create a diploid strain homozygous at every locus genome-wide, with the exception of the mating type locus [31]. This strain was then passaged independently in 151 replicates by streaking a single colony every 2 days for ~2000 generations on YPD media ('2000-generation' experiment) [41]. To generate MA lines deficient in SSR slippage repair, the *MSH3* gene was deleted in a strain (*MAT0.a1*) derived from a spore of the diploid ancestor of the 2000-generation experiment, and the resulting strain was passaged independently in 36 replicates as above for ~200 generations [38]. Because respiring *ade2* mutant colonies are red, petites could be detected by their white color and were not passaged to the next generation. To avoid unconscious bias in the passaging procedure, the red colony closest to a pre-marked spot on the plate was chosen at every passage [31] [38].

The haploid 2000-generation *MAH* strains used in this study were created previously: a subset of the MA lines were sporulated, and a random spore of *a* mating type was selected [40,55]. Two *a* mating type spores from a full tetrad derived from the diploid ancestor, *MAT0.a1* and *MAT0.a2*, were phenotyped alongside the 2000-generation *MAH* lines. These two strains were also streaked out onto YPD plates, and six independent white colonies on these plates were picked and used as petite control strains in the 2000-generation growth assays; for the 200-generation assays, three petite colonies from the *MAT0.a1* strain were selected for use as the microcolony phenotyping

assay petite controls.

To construct a GFP-marked ancestral reference strain, a *GFP* gene driven by an *Scw11* promoter was cloned upstream of a *HERP1.1* positive/negative selection cassette [56] that was flanked by two *Cyc1* terminator sequences. This construct was inserted into a neutral locus (*YFR054C* dORF) [34] in either the diploid ancestor or the *msh3Δ* haploid ancestor for the 2000 and *msh3Δ* MA experiments, respectively, and, after selection on hygromycin and genotyping, yeast were re-selected on 50 μg/ml 5-fluorodeoxyuridine. The resulting strain was *YFR054C/YFR054CΔ::pScw11-GFP-Cyc1T* in the ancestral background of the 2000-generation MA experiment, or *YFR054CΔ::pScw11-GFP-Cyc1T; msh3Δ* in the ancestral background of the *msh3Δ* MA experiment. For the 2000-generation experiment, this strain was sporulated, and haploid, GFP-marked, *a*-mating type spores were selected to act as in-well ancestral reference strain controls.

For the *msh3Δ* MA experiment, we previously reported that we have likely identified every substitution in these strains that falls into a region of the genome that was sequenced at 10x or higher and that is not repetitive (telomere, centromere, or long terminal repeat) [38]. We therefore selected 28 ‘high-coverage’ strains in which no more than 10% of the genome was sequenced at <10x or was part of a repetitive sequence, and then selected strains with no further mutations either at the final (200th) generation of MA or at the 100th MA generation.

Growth rate assays

Strains were randomized into 96-well U-bottom plates and stored frozen at –80°C in 20 μL of 50% YPD + 15% glycerol. ‘Petite-only’ control strains were included in each experimental plate. Three days before each growth rate assay, a plate each of MA and reference strains was thawed and 180 μL SC media supplemented with 50 mg/L adenine (SC+Ade) added to each well (adding adenine decreases selection pressure for Ade⁺ phenotypes, including [PSI⁺] cells). After one day of growth in a shaking incubator at 30°C, each strain was diluted 1:10 in SC+Ade in a new plate. The experiment was performed following an additional two days of growth from the resulting saturated cells of each line.

The microscope growth rate assay was performed largely as described in [35]. On the day of the growth rate assay, MA line and reference strains were mixed in a 2:1 ratio and diluted ~1x10⁻⁴-fold with vigorous mixing. For the 2000-generation experiments, in an attempt to identify petite microcolonies directly rather than through statistical modeling, strains were stained with MitoTracker Red CMXRos dye for 10 mins as described in [33], followed by 10⁻⁴ dilution in SC media. However, this treatment was found not to efficiently stain mitochondria in the high-throughput experimental setup used here, so the fluorescence values were not used and the staining was not repeated for the *msh3Δ* MA experiment. The MitoTracker dye does not affect microcolony growth [33]. Cells were imaged hourly for 10 hours in brightfield, followed by a single GFP exposure, as described previously [34]. Image analysis was performed using the PIE software [39]. PIE settings are listed in **S1 File**.

