Abstract. A stratospheric sudden warming (SSW) is a dynamical phenomenon of the wintertime stratosphere caused by the interaction between planetary Rossby waves propagating from the troposphere and the stratospheric zonal-mean flow. While the effects of SSW events are seen predominantly in high latitudes, they can also produce significant changes in middle and low latitude temperature and winds. In this study we quantify the middle and low latitude effects of SSW events on temperature and zonal-mean winds using a composite of SSW events between 1988 and 2010 simulated with the specified dynamics version of the Whole Atmosphere Community Climate Model (WACCM). The temperature and wind responses seen in the tropics also extend into the low latitudes in the other hemisphere. There is variability in observed zonal-mean winds and temperature depending on the observing location within the displaced or split polar vortex and propagation direction of the planetary waves. The propagation of planetary waves show that they originate in mid–high latitudes and propagate upward and equatorward into the mid-latitude middle atmosphere where they produce westward forcing reaching peak values of $\sim 60\text{--}70\text{ m s}^{-1}\text{ day}^{-1}$. These propagation paths in the lower latitude stratosphere appear to depend on the phase of the quasi-biennial oscillation (QBO). During the easterly phase of the QBO, waves originating at high latitudes propagate across the equator, while in the westerly phase of the QBO, the planetary waves break at $\sim 20\text{--}25^\circ\text{ N}$ and there is no propagation across the equator. The propagation of planetary waves across the equator during the easterly phase of the QBO reduces the tropical upwelling and poleward flow in the upper stratosphere.

Keywords. Meteorology and atmospheric dynamics (general circulation, middle atmosphere dynamics)

1 Introduction

A stratospheric sudden warming (SSW) is a dynamical phenomenon of the wintertime middle atmosphere that involves dramatic reversals of the temperature gradient, zonal-mean winds and meridional circulation in the stratosphere and mesosphere. The mechanism for SSW events, first proposed by Matsuno (1970), involves the upward propagation of planetary waves from the troposphere, which decelerate or reverse the eastward zonal-mean flow in the stratosphere. The planetary waves thus drive the meridional circulation, inducing upwelling (and adiabatic cooling) over the equator and downwelling (warming) over the poles in the stratosphere (Garcia, 1987). The breaking wintertime planetary waves thus act to enhance the Brewer–Dobson circulation. Because of the reversal of the stratospheric jet in mid–high latitudes from eastward to westward, the gravity wave forcing in the polar mesosphere and lower thermosphere (MLT) also reverses during this period due to filtering of westward-propagating gravity waves and penetration of eastward-propagating gravity waves into the mesosphere (Siskind et al., 2007, 2010; Chandran et al., 2011). In the mesosphere the eastward gravity waves drive upwelling and adiabatic cooling at high latitudes and downwelling and adiabatic warming over the equator. The changes in residual circulation in the stratosphere and mesosphere also affect the concentration of atmospheric constituents in the stratosphere and MLT region (Siskind et al., 2007; Manney et al.,

2009, 2011; Marsh, 2011, and references therein). Extensive observational and theoretical studies have shown changes in the troposphere–stratosphere–mesosphere–thermosphere and ionosphere during SSW events (Baldwin and Dunkerton, 2001; Chandran et al., 2011; Goncharenko et al., 2010).

An SSW is defined by the World Meteorological Organization (WMO) as a reversal of the poleward temperature gradient from 60° latitude to the pole accompanied by a reversal of the zonal-mean zonal wind at 60° latitude at or below 10 hPa. While the effects of SSW are predominantly seen at high latitudes, where the changes in residual circulation are magnified due to the smaller area compared to middle and low latitudes, SSW effects can also be seen in middle and low latitudes as well as in the other hemisphere through inter-hemispheric coupling mechanisms (Karlssohn et al., 2009; Kornich and Becker, 2010). Fritz and Soules (1970) showed equatorial cooling in the stratosphere associated with a stratospheric warming using satellite data. Pawson et al. (1995) used a general circulation model under perpetual January conditions to show that SSW events have an impact on the equatorial middle atmosphere. Koder (2006) showed that a warming of the equatorial stratosphere and upper troposphere during an SSW can lead to a suppression of convective activity in the tropical Northern Hemisphere (5–15° N) and enhancement in the tropical equatorial Southern Hemisphere (equator–10° S).

Recently there have been a number of observational studies describing the wind and temperature changes in the middle atmosphere from mid- and low latitude sites. Hoffman et al. (2007) used multiple wind measurements at mid-high latitude sites (75 to 54° N) and characterized latitudinal and longitudinal variability during the SSW events of 2005–2006 and 1998–1999. Hoffman et al. (2007) concluded that the strength of wind reversal decreases with latitude, and they found only weak longitudinal variations in zonal-mean wind and temperature at mesopause heights. However, they found strong longitudinal variations in meridional winds. Yuan et al. (2012) reported changes in mesospheric zonal-mean winds and temperature from lidar observations from a mid-latitude location (Fort Collins, 41° N and 105° W) during the 2009 major SSW event in January. Yuan et al. (2012) found significant anomalies from climatological means with temperature anomalies as low as 30 K from climatological mean and zonal-mean wind turning eastward in the lower thermosphere in a reversal of climatological mean wind profile, which were directly attributed to the SSW. Chen et al. (2012) reported changes in the wind structure during the SSW events of 2000–2001 over Wuhan (30° N) and 2009–2010 over Langfang (39° N) and found variability in wind responses at the two sites. Sathishkumar et al. (2009) also reported low and mid-latitude winds during the SSW events of 1998–1999, 2003–2004, and 2005–2006. Sathishkumar et al. (2009) found differences in the behavior of MLT winds at Tirunelveli (8.7° N, 77.8° E) and Collm (52° N, 15° E) and attributed the differences to variability in local

gravity wave activity during the SSW events. Sathishkumar and Sridharan (2009) also found that the mean meridional wind observed at Tirunelveli (8.7° N) became more equatorward during the 2005–2006 event as compared to the 1998–1999 event. Observations at Gadanki (13.5° N, 79.2° E) have shown increases in the mesospheric temperature and gravity wave activity (Sridharan et al., 2010) and a change in the direction of mesospheric gravity wave propagation from westward to eastward (Nath et al., 2013) during the 2009 SSW. Butler and Polvani (2011) found that SSW events are nearly twice as frequent during El Niño–Southern Oscillation (ENSO) winters than during non-ENSO winters, while SSWs occur with equal probability during El Niño and La Niña winters.

The propagation of planetary waves into the lower latitude stratosphere and mesosphere and their effect on mid- and low latitude winds have also been a topic of recent interest. Matthias et al. (2013) find a continuous band of westward wind extending from the pole to the tropics in the stratosphere during the SSW events of 2009, 2010 and 2012, while no such band exists in 2006. Matthias et al. (2013) attribute the differences between SSW events to increased planetary wave activity between 30 and 50° N. Vineeth et al. (2010) showed a latitudinal connection between low and high latitudes through the presence of a quasi-16-day wave during the 2003–2004 and 2005–2006 SSW and speculated that this might be due to the phase of the quasi-biennial oscillation (QBO). They however concluded that there was wave propagation from the equator to the pole during SSW, which modulates the zero wind line at 10 hPa. Recently Gómez-Escobar et al. (2014), in their study of the response of the tropical stratosphere to SSW, found that tropical cooling during the westerly phase of the QBO persists longer in the upper stratosphere (above 40 hPa), while, during the easterly phase of the QBO, enhanced cooling occurs in the lower stratosphere (below 50 hPa).

In this study, we simulate SSW events between 1988 and 2010 using the specified dynamics version of the Whole Atmosphere Community Climate Model (SD-WACCM) and build a composite of the zonal-mean temperature and winds from all major SSW events during the period of simulation to quantify the temperature and zonal-mean wind anomalies from their climatological means at high (60–90° N), middle (30–60° N) and low latitudes (0–30° N). Using a fully coupled chemistry–climate global circulation model such as WACCM offers a global perspective which can be used to explain the response to SSW events that have been reported from sites at different latitudes (e.g., Hoffman et al., 2007; Sathishkumar and Sridharan, 2009; Yuan et al., 2012). We show the latitudinal response in zonal-mean temperatures and winds during two case studies of the 2006 and 2009 SSW events to compare with the composite from multiple events. Since the QBO is a major source of stratospheric variability in the tropics (e.g., Baldwin et al., 2011) and can modulate the propagation of planetary waves across the tropics

(Ortland, 1997; O'Sullivan, 1997), we investigate differences in planetary wave propagation in the low latitude stratosphere in two winters that are in different phases of the QBO during SSW events. We also investigate the effect of variation in planetary wave propagation in the tropics on the residual circulation and its effect on the tropical stratospheric cooling observed during SSW events. Finally, we show the model-simulated variability in temperature and winds at three locations covering high, middle and low latitudes during the 2006 and 2009 SSW events. We discuss the differences in evolution of the middle atmosphere temperature and wind structure at these sites with respect to their location within the disturbed polar vortex.