Petite proportion experiments

To independently estimate the proportion of petites in 200-generation *msh3Δ* MA strains, we used a subset of the cells cultured on two experimental days and plated ~200 colonies per plate onto YPD plates. We tested at least three replicates of each strain per experimental day, and the assay was repeated on two different experimental days. Plates were grown for 2 days at 30°C and then left at room temperature for an additional 8 days before counting. Red colonies were counted as wild type, whereas white colonies were counted as petites.

To estimate the significance of variance in non-red colony proportion across strains as measured by the colony color assay, we fit a mixed effect logistic regression to estimate the odds of a colony being non-red, with strain as a random effect. We compared this model to one without the strain effect by a likelihood ratio test.

To estimate the significance of the improved fit of the individual line effect model when accounting for the existence of petites in the 2000-generation MA experiment, we compared likelihoods of a ‘full’ model, in which MA strain growth rates were estimated as described in **Equation 3** below, to a model in which all petite proportions were set to 0, meaning that MA strain growth rates were estimated as a Gaussian with a common standard deviation across all MA strains and a strain-specific mean.

Outline of parameter estimation

We are interested in identifying the values of the parameters of the DME, θ_{DME} , based on a set of observations of colony growth (here generally denoted O). Within a single strain i , this probability is the convolution of the probability of mutational effect S_i (e.g. as defined in **Equation 1**) being drawn from a DME with parameters θ_{DME} , and the probability of the set of observations of strain i given s :

Equation 2

$$P(O_i | \theta_{DME}) = P(S_i = s | \theta_{DME}) * P(O_i | s)$$

where $*$ denotes convolution. The overall likelihood of θ_{DME} is the product of all the likelihoods over strains i , and is maximized by maximizing the sum of the log likelihoods across all strains, as discussed in detail below.

Below, we first outline the computation of the probability of colony growth observations given s . We then describe the computation of the distribution of mutational effects for different classes of candidate probability functions. We present two ways in which we combined these two functions (one summary statistic-based, and one jointly performing the likelihood computation across every individual observation) to calculate the total likelihood of a set of θ_{DME} values given a set of growth observations. Finally, we briefly describe the computational methods used to perform likelihood maximization. Note that parameters in θ_{DME} are described in **S2 Table**, and other parameter names used in this section are listed in **S4 Table**.

Computation of the likelihood of single-strain growth rate observations

In this section, we describe the calculation of the probability of making growth observations of a strain given its mutational effect, $P(O_i|s)$. We discuss the need to account for the fact that growth rate distributions consist of populations of both respiration-deficient (petite) and respiring colonies, as well as for the substantial batch effects in growth rate estimation. We show that using the differences in growth rates between randomly paired MA and reference strain colonies as the observations of interest allows us to account for both factors in a computationally efficient manner.

Accounting for petites

The colonies of a single strain consist of two distinct subpopulations that grow at different rates. The first subpopulation, constituting the majority of the population, consists of cells with a strain-characteristic growth rate for each strain i (μ_i) and with a standard deviation that we model with a parameter that is common to all strains within a MA experiment ($\sigma_{nonpetite-bio}$). Each population also contains a smaller proportion of petite colonies, which have lost the ability to respire and grow at a lower rate than their non-petite counterparts in fermentation conditions. We model these petite cells as having a common mean growth rate (μ_{petite}) and standard deviation ($\sigma_{petite-bio}$) across all strains. Experimental data show that the strains in our experiment vary in the proportion of petites, ρ_i . Therefore, we model the growth rate, g , of each colony a of strain i as being drawn from the distribution:

Equation 3

$$g_{ai} \sim (1 - \rho_i)N(\mu_i, \sigma_{nonpetite-bio}^2) + \rho_i N(\mu_{petite}, \sigma_{petite-bio}^2)$$