2 The Whole Atmosphere Community Climate Model (SD-WACCM)

The version of SD-WACCM (WACCM v3.48) used in this study is a fully coupled chemistry–climate general circulation model, derived from the Community Atmosphere Model (CAM3) developed at the National Center for Atmospheric Research (NCAR). The model domain extends from the Earth's surface to ~ 145 km (4.5×10^{-6} hPa) and has a horizontal resolution of $1.9^\circ \times 2.5^\circ$ (latitude \times longitude). To reproduce observed meteorological phenomena like SSW events, WACCM can be run with the model dynamical and temperature fields in the troposphere and stratosphere constrained by relaxing the horizontal winds and the temperature to GEOS-5.2 reanalysis data from the surface to 40 km. The strength of the relaxation is linearly reduced between 40 and 50 km, such that the model becomes free running above 50 km. This version of WACCM is referred to as specified dynamics WACCM, or SD-WACCM and has been previously used by Marsh (2011) and Chandran et al. (2013b) to study the major SSW of 2006 and the minor SSW of 2012, respectively. SD-WACCM has 88 vertical levels, with a resolution of approximately two grid-points per scale height in the MLT. In this study, we have used SD-WACCM simulations between January 1988 and May 2011 to identify multiple major SSW events. These major SSW events include both vortex displacement and vortex splitting events as well as major SSW events during the west and east phases of the QBO.

Planetary waves and other large-scale waves are resolved in WACCM, while the effect of mesoscale orographic and non-orographic small-scale gravity waves is parameterized (Garcia et al., 2007; Richter et al., 2008, 2010). The Eliassen–Palm (EP) flux divergence due to planetary-scale Rossby waves is determined from the daily output of the model using established definitions (Andrews et al., 1987). The daily output does not include daily values of gravity wave forcing, which are instead inferred as a residual in the transformed Eulerian mean (TEM) zonal momentum budget (Andrews et al., 1987). This approach to determining

gravity wave forcing has been used in analysis of both observations and models (Liu et al., 2009; Chandran et al., 2011). WACCM has been previously shown to reproduce both SSW and elevated stratopause events in long-term climatological simulations with occurrence frequencies close to observations (de la Torre et al., 2012; Chandran et al., 2013a) and hence provides a comprehensive tool for studying the latitudinal response in the mid-atmosphere winds and temperatures.

3 Results

3.1 A composite view of SSW effects on mid- and low latitude temperature and winds

To investigate the effects of SSWs on mid- and low latitude temperature and winds, we make a composite of all major SSWs between 1988 and 2010 from SD-WACCM and compare the differences in the mid- and low latitude temperature and winds with respect to climatological values. The climatological values of zonal-mean temperature and winds are calculated as the 22-year (1988–2010) seasonal average over the winter months of December, January and February. The climatological zonal-mean temperature (T), zonal wind (U) and meridional wind (V) are shown in Fig. 1a, b and c respectively. The normal wintertime separated polar stratopause (Fig. 1a), the eastward zonal-mean stratospheric winds and westward upper MLT zonal winds (Fig. 1b) and the poleward meridional wind in the mesosphere in the Northern Hemisphere can be clearly seen. It should be noted that observations at single site locations during specific winters do not always show the MLT westward wind (e.g., Hoffman et al., 2007; Matthias et al., 2013). The westward MLT wind reversal shown in WACCM climatology, however, agrees with climatological observations at 40° N shown in Yuan et al. (2008) and with zonal-mean winds shown in SSW studies using reanalysis data from MERRA (Chandran et al., 2013a) and ECMWF (Salmi et al., 2011). The radar do not usually report winds above 90 km and hence might not detect the westward MLT wind reversal. Alternatively, the model might not be reproducing local variability in the gravity wave activity and zonal wind profile. The middle panels (Fig. 1d, e and f) in Fig. 1 show the T , U and V composites of major SSW events between 1988 and 2010. To detect major SSW events, we have used the algorithm of de la Torre et al. (2012) and Chandran et al. (2013a). Ten major SSWs between December and February during the period 1988–2010 have been detected using this algorithm. The winters with major SSWs were 1988–1989, 1998–1999, 2000–2001, 2001–2002, 2002–2003, 2003–2004, 2005–2006, 2007–2008, 2008–2009 and 2009–2010. Out of the 10 SSW winters, the 1998–1999, 2003–2004, 2005–2006, 2007–2008 and 2009–2010 SSW winters happened during the easterly phase of the QBO with the others in the westerly

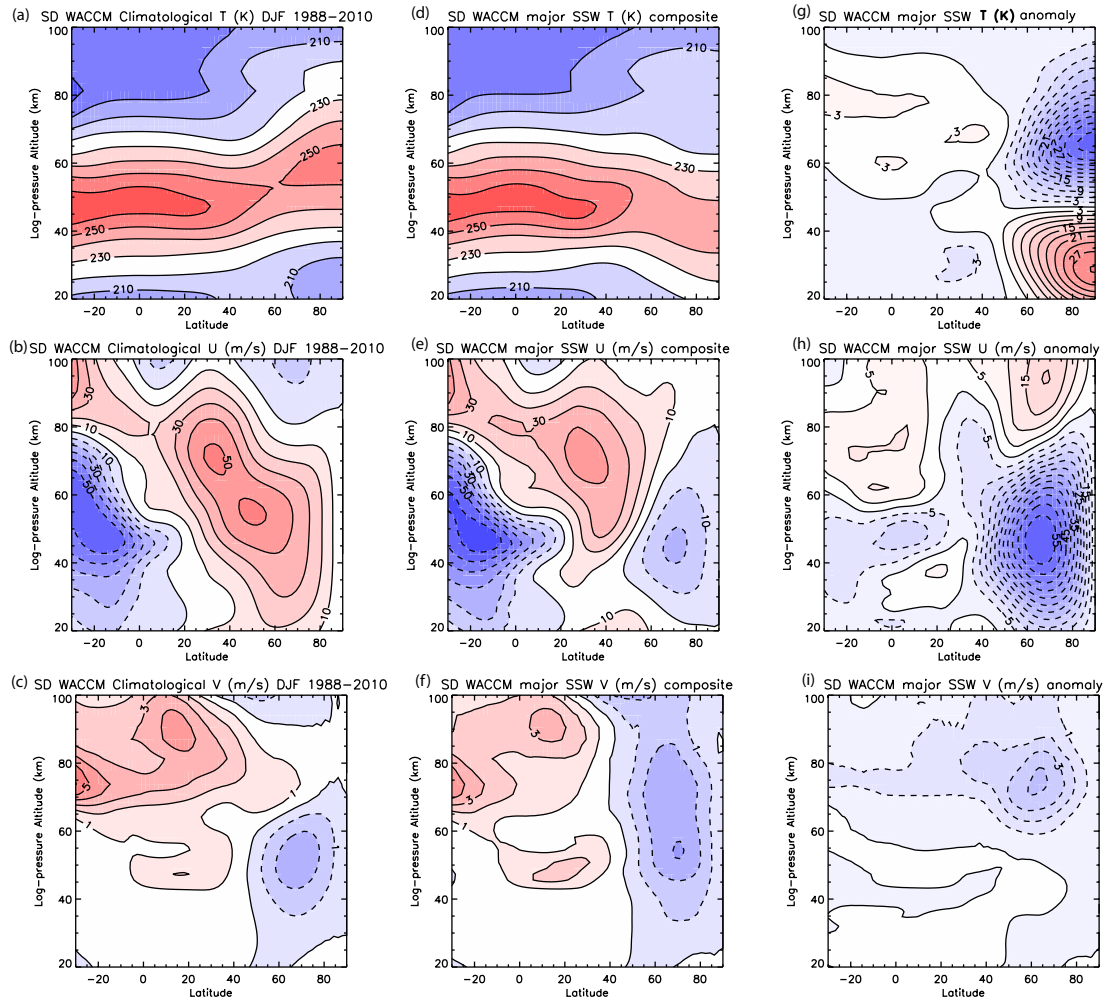

Figure 1. The climatological average zonal-mean (a) temperature (T), (b) zonal wind (U) and (c) meridional wind (V) between December and February from 1988 to 2010, the zonal-mean (d) temperature (e) zonal wind and (f) meridional wind during seven days centered around 10 major SSW events between 1988 and 2010 event and the zonal-mean anomalies from climatological mean during the composite SSW event in (g) temperature (h) zonal wind and (i) meridional wind.

phase of the QBO. To make the composites for zonal-mean temperature and winds, the temperature and wind were averaged for 7 days during the SSW centered on the day of wind reversal at 10 hPa at 60° N. In Fig. 1d, the lowering of the polar stratopause associated with the SSW can be seen along with a reversal of the high latitude polar zonal-mean jet in Fig. 1e from eastward to westward. The pole-to-pole flow in the mesosphere is disrupted at the time of the SSW and the NH polar high and middle latitudes show an equatorward meridional wind in Fig. 1f.

Figure 1g, h and i show the zonal-mean temperature, zonal-mean zonal wind and zonal-mean meridional wind anomaly during the SSW calculated as the difference between the zonal-mean temperature and winds during the SSW from the climatological mean values. In the high latitude regions (poleward of 60° N), the anomalous stratospheric warming and mesospheric cooling can be clearly

seen in Fig. 1g. The stratospheric warming (caused by breaking planetary waves) and mesospheric cooling (caused by reversal in gravity wave forcing in the mesosphere) reach peak values of ~ 30 K in these composite plots. For individual years, the magnitudes can be even larger. In the middle and low latitudes in the stratosphere there is generally a cooling and in the mesosphere there is generally a warming. In the composite plots the maximum magnitudes of warming and cooling are less than 3 K. These alternating warming and cooling cells in the stratosphere and mesosphere are a robust feature associated with branches of the residual circulation changes that are driven by breaking planetary wave gravity waves (Chandran et al., 2014). The zonal-mean wind anomaly plot of Fig. 1h shows large westward wind reversal in the stratosphere poleward of 40° N. In the upper MLT there is a net eastward acceleration of the zonal-mean wind caused by enhanced penetration of eastward gravity waves into this

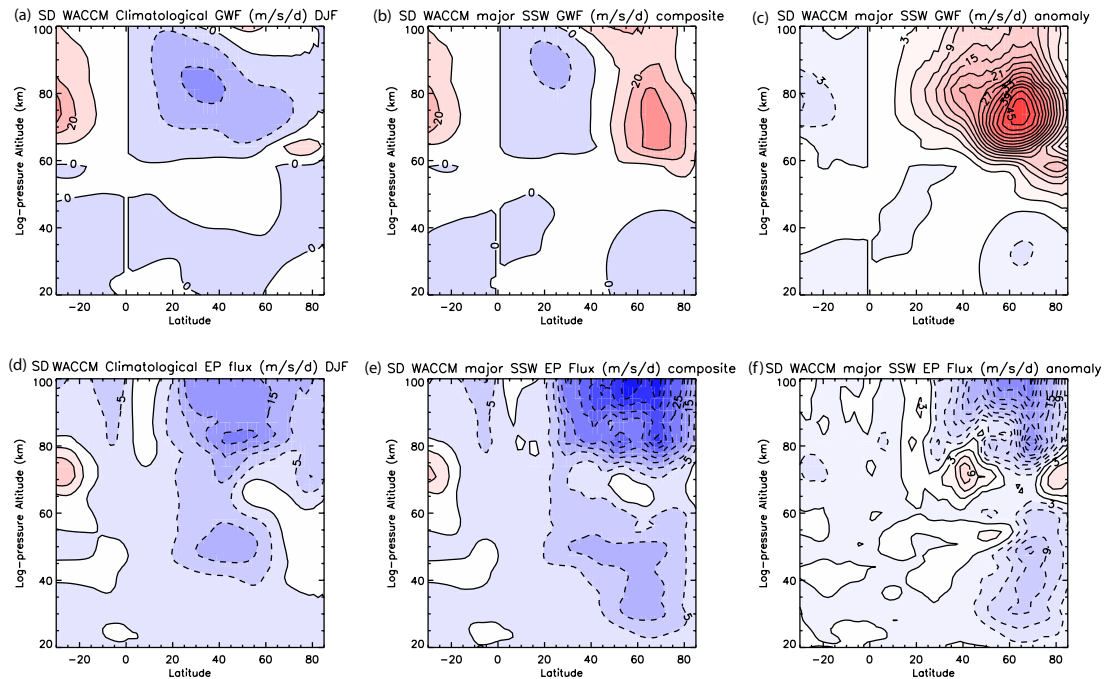

Figure 2. The climatological average zonal-mean gravity wave forcing (top) and Eliassen–Palm flux (bottom panels), respectively, (a, d) between December and February from 1988 to 2010, (b, e) during seven days centered around 10 major SSW events between 1988 and 2010 and (c, f) Gravity wave forcing anomaly calculated as difference during the composite SSW event from the climatological mean.

region. The mesospheric wind, which is normally westward in winter in mid–high latitudes, reverses to eastward during SSW events. Another interesting feature during SSW is the deceleration of the eastward zonal-mean zonal wind between 20 and 40° N in the mesosphere. Below 40 km in the low latitudes (between 0 and 20° N), there is an eastward acceleration of the zonal-mean flow, while above that region (between 40 and 60 km) there is a westward acceleration of the zonal-mean flow and eastward acceleration between 60 and 100 km. The southern hemispheric low latitudes experience a net westward forcing (with \sim peak values of 10 m s^{-1}) of the zonal-mean flow between 40 and 70 km and an eastward forcing in the mesosphere (60–100 km), with peak values between 5 and 10 m s^{-1} . The meridional wind anomaly shown in Fig. 1h shows a deceleration of the middle atmosphere pole-to-pole flow in the Northern Hemisphere and in southern hemispheric low latitudes. The meridional circulation reverses in the northern hemispheric high latitudes and becomes equatorward driven by the gravity wave upwelling there.

In Fig. 2, we show the climatological gravity wave forcing (GWF) in the model averaged over December, January and February (Fig. 2a), the GWF during SSW events (Fig. 2b) and the GWF anomaly at the time of SSW events (Fig. 2c). In the bottom panels, we show the climatological EP flux in the model averaged over December, January and February (Fig. 2d), the EP flux during SSW events (Fig. 2e) and the EP flux anomaly at the time of SSW events (Fig. 2f).

The climatological GWF in the Northern Hemisphere in winter is westward in the MLT (reaching maximum values of $\sim 30 \text{ m s}^{-1} \text{ d}^{-1}$) since the eastward stratospheric zonal-mean wind filters out the eastward waves while allowing the westward gravity waves to propagate up in to the mesosphere. Conversely, the GWF in the Southern Hemisphere is eastward in the MLT due to filtering of westward gravity waves by the eastward stratospheric zonal-mean wind. At the time of the SSW, the reversal of the zonal-mean wind from eastward to westward in the high and mid-latitudes now filters out the westward gravity waves while allowing the eastward gravity waves to propagate into the mesosphere; as a consequence, the GWF in the mesosphere poleward of 40° N becomes eastward, reaching maximum values of $\sim 30 \text{ m s}^{-1} \text{ d}^{-1}$ in the opposite direction, as can be seen in Fig. 2b. The GWF anomaly shown in Fig. 2c is eastward at all latitudes above 10° N, which can be attributed to the enhanced westward acceleration in the zonal wind anomaly shown in Fig. 1h, which filters out more of the westward gravity waves. In the bottom panels from Fig. 2d and e, the EP flux shows enhanced values at the time of the SSW in both the lower stratosphere ($\sim 10 \text{ m s}^{-1} \text{ d}^{-1}$ below 45 km) and MLT ($\sim 45 \text{ m s}^{-1} \text{ d}^{-1}$) compared to climatological values of $\sim 0\text{--}5 \text{ m s}^{-1} \text{ d}^{-1}$ below 45 km and $\sim 15 \text{ m s}^{-1} \text{ d}^{-1}$ in the MLT. This is due to the enhanced planetary wave activity, which causes the SSW. At the time of the SSW, the enhanced EP flux in the MLT may in part be due to in situ

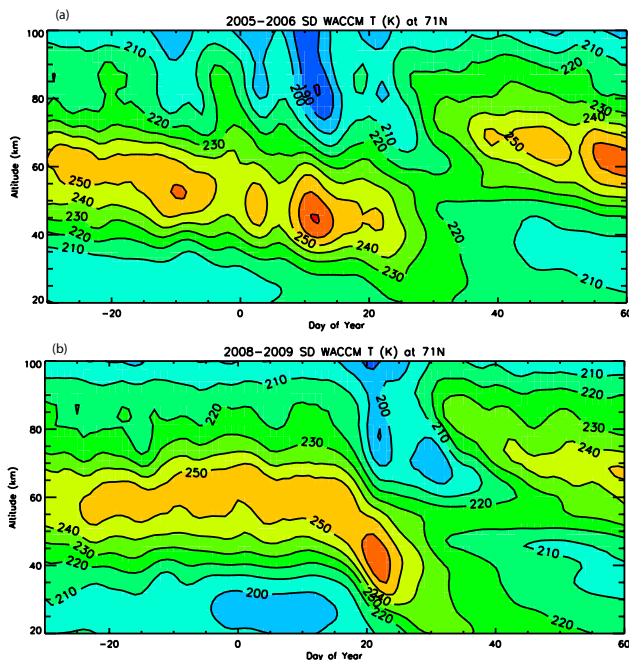

Figure 3. The zonal-mean temperature at 71°N from December to February end with day of year (DOY) 0 representing 1 January, during (a) the Arctic winter of 2005–2006 and (b) 2008–2009.

generation of planetary waves in the upper stratosphere and mesosphere (Chandran et al., 2013b).

3.2 Case studies of different types of SSW during 2006 and 2009

In Fig. 3 we show the zonal-mean temperature at 71°N from December to February, with day of year (DOY) 0 representing 1 January, during the Arctic winter of 2005–2006 (Fig. 3a) and during 2008–2009 (Fig. 3b). These two Arctic winters were characterized by strong SSW events, in January 2006 and January 2009, followed by the formation of elevated stratopause events. Both the 2006 and 2009 SSWs have been studied in great detail (e.g., Manney et al., 2008, 2009; McLandress et al., 2013). While the 2006 SSW was characterized by a vortex displacement, the 2009 SSW was a vortex splitting event. The 2006 event occurred during the easterly phase of the QBO while the 2009 event occurred during the westerly phase of the QBO. In this study we use these two events as case studies to explore the effect of SSW events on mid- and low latitude temperature and winds during the different phases of the QBO.

The peak of the 2006 SSW occurred between 9 and 14 January (DOY 8–13) and the peak of the 2009 SSW between 19 and 24 January (DOY 18–23). Manney et al. (2008, 2009) and McLandress et al. (2013) discuss the 2006 and 2009 SSW events. In Figs. 4 and 5, we show the zonal-mean temperature, zonal-mean wind and meridional mean wind as a seasonal average (December to February) in panels a, b and

c, averaged during the SSW event in panels d, e and f, and the zonal-mean anomalies in temperature, zonal wind and meridional wind calculated as difference between the SSW values from the seasonal mean in panels g, h and i. The seasonal average (from 1 December to 28 February) of zonal-mean temperature, zonal wind and meridional winds (panels a, b and c in Figs. 4 and 5) during 2005–2006 and 2008–2009 are generally similar to the climatological zonal-mean temperature shown in Fig. 1a, b and c. However, there are some significant differences in the zonal wind in 2005–2006. The zonal-mean zonal wind in Fig. 4b for 2005–2006 shows differences from the climatology plot shown in Fig. 1b at low latitudes (between 0 and 20°N) in the Northern Hemisphere below 30 km , where it is westward indicating it is the easterly phase of the QBO. Above that at low latitudes from 30 to 40 km , the wind is eastward. In Fig. 5b, the zonal-mean zonal wind is eastward at 20 km at the equator, indicating it is the westerly phase of the QBO. The zonal-mean wind above this region is westward in the low latitudes. The stratospheric winds in the tropics during the easterly phase of the QBO are weaker than during the westerly phase (Baldwin and Dunkerton, 2001) and hence the climatological plots show tropical stratospheric wind structure similar to the westerly phase of the QBO.