The setup of the growth rate assays described in this paper is such that ρ_i may vary among strains for non-biological reasons: after the completion of the mutation accumulation, the strains are passed through a relatively narrow bottleneck before being frozen, followed by 6–8 generations of subculture. As a result, ρ_i may vary as a result of jackpotting events rather than underlying biology. Because of this, we chose to focus on understanding mutational effects affecting μ_i , not ρ_i , such that **Equation 1** can be restated as

Equation 4

$$s_i = \frac{\mu_i}{\mu_{anc}} - 1$$

Note that although ρ_i is not the focus of our study, it is important to estimate this strain-specific proportion of petites in order to accurately estimate μ_i , and it is therefore estimated for each strain as part of our model fitting.

Accounting for batch effects and colony measurement noise in experimental setup

The growth rate assay is performed in batches. In the assay for the 2000-generation experiment, each MA strain is assayed in a single well on an experimental plate, with a total of 14 experimental plates assayed. In the assay for the *msh3Δ* experiment, each MA strain is assayed in three wells per plate, and the ancestral strain is present in 9 wells per plate, with a total of 10 experimental plates assayed. For each well, growth rates were typically obtained for ~500 microcolonies of the strain being assayed as well as ~500 microcolonies of a single GFP-marked reference strain.

Previous work has shown that the experimental organization can result in significant batch effects across wells within a plate and across plates (which correspond to experimental days) [36]. These batch effects can be accounted for in the context of a mixed effect model:

Equation 5

$$\mathbf{g}^{obs} \sim N(\vec{\mu}, \Sigma)$$

Where \mathbf{g}^{obs} is the vector of measured (observed) growth rates, μ is the vector of mean growth rates and Σ is the covariance matrix of colony growth rates derived from the block design.

Colonies from ‘petite-only’ samples can be analyzed in the above way. However, as described in **Equation 3**, the growth rates of MA and reference strains are described by bimodal distributions with an unknown proportion of petites, complicating the computation of the likelihoods of observing specific growth rates.

If random batch effects are additive on the growth rate scale, then their effects can be eliminated by calculating the difference in growth rate between a reference strain colony and an MA colony that share the same experimental plate and well. For example, consider the *observed* growth rates, g_{ai}^{obs} and g_{bj}^{obs} , of two colonies a and b of MA strain i and reference strain j , respectively, growing in the same microscope plate k , in well l . The genetic component of the growth rate of each colony is distributed as described in **Equation 3**: two sources of measurement error are responsible for the difference between observed and ‘genetic’ growth rates: ε_{kl} , which is the sum of the batch effect of the plate and well in which the colonies are grown (with standard deviations σ_{plate} and σ_{well} , respectively) and an independent and identically distributed (iid) measurement noise across colonies (with standard deviation σ_{col}):

Equation 6

$$\begin{aligned} g_{ai}^{obs} &= g_{ai} + \varepsilon_a + \varepsilon_{kl} \\ g_{bj}^{obs} &= g_{bj} + \varepsilon_b + \varepsilon_{kl} \\ \varepsilon_{a,b} &\sim N(0, \sigma_{col}^2) \\ \varepsilon_{kl} &\sim N(0, \sigma_{plate}^2) + N(0, \sigma_{well}^2) \end{aligned}$$

(note that indices kl were left off of g_a and g_b , respectively, to streamline notation).

Because the colony measurement terms ε_a and ε_b are iid random variables, we can subsume them into a combined noise term that includes both the biological variation in colony growth rates and the independent cross-colony measurement noise:

Equation 7

$$\begin{aligned}\sigma_{nonpetite}^2 &= \sigma_{col}^2 + \sigma_{nonpetite-bio}^2 \\ \sigma_{petite}^2 &= \sigma_{col}^2 + \sigma_{petite-bio}^2\end{aligned}$$

This eliminates the ε_a and ε_b terms from **Equation 6**, although it also means that we are not able to independently estimate the biological and measurement noise components of petite and nonpetite colony growth variance.