During the SSW period, averaged between 9 and 14 January in 2006 and 19 and 24 January in 2009, the zonal-mean temperature (Figs. 4d and 5d) shows the warming and descent of the polar stratopause and the mesospheric cooling above; the zonal winds (Figs. 4e and 5e) show reversal of the zonal-mean flow at latitudes poleward of 40°N . In 2009, during the westerly phase of the QBO, when the zonal wind in the low latitude (0 – 20°N) stratosphere is westward, the wind reversal during the SSW at mid- and high latitudes links with the low latitude westward wind and results in a band of westward wind in the stratosphere from the equator to the pole. The meridional wind (Figs. 4f and 5f) shows considerable equatorward flow poleward of 40°N in the MLT. In the low latitude (10°S to 40°N) stratosphere breaking planetary waves enhance the poleward flow.

During both SSW events, the temperature anomaly plot (Figs. 4g and 5g) shows the stratospheric warming below 60 km and poleward of 40°N which reaches peak values of $\sim 40\text{ K}$. The mesospheric cooling at these latitudes also shows peak magnitudes of $\sim 45\text{ K}$. In the stratosphere below 60 km , at low and mid-latitudes there is a cooling with peak magnitudes of $\sim 6\text{ K}$ at the equator at $\sim 50\text{ km}$. The cooling region extends into the southern hemispheric low latitudes as well. In the low and mid-latitude mesosphere there is a warming with peak values of $\sim 6\text{ K}$ at 30°N between 70 and 75 km . This anomaly extends into the lower latitudes in the Southern Hemisphere in the 60 – 90 km altitude range.

The zonal wind anomaly with respect to the seasonal mean shown in Figs. 4h and 5h shows patterns similar to the composite zonal wind anomaly shown in Fig. 1h. In the Northern Hemisphere, poleward of 40°N in the upper stratosphere and

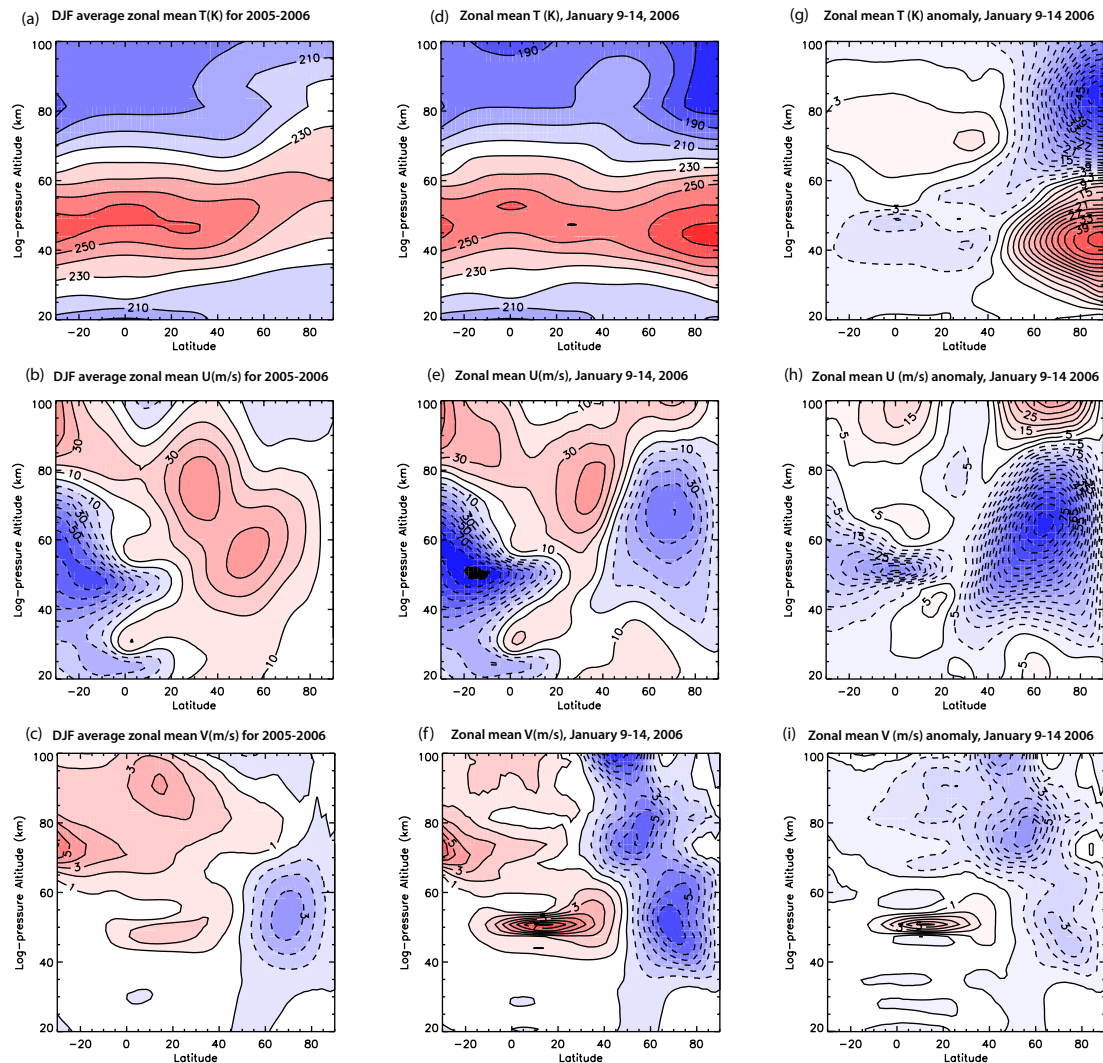

Figure 4. The seasonal average zonal-mean (a) temperature (T), (b) zonal wind (U) and (c) meridional wind (V) between December and February during the winter of 2005–2006, the zonal-mean (d) temperature (e) zonal wind and (f) meridional wind during 9–14 January days centered around 2006 SSW event and the zonal-mean anomalies as difference from climatological mean during the SSW event in (g) temperature (h) zonal wind and (i) meridional wind.

lower mesosphere (between 30 and 85 km), there is a westward anomaly in the zonal wind. In the upper MLT there is an eastward anomaly. Between 20 and 40° N, there is a westward anomaly (or deceleration) of the eastward zonal-mean flow (at peak values of $\sim 5 \text{ m s}^{-1}$ in 2006 and $\sim 20 \text{ m s}^{-1}$ in 2009). In the lower latitudes (between 0 and 20° N), there is an eastward anomaly below 40 km, westward anomaly between 40 and 60 km and eastward anomaly between 60 and 100 km altitudes. The southern hemispheric low latitudes shows a westward anomaly (with peak values of $\sim 25 \text{ m s}^{-1}$) in the zonal-mean flow between 40 and 70 km and an eastward anomaly of the zonal-mean flow in the mesosphere (60–100 km) with peak values between 5 and 10 m s^{-1} . The meridional wind anomaly during the SSW events (Figs. 4h and 5h) shows the equatorward flow in the MLT which

reaches peak values of 7 m s^{-1} at 50° N in 2006 and 9 m s^{-1} at $\sim 40^\circ \text{ N}$ in 2009. This equatorward anomaly extends to the low latitude MLT region and acts to decelerate the pole-to-pole flow in the tropics. The low latitude stratosphere shows a poleward flow (between 10° S to 40° N) driven by the breaking planetary waves.

3.3 Planetary wave propagation during 2006 and 2009 SSWs

To investigate the propagation of planetary waves and the net EP flux divergences before and during the 2006 and 2009 SSW events, we examine the behavior of the quantity $\cos^2 \theta F$, where F is the zonal-mean zonal acceleration due to wave growth or dissipation. The actual EP flux vector,

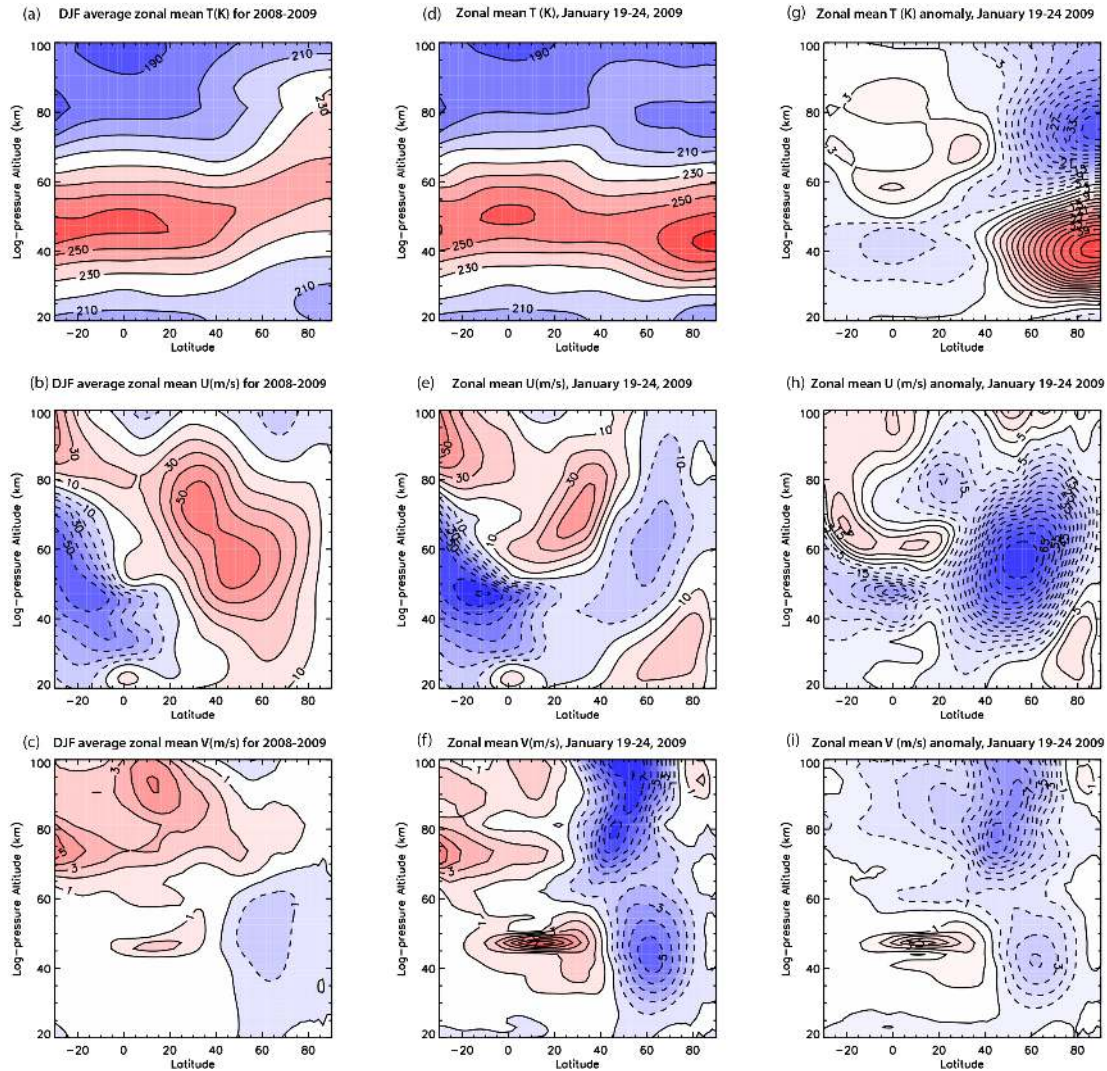

Figure 5. The seasonal average zonal-mean (a) temperature (T), (b) zonal wind (U) and (c) meridional wind (V) between December and February during the winter of 2008–2009, the zonal-mean (d) temperature (e) zonal wind and (f) meridional wind during 19–24 January days centered around 2009 SSW event and the zonal-mean anomalies as difference from climatological mean during the SSW event in (g) temperature (h) zonal wind and (i) meridional wind.

F , cannot in practice be plotted over a deep layer of the atmosphere because it varies by several orders of magnitude between the stratosphere and the MLT. Following Chandran et al. (2013b), F' is a wave activity flux vector, akin to the EP flux. The contours of $\cos^2 \theta F$ will be consistent with the apparent convergence/divergence of F' in the Cartesian coordinate system ($a\theta, z$). F' can be viewed as a tool to visualize qualitatively the propagation and dissipation of wave activity flux over an extended altitude range (Chandran et al., 2013b).

Figure 6 shows F' vectors superimposed on contours of $\cos^2 \theta F$, both averaged over 5–14 January, 2006 (Fig. 6a) and 15–24 January, 2009 (Fig. 6c). This period encompasses the time during which the planetary wave activity reaches its maximum values. The plots on the right (Fig. 6b and d) highlight the propagation of wave vectors in the low latitude

stratosphere, since the wave activity is much weaker in this region and cannot be clearly seen when plotting over the whole latitude range. The zonal-mean zonal wind is plotted as black contours (at 10 m s^{-1} intervals); the red contours indicate the zero wind line. The regions of positive EP flux (red color contours) indicate regions of EP flux divergence or regions of wave sources and the blue regions indicate regions of EP flux convergence or regions of planetary wave breaking. In both the SSW events, it can be seen that the planetary wave activity causing the SSW originates mostly in the mid–high latitudes. The waves propagate vertically upward and equatorward breaking between 40 and 60 km, mostly between 30 and 70° N, causing the reversal of the stratospheric zonal-mean flow. The F' vectors also indicate propagation to the mid-latitude (between 20 and 60° N) MLT region, along

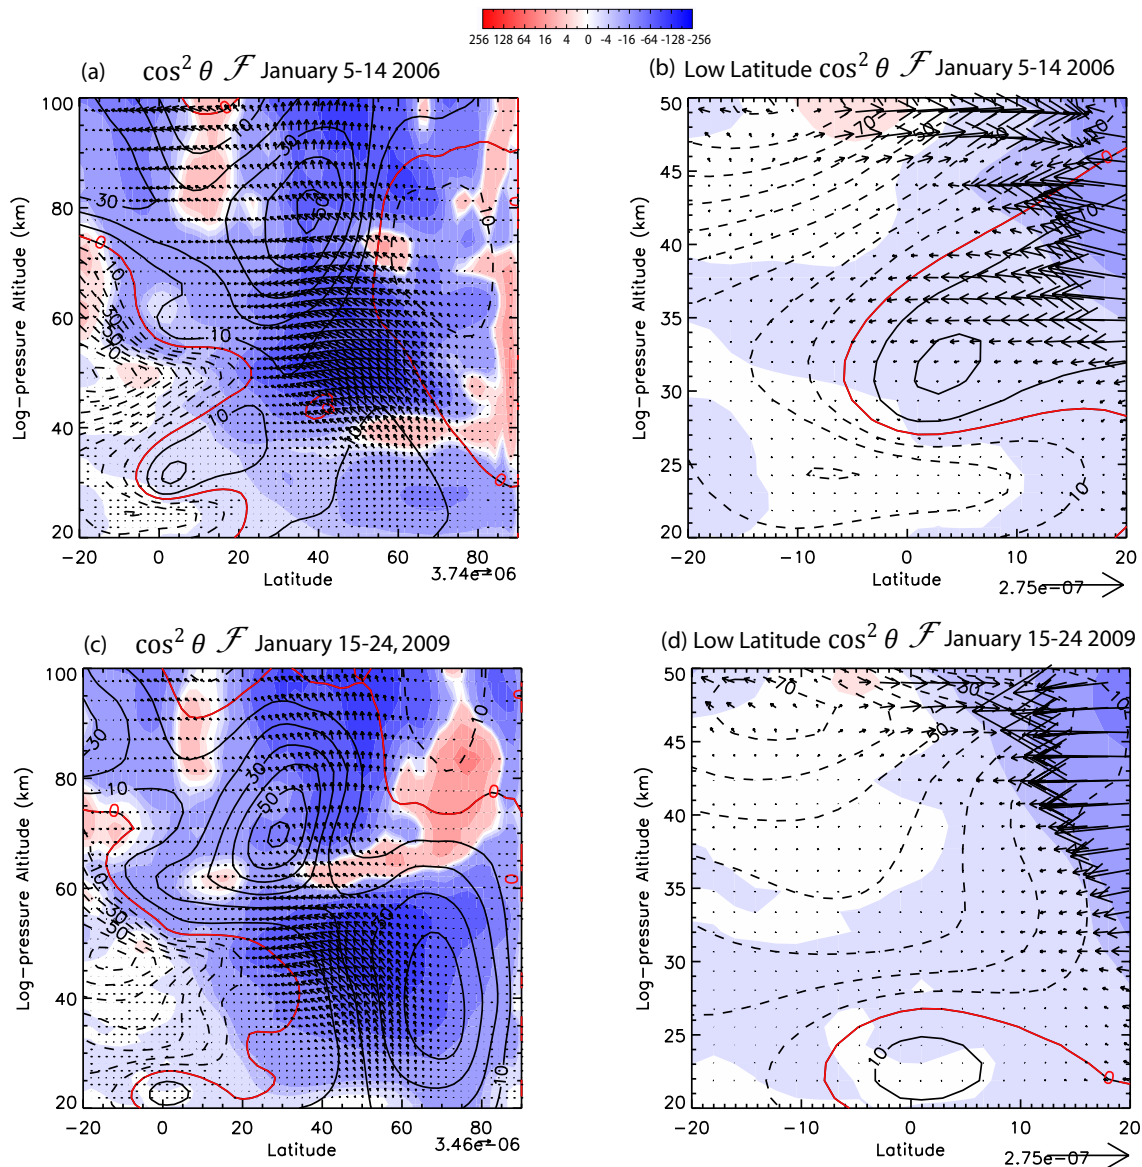

Figure 6. Plot of F' vectors superimposed on contours of $\cos^2 \theta F$, (a) between 20 and 100 km and 20° S to 90° N averaged over 5–14 January 2006, (b) between 20 and 50 km and 20° S to 20° N averaged over 5–14 January 2006, (c) between 20 and 100 km and 20° S to 90° N averaged over 15–24 January 2009 and (d) between 20 and 50 km and 20° S to 20° N averaged over 15–24 January 2009. The zonal-mean zonal wind is plotted as black contours (at 10 m s⁻¹ intervals); the red contours indicate the zero wind line.

the eastward winds prevailing in this region. It needs to be investigated whether these are secondary waves generated in the middle atmosphere following reversals in the zonal-mean winds similar to the secondary planetary waves shown in Chandran et al. (2013b).