Next, subtracting the growth rates of colonies a and b from each other yields the formula for the growth rate difference, D , eliminating the random batch effect term ε_{kl} . Thus, by estimating the likelihood of the difference in growth rates between two colonies that share random batch effects, D , we eliminate the necessity of using a mixed effect model to estimate likelihood. Instead, the probability of observing a particular difference in colony growth rates between a same-well colony pair becomes dependent on a mixture of independent normal distributions:

Equation 8

$$\begin{aligned}D &\sim (1 - \rho_i)(1 - \rho_j)N(\mu_i - \mu_j, 2\sigma_{nonpetite}^2) \\ &+ (1 - \rho_i)(\rho_j)N(\mu_i - \mu_{petite}, \sigma_{nonpetite}^2 + \sigma_{petite}^2) \\ &+ (\rho_i)(1 - \rho_j)N(\mu_{petite} - \mu_j, \sigma_{nonpetite}^2 + \sigma_{petite}^2) \\ &\quad + \rho_i\rho_jN(0, 2\sigma_{petite}^2)\end{aligned}$$

We select random pairs of colonies without replacement from an MA strain and the GFP-marked reference strain within each imaging field in each well, and estimate the likelihood of the parameter values above given each pair's difference in growth rates.

The logs of these likelihoods are then added to the sum of the log likelihoods of the petite parameters given each colony growth rate in the petite-only samples to calculate the total likelihood of our data. To identify the maximum likelihood parameter values, we iterate over values of each of the following 'general' parameters: $\mu_{ancestor}$, μ_{petite} , $\rho_{ancestor}$, $\sigma_{nonpetite}$, σ_{petite} , σ_{plate} , σ_{well} ; and find the maximum likelihood parameter values of the MA strain petite proportions ρ_{MA} and selection coefficient s_{MA} for each MA strain (as defined in **Equation 4**). We then find the values of the 'general' parameters that result in the maximum overall likelihood.

In the 2000-generation experiment, the GFP-marked reference strain was treated as the 'ancestral' strain, and indeed this strain did not differ significantly in growth rate from two haploid strains derived from the diploid MA ancestor. In the 200-generation *msh3Δ* experiment,

the in-well GFP reference strain was found to have a different growth rate than the ancestral *msh3Δ* strain, so the s value for each MA strain was estimated relative to the ancestral *msh3Δ* strain.

Computation of the probability density function for the distributions of mutational effects

To jointly estimate the distributions of effect sizes of SNMs and unidentified mutations based on the MA lines, we expanded on a modeling approach developed by Keightley [11,12]. As described in *Results*, we model the distribution of mutational effects as a reflected gamma distribution with shape k and mean m ; the two sides of the distribution are weighted by the proportion of non-neutral beneficial mutations q . The distribution of MA line phenotypes is the convolution of a Poisson random number of single DFE distributions with mean U .

Previous work has found that fitting the model described in [12] is non-trivial due to the significant amount of time required for the numerical integration used to estimate the combined probability density function of mutational effects caused by multiple mutations. Rather than performing multiple numerical integrations, we transferred the computation of the density function into the Fourier domain, as follows.

First, consider a mutation whose mutational effect, Y , is gamma-distributed. We can describe the probability density function (PDF) of observing a mutational effect s of this mutation using its characteristic function (the Fourier transform of the PDF):

Equation 9

$$F_Y(\omega) = \frac{1}{(1 - i\omega \frac{m}{k})^k}$$

where m and k are the mean and shape parameters of the distribution, as described above.