During 2006, which is in the easterly phase of the QBO, the wind is eastward in the low latitudes between 30 and 45 km and this enables the planetary waves to propagate across the equator at this altitude (Fig. 6b). In 2009, which is in the westerly phase of the QBO, the westward wind in this region causes the planetary waves to break near the zero

wind line which is at 25–30° N and hence there is no planetary wave activity in the equator (Fig. 6d). The planetary wave driven westward acceleration of the zonal-mean flow reaches peak values of ~ 5 to $10 \text{ m s}^{-1} \text{ day}^{-1}$ at altitudes as low as ~ 35 km in the easterly phase of the QBO and ~ 30 km in the westerly phase of the QBO. The propagation of planetary waves across the equator during the easterly phase of the QBO is consistent with studies from Ortland (1997) who showed a similar pattern of planetary wave propagation in November of 1994 during the easterly phase of the QBO. The propagation of planetary waves across the tropics also

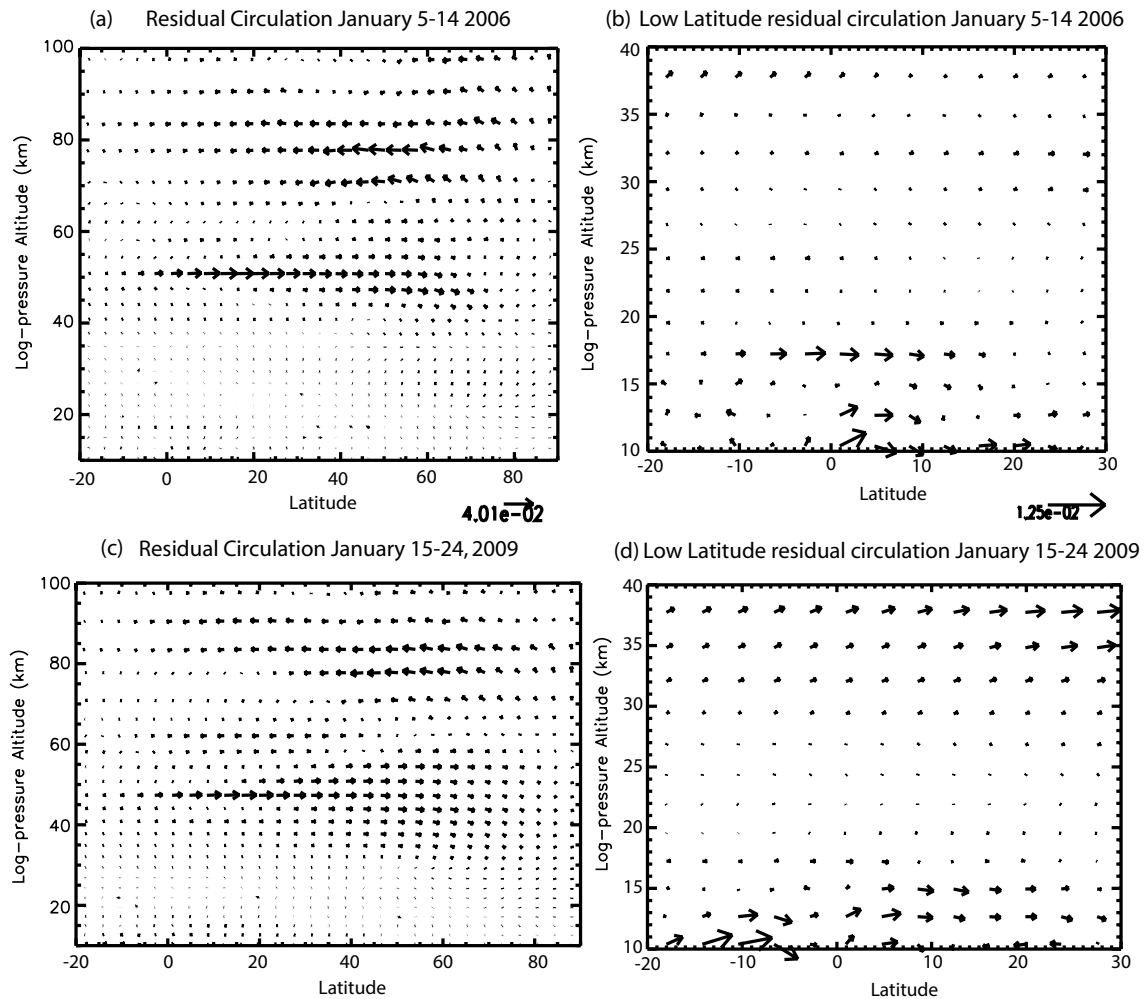

Figure 7. Plot of residual circulation vectors (a) between 10 and 100 km and 20° S to 90° N averaged over 5–14 January 2006, (b) between 10 and 40 km and 20° S to 30° N averaged over 5–14 January 2006, (c) between 10 and 100 km and 20° S to 90° N averaged over 15–24 January 2009 and (d) between 20 and 50 km and 20° S to 30° N averaged over 15–24 January 2009.

has implications for constituent exchange between the extratropics and tropics (O’Sullivan, 1997) and in contributing to the momentum budget of the QBO in the upper stratosphere (Dunkerton, 1983).

In Fig. 7, we show the residual circulation vectors in 2006 (averaged between 5 and 14 January) and 2009 (averaged between 15 and 24 January) in Fig. 7a and c, respectively. The residual circulation in the tropics and extra-tropics during the same period are shown in detail in Fig. 7b and d. The residual circulation plots in Fig. 7a and c show the enhanced poleward flow in the stratosphere in the low and mid-latitudes and downwelling over the poles leading to the stratospheric warming. It also clearly shows the upwelling in the mesosphere over the poles leading to the mesospheric cooling and the resulting equatorward flow in the MLT. In the tropical stratosphere, during the easterly phase of the QBO in 2006, the upwelling over the tropics and poleward flow in the stratosphere (between 30 and 40 km) is much weaker

compared to 2009. During the easterly phase of the QBO, the peak upwelling and poleward flow occur in the lower stratosphere (between 10 and 20 km). The penetration of westward planetary waves across the equator in the upper stratosphere during the easterly phase of the QBO as shown in Fig. 6 reduces the upwelling and poleward flow resulting in less cooling of the tropical upper stratosphere. In the westerly phase of the QBO, since the planetary waves do not penetrate into the tropics, the upwelling and poleward flow is much stronger between 30 and 40 km.

3.4 Variability during the 2006 and 2009 SSWs

While the zonal-mean diagnostics shown previously can provide useful information on temperature and wind changes in the high, mid- and low latitude regions, very often observations at the same latitudes show variability in terms of the observed temperature and winds. In Fig. 8 we show

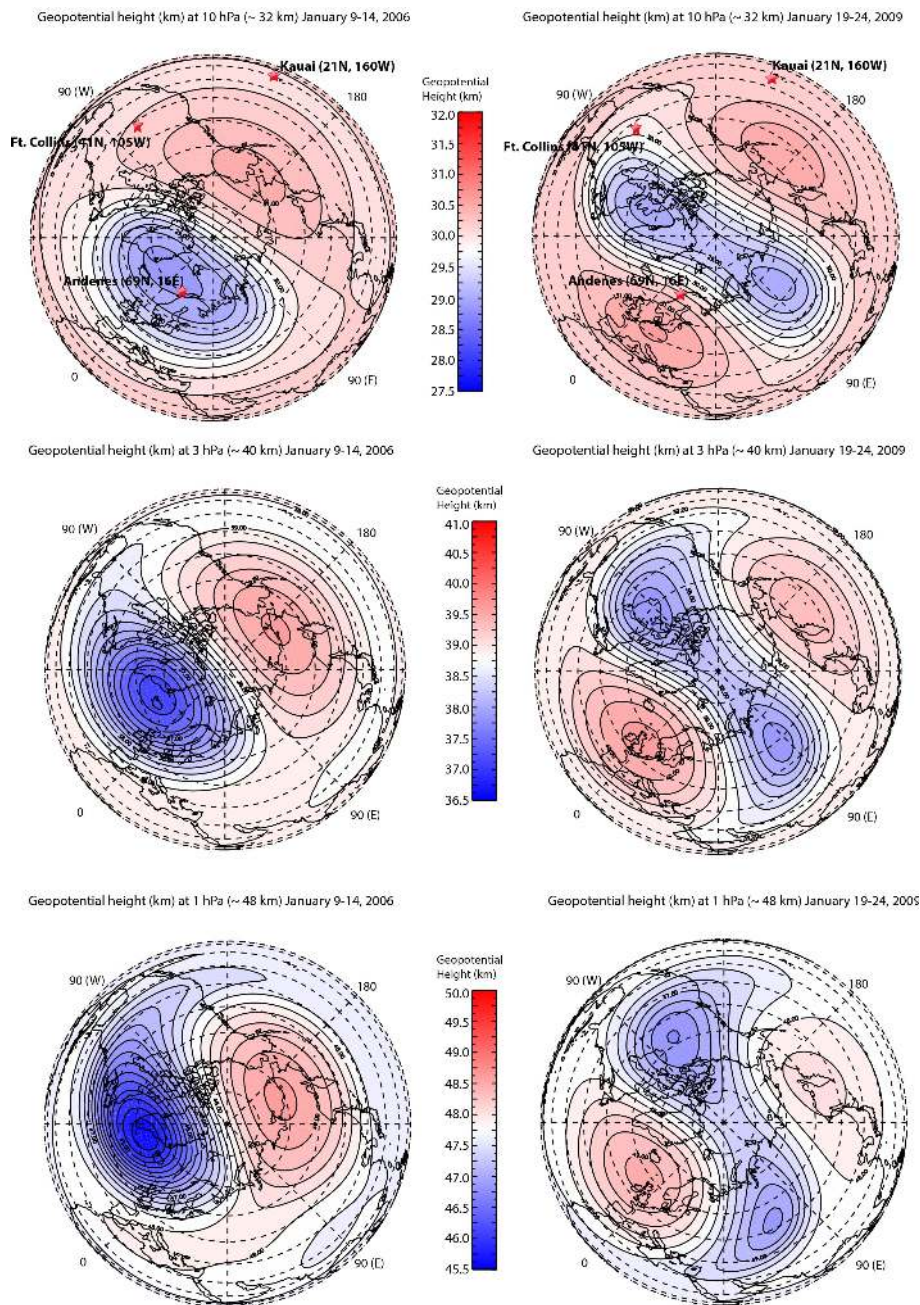

Figure 8. The geopotential height during 2006 SSW event (left panels) and 2009 SSW event (right panel) averaged between 9 and 14 January at (top panel) 10 hPa (~ 32 km), (middle panel) 3 hPa (~ 40 km) and (bottom panel) 1 hPa (~ 48 km). The red star in Fig. 7a indicates locations for which temperature and mean winds are shown in Fig. 8.

the geopotential height at 10 hPa (~ 32 km), 3 hPa (~ 40 km) and 1 hPa (~ 48 km) in the top, middle and bottom panels averaged between 9 and 14 January 2006 (left panels) and between 19 and 24 January 2009 (right panels). From the geopotential height perturbations it can be ascertained that the 2006 event is a vortex displacement event while the 2009 event is a vortex splitting event. The planetary wave activity leading to the SSW in 2006 is planetary wave 1 (PW1), while

in 2009 the triggering planetary wave activity for the SSW is planetary wave 2 (PW2). During the 2006 event (left panels), the vortex is displaced over Europe and the Atlantic between 90° W and 90° E while there is an anticyclone over western North America and most of Asia and the Pacific. This anticyclone drives the SSW and the peak downwelling over the stratosphere and upwelling in the mesosphere is occurring over the anticyclone sectors (between 65 – 70° N over the

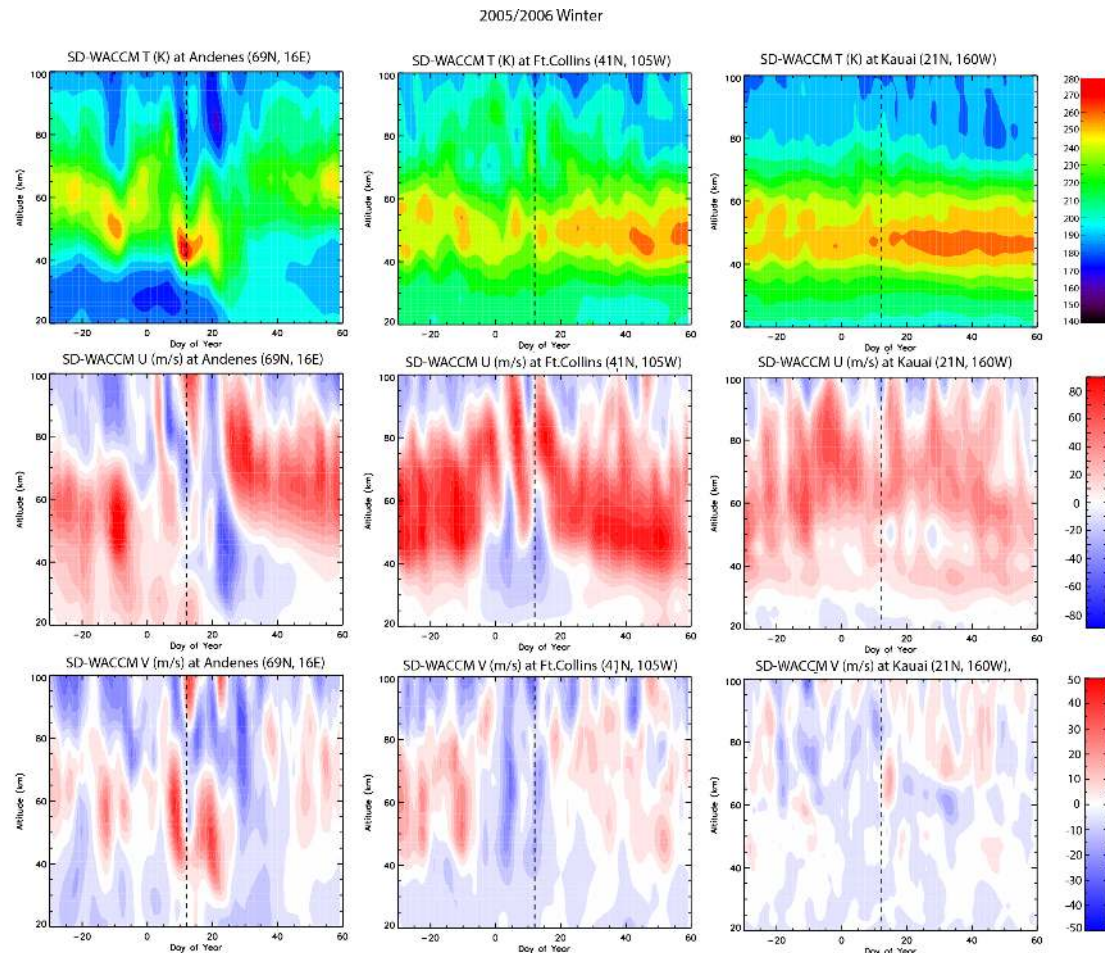

Figure 9. The temperature (top panel), zonal-mean zonal wind (middle panel) and mean meridional wind (bottom panel) from the WACCM at grid points closest to Andenes (69° N, 16° E), Fort Collins (41° N, 105° W) and Kauai (21° N, 160° W) from left to right during the 2005–2006 northern hemispheric winter. The dotted line indicates the day of peak warming (12 January) over the polar caps.

Aleutians). The westward tilt in the anticyclone and cyclone can also be observed. In 2009, the vortex is clearly split with two cells of the split vortex existing between latitudes (going clockwise) 45° – 135° W and 135° – 45° E. The anticyclone is most predominant (going anti-clockwise) between 135° E and 135° W and between 45° E and 45° W. As the altitude increases, the anticyclone appears more westward and poleward and the vortex tilted westward as we go higher in altitude indicating westward planetary wave propagation. With increasing altitude, the anticyclone over the Atlantic (between 45° E– 45° W) appears stronger than the anticyclone over the Pacific (between 135° E and 135° W) and hence is the primary driver for the SSW and mesospheric cooling during the 2009 SSW event.

In Figs. 9 and 10, we show the temperature (top panel), zonal-mean zonal wind (middle panel) and mean meridional wind (bottom panel) from SD-WACCM simulations of the 2006 and 2009 SSW events, respectively, at grid points closest to Andenes (69° N, 16° E) – a high latitude location (left

panels), Fort Collins (41° N, 105° W) – a mid-latitude location (central panels) and at Kauai (21° N, 160° W) – a low latitude location (right panels). The locations are marked by a red star and labeled in the top panels of Fig. 8. The choice of locations were motivated by previous studies from these locations, the presence of active instruments, and their geographic relevance. Hoffman et al. (2007) and Matthias et al. (2013) have previously shown wind measurements from Andenes during the 2006 and 2009 SSWs, while the Colorado State University (CSU) temperature and winds were shown by lidar measurements during the 2009 SSW event by Yuan et al. (2012). Pancheva et al. (2008) have shown wind measurements from Kauai during the 2003–2004 SSW event. During the 2006 and 2009 events there is an anticyclone over the Pacific and hence the effects of the SSW were most likely to be seen in a low latitude location such as Kauai situated equatorward of the anticyclone. The dashed line indicates the day of peak warming (12 January in 2006 and 22 January in 2009) over the polar caps.