We would like to instead model the distribution of single mutational effects Z as a reflected gamma distribution weighted by q and $1-q$ for positive and negative mutational effects. The characteristic function of Z is then

Equation 10

$$F_Z(\omega) = \frac{1-q}{(1 + i\omega \frac{m}{k})^k} + \frac{q}{(1 - i\omega \frac{m}{k})^k}$$

For a strain with a known number of mutations, n , the combined mutational effect S can be expressed as:

$$S = Z_1 + Z_2 + \dots + Z_n$$

The PDF of S , f_S , is the convolution of n PDFs of Z , and the characteristic function of S in this known-mutation number case is thus

Equation 11

$$F_S^{known\ mut\ \#}(\omega) = \left(F_Z(\omega)\right)^n$$

In our analysis of haploid 2000-generation MA strains, the number of mutations in the strains is not known exactly, even for substitutions. However, the mean number of mutations across the parental diploid strains has been precisely estimated [42]. We therefore treat the number of non-neutral mutations in each MA strain as a Poisson-distributed random variable, N , with mean U :

$$f_N(N = n) = \sum_{n=0}^{\infty} \frac{U^n}{n!} e^{-U}$$

For a set of strains each containing an unknown number of non-neutral mutations drawn from a single Poisson distribution with mean U the characteristic function of the combined mutational effect S observed in the MA strains is therefore

Equation 12

$$F_S^{SNM-only}(\omega) = F_S^{single\ DME}(\omega) = \sum_{n=0}^{\infty} \frac{\left(U F_Z(\omega)\right)^n}{n!} e^{-U} = e^{U F_Z(\omega) - U} = e^{U (F_Z(\omega) - 1)}$$

This equation applies to both the ‘*single DME*’ model, in which U is a parameter estimated by the model, and the ‘*SNM-only*’ model, in which U is a function of $M_{diploid}$ (the mean number of mutations per diploid MA strain) and the parameter p_0 (the probability that any single mutation is neutral, with $s = 0$), which is in turn estimated by the model:

Equation 13

$$U^{SNM-only} = \frac{M_{diploid}}{2} p_{0\ SNM}$$

For the models that treat SNMs and unidentified mutations as being drawn from distinct distributions, f_S is a convolution of the distributions of SNMs and unidentified mutational effects in each strain; thus, for the ‘*two-gamma*’ model described in the text, there are two distinct reflected gamma distributions with different parameters, one for the sequenced SNMs (‘*SNM*’) and one for the unidentified mutations (‘*unid*’):

Equation 14

$$F_S^{two-gamma}(\omega) = e^{U^{SNM}(F_Z^{SNM}(\omega) - 1)} e^{U^{unid}(F_Z^{unid}(\omega) - 1)}$$

and for the ‘*Gaussian*’ model described in the text, the unidentified mutational effects are normally distributed:

Equation 15

$$F_S^{Gaussian}(\omega) = e^{U^{SNM}(F_Z^{SNM}(\omega)-1)} F_N^{unid}(\omega)$$

Where $F_N^{unid}(\omega)$ is the fourier transform of a Gaussian PDF with mean and standard deviations μ_{unid} and σ_{unid} , respectively.

Estimation of the distribution of mutational effects from MA-line-wise summary statistics

One approach described in the Results section for calculating the likelihood of the observed growth data was to first estimate a mutational effect S_i and standard error of the S_i estimate for each 2000-generation MA strain, and then use sampling distributions parameterized by these values as the probability of the observed growth rate differences in **Equation 2**. To calculate the likelihood of the observed results, the distribution of MA line phenotypes (relative to the ancestral strain) is convolved with a normal distribution whose standard deviation is the error estimate based on the confidence intervals of each line's mutational effect S_i , following [11,12], here with an individual strain-specific error estimate derived from likelihood profiles of each strain's mutational effect estimates. In practice, f_s is also convolved with a narrow Gaussian kernel to resolve numerical issues that occur in computing f_s in certain parts of parameter space.

As a result, the characteristic function of the estimated mutational effect of MA strain i , S_i^{est} , is

Equation 16

$$F_{S_i^{est}}(\omega) = F_S(\omega) F_N^{kernel}(\omega|0, 2^{-16}) F_N^{error}(\omega|0, \sigma_{MA_i})$$

Where $F_S(\omega)$ is given by **Equation 12**, **14**, or **15** above, depending on the model.

By computing this convolution in the Fourier domain, and then performing a discrete inverse Fourier transform, we compute the probability density function of estimating a mutational effect given a set of DME parameter values. We then interpolate estimated mutational effects measured in each MA strain, S_i^{est} , (**S1 Table**) within the computed values for this density function to compute the likelihood of each mutational effect estimate. This likelihood is maximized across all parameters shown in **S2 Table**.

Estimation of the distribution of mutational effects from complete colony growth data

To directly jointly estimate the likelihood of observing v differences $D_{i...v}^{(j)}$ in growth rates between each MA strain colony of a single strain i and ancestral reference colony given a distribution of mutational effects f_s , we computed the likelihood of the DME parameters (θ_{DME}), the strain-specific petite proportions, and the 'general' parameters described above ($\theta_{general}$, which includes the mean petite and ancestral strain growth rates, the petite proportion of the reference strain, the standard deviations of petite and non-petite colony growth rates, and random batch effect standard deviations), given the observed set of growth rate differences between random

pairs of MA and reference colonies in each well:

Equation 17

$$\begin{aligned}
 P(\text{observed growth differences} = D_{1\dots v_i}^{(i)} | \theta_{DME}, \theta_{general}, \rho_i) \\
 = \int P(\text{mutational effect } S_i = s | \theta_{DME}) * \\
 \left(\prod_{j=1}^{t_i} \left[P(\text{observed growth difference} = D_j^{(i)} | \theta_{general}, s, \rho_i) \right] \right) ds
 \end{aligned}$$

where $D_j^{(i)}$ is the j^{th} difference observed in strain i , and v_i is the number of observed differences (colony pairs) in strain i .

The integral above was computed using numerical integration, with the individual probabilities inside computed as described above: using **Equation 12**, **14**, or **15** to calculate the PDF over s for the first half of the integral, and **Equation 8** to calculate the probability inside the product. Note that the random variable μ_i from **Equation 8** appears in every term of the product in **Equation 17**, and that the change of variable

$$\mu_i = \mu_{\text{ancestor}} * (1 + S_i)$$

is done before doing the integration in **Equation 17**, also within the product. All of the terms within the integral are initially calculated as log likelihoods and only exponentiated for integration. The log likelihood of the complete set of measurements across strains is computed by summing over all strains the log of the likelihoods as in **Equation 17**; for each term, the strain-specific set of D values is used.

The maximum likelihood parameters were identified by iterating over sets of parameter values in a nested algorithm similar to that described above for strain mutational effects: the maximum likelihood parameter values of ρ_{MA} are identified for fixed values of θ_{DME} and $\theta_{general}$; the maximum likelihood of θ_{DME} are found for a fixed set of values of $\theta_{general}$.

Maximum likelihood parameter value and confidence interval identification

Maximum likelihood parameter values were identified by implementing an interior-point minimization algorithm in MATLAB and minimizing the negative log likelihood [57], using constrained optimization with wide bounds on possible parameter values. Optimization code can be found at <https://github.com/plavskin/MutationEffectEstimation>, and likelihood calculation code can be found at https://github.com/plavskin/GR_diff_DFE. The data and additional analysis code can be found at https://osf.io/h4j9f/?view_only=4229c3876f28477a898acda665fcf33a.

Confidence intervals on all parameter values were calculated using the profile likelihood method following [11], where the value of a single parameter is fixed at various points, and likelihood is

maximized with respect to all other parameters. 95% confidence interval bounds were then identified via quadratic interpolation between points along the parameter of interest to identify the point corresponding to a log likelihood change of ~ 2.5 .

To ensure global likelihood maxima were identified, constrained maximum likelihood estimation was started at multiple points across most parameters. The maximum likelihood parameter search was repeated multiple times, starting at the optimal parameter values from the previous run and additional points in parameter space, until a consistent maximum likelihood value was identified regardless of starting point, and each parameter's log likelihood profiles were monotonically ascending from the left and monotonically descending to the right of the maximum likelihood parameter values.

Acknowledgements

This work was supported in part through the NYU IT High Performance Computing resources, services, and staff expertise; we especially thank Shenglong Wang for support setting up the likelihood estimation code on the NYU High Performance Cluster. We are grateful to Federica Sartori and Cassandra Buzby for comments on this manuscript, and to Dmitri Petrov for helpful discussions.