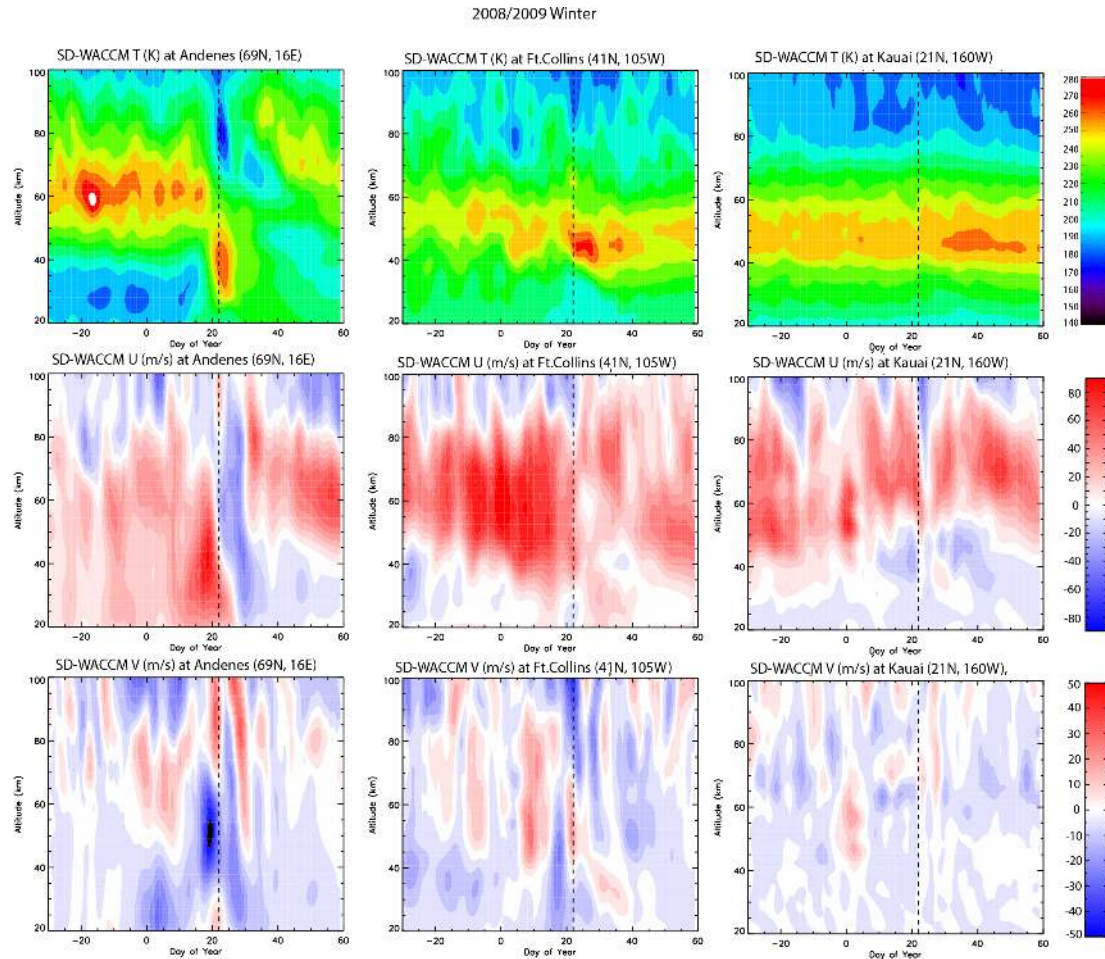

Figure 10. The temperature (top panel), zonal-mean zonal wind (middle panel) and mean meridional wind (bottom panel) from the WACCM at grid points closest to Andenes (69° N, 16° E), Fort Collins (41° N, 105° W) and Kauai (21° N, 160° W) from left to right during the 2008–2009 northern hemispheric winter. The dotted line indicates the day of peak warming (22 January) over the polar caps.

From the left panels in Figs. 9 and 10, it can be seen that the SSW is most strongly observed in temperature and wind reversals at the high latitude location of Andenes. The stratospheric warming is higher (~ 300 K) during the 2006 SSW than in the 2009 SSW (~ 270 K). The zonal-mean wind also reverses during both the events. Interestingly the meridional winds during the 2006 and 2009 are opposite in phase in both the upper stratosphere and MLT. Normally over the polar cap, during an SSW event, it would be expected to see poleward flow in the upper stratosphere (resulting in downwelling over the polar cap) and equatorward flow in the MLT (resulting from upwelling over the polar cap); however this assumes the downwelling and upwelling are occurring centered over the pole. During the 2006 SSW, as can be seen by the location of the anticyclone over the Aleutians in Fig. 8, the peak stratospheric downwelling and mesospheric upwelling are occurring centered at $\sim 70^\circ$ N and 180° longitude. Hence over Andenes, a poleward flow in the upper stratosphere and equatorward flow in the MLT is observed. Hoffmann et al. (2007) noted that wind observations at Andenes and Resolute Bay

(75° N, 95° W) during the 2006 SSW (their Fig. 6) are in opposite phases in the MLT. This is understandable since the anticyclone is located equatorward of the Resolute Bay location. During the 2009 SSW, the anticyclone (where the upper stratosphere downwelling and MLT upwelling is occurring) is located equatorward of Andenes at $\sim 60^\circ$ N and 0 – 20° E longitudes. Hence the meridional wind observations at Andenes show equatorward flow in the stratosphere and poleward flow in the MLT region.

The SSW event can be seen in temperature and winds at the mid-latitude location (CSU) located at $\sim 40^\circ$ N in both 2006 and 2009. The warming effect in temperature is higher during the 2009 event (~ 270 K) than during the 2006 event (~ 260 K). During the 2006 SSW, the zonal-mean zonal wind reverses below 50 km, while only a weakening of the zonal-mean zonal wind is seen during the 2009 event. It is interesting to note that the model captures the mesospheric cooling by ~ 30 K from climatological values observed at Fort Collins during the 2009 event (Yuan et al., 2012). The meridional wind showing equatorward flow in both stratosphere

and MLT is consistent with the pattern seen in Fig. 4f. At the low latitude site at Kauai the upper stratosphere warms by ~ 10 K during the 2006 SSW and by ~ 4 –5 K during the 2009 SSW. The zonal-mean wind also weakens and even reverses in the lower stratosphere at Kauai during both the events. The meridional wind shows variability, which is along similar patterns as seen in the zonal-mean wind plots of Figs. 1, 4 and 5.

4 Summary and discussion

While the effects of SSW events are most evident in the high latitudes, where the changes in residual circulation are magnified by the relatively smaller area compared to the mid- and low latitudes, SSW effects can also produce significant changes in mid- and low latitude temperature and winds. In this study we quantify these changes during SSW events from a composite of SSW events between 1988 and 2010. The changes in temperature during SSW events can be summarized as follows: poleward of 40° N there is warming in the stratosphere below 60 km and cooling at 60–100 km. In the mid- and low latitude stratosphere there is cooling below 60 km while there is warming at 60–90 km. These stratospheric cooling and mesospheric warming regions also extend into the low latitudes in the Southern Hemisphere.

The changes in the zonal-mean zonal wind can be summarized as follows: in the Northern Hemisphere, poleward of 40° N, in the upper stratosphere and lower mesosphere (~ 30 –85 km) there is a westward acceleration of the zonal-mean flow and in the upper MLT (~ 85 –100 km) there is an eastward acceleration of the zonal-mean flow. At 20 – 40° N there is a westward acceleration, or deceleration, of the eastward zonal-mean flow. In the lower latitudes (0 – 20° N), there is an eastward acceleration below 40 km, westward acceleration at 40–60 km and eastward acceleration at 60–100 km. In the low latitudes of the Southern Hemisphere there is westward acceleration in the zonal-mean flow at 40–65 km and an eastward acceleration of the zonal-mean flow at 65–100 km. The meridional wind changes can be summarized as follows: poleward of 40° N, there is a reversal of the middle atmosphere pole-to-pole flow, which becomes equatorward. There is a deceleration of pole-to-pole flow in the middle and low latitude middle atmosphere, which extends to the southern hemispheric low latitudes as well. There is also a poleward flow in the northern hemispheric stratosphere in the low and middle latitudes (0 – 40° N).

While the above summary of changes in temperature and zonal-mean wind prevails for most SSW events, there may be differences in observed zonal-mean winds and temperature depending on location within the displaced or split polar vortex depending on the triggering planetary wave activity being PW1 or PW2. During SSW the vortex is displaced (during PW1 events) or split (during PW2 events) and lies off the pole and usually lies in one hemisphere, while the

other hemisphere will have an anti-cyclonic flow. In regions where the polar vortex still exists, the mid-latitude zonal winds still remain eastward in the stratosphere and westward in the mesosphere, while in the opposite hemisphere the mid-latitude winds would have reversed in both the stratosphere and mesosphere. Observations from individual mid-, low and high latitude sites have to be interpreted with respect to their location within or outside the displaced or split polar vortex. So it is entirely possible that such locations might see reversals in zonal-mean winds, warming/cooling in the stratosphere/mesosphere during one SSW event while not observing such effects during another SSW event which may look very similar while analyzed in the zonal mean. The location of the anticyclone driving the SSW and mesospheric cooling can affect meridional wind observations at high latitude sites depending on whether the anticyclone is located equatorward or poleward of the observing site.

Planetary waves show upward and equatorward propagation originating from mid-high latitudes during SSW. The planetary waves also propagate into the mid-latitude MLT region and can produce significant westward forcing reaching peak values of ~ 60 – $70 \text{ m s}^{-1} \text{ day}^{-1}$. It remains to be investigated if the planetary waves propagating to the MLT region are secondary planetary waves generated due to wind reversals in the upper stratosphere and lower mesosphere causing the presence of instabilities or planetary waves propagating from the troposphere and lower stratosphere. The propagation of these planetary waves in the tropical stratosphere depends on the phase of the QBO. During the easterly phase of the QBO, there is propagation of these planetary waves (originating in the high latitudes) in the stratosphere across the equator, while in the westerly phase of the QBO, the planetary waves break at ~ 20 – 25° N and there is no propagation across the equator. Hence a spectral analysis of winds at the low latitudes during the easterly phase of the QBO could indicate the presence of planetary waves with periods comparable to the ones causing the onset of the SSW as in 2005–2006 and reported on by Vineeth et al. (2010). However, our analysis indicates that the planetary wave propagation is equatorward from the mid-high latitudes during the SSW events and gives no indication of poleward propagation of planetary waves in the tropics as reported by Vineeth et al. (2010). The effects of the planetary wave propagation across the tropical stratosphere during the easterly phase of the QBO have been reported during the early winter months of November and December (Ortland, 1997; O’Sullivan, 1997). This study indicates a similar pattern of planetary wave propagation during SSW events with implications for contribution to the QBO’s momentum budget (Dunkerton, 1983), constituent mixing and transport between the extratropics and tropics. The penetration of planetary waves into the tropical stratosphere during the easterly phase of the QBO affects the residual circulation by reducing the tropical upwelling and poleward flow in the upper stratosphere.
