Abstract: Ground granulated blastfurnace slag (GGBS) is widely used as a partial replacement for Portland cement or as the major component in the alkali-activated cement to give a clinker-free binder. In this study, reactive MgO is investigated as a potentially more practical and greener alternative as a GGBS activator. This paper focuses on of the hydration of GGBS, activated by two commercial reactive MgOs, with contents ranging from 2.5 to 20% up to 90 days. The hydration kinetics and products of MgO-GGBS blends were investigated by selective dissolution, thermogravimetric analysis, X-ray diffraction and scanning electron microscopy techniques. It was found that reactive MgO was more effective than hydrated lime in activating the GGBS based on unconfined compressive strength and the efficiency increased with the reactivity and the content of the MgO. It is hence proposed that reactive MgO has the potential to serve as an effective and economical activator for GGBS.

Key words: reactive magnesia; slag; hydrotalcite; hydration; strength; microstructure

1. Introduction

Alkali-activated ground granulated blast-furnace slag (GGBS) are sustainable alternatives to PC due to their low initial capital cost of the raw material and the saving of energy and resources, and the elimination of CO₂ emissions from chemical reactions in the kiln, leading to much lower CO₂ emissions [1]. The properties of alkali-activated slags (AAS) depend on several variables such as the GGBS composition [2], activator type and content [3,4], and curing conditions [5,6]. According to [7], the slag activation process begins with a destruction of the slag bonds (e.g., Ca-O, Mg-O, Si-O-Si, Al-O-Al and Al-O-Si) followed by the formation of a Si-Al layer all over the surface of slag grains and finally, the formation of the hydration products such as C-S-H and hydrotalcite [4]. pH is reported to be the major factor controlling the slag activation process (rather than the activating cation) with higher pH environment inducing better slag activation and higher mechanical strength [4,8,9]. Numerous research efforts have focussed on the activation of GGBS by various alkali-metal hydroxides and silicates such as NaOH, KOH or alkali salts such as waterglass and Na₂SO₄ and their mixtures [4]. However, several issues concerning the use of such strong alkalis exist, which prevent the widespread use of AAS including over-rapid setting, the difficulty of handling the caustic alkali, uneconomical efficiency and high shrinkage levels [1] in addition to potential alkali-aggregated reaction [10]. In this context, alkaline-earth hydroxides such as Ca(OH)₂, Sr(OH)₂ and Ba(OH)₂ have also been studied and have been found to be able to facilitate the hydration of GGBS [5,8]. Quicklime (CaO) has also been used in the activation of slags [11,12].

Recently, reactive MgO has been investigated as an activator for GGBS. Yi et al. [13] compared the strength of reactive MgO activated GGBS and Ca(OH)₂ activated GGBS paste at 5% and 10% activator content, and found that the former achieved ~30% higher strength than the latter after 28 days' curing at water to cement ratio (w/c) of 0.35. The use of reactive

1 MgO activated GGBS blends in the ground improvement application showed that 10-20%
2 addition outperformed corresponding Ca(OH)₂ activated GGBS with strength values of up to
3
4 4 times higher [14]. In addition, the effect of MgO in the AAS system has been investigated
5
6 by a number of researchers, either in the form of internal MgO from slag composition [15],
7
8 where Mg act as an element of the glass network [16], or external MgO by additional mixing
9
10 [17]. It should be noted the reactive grade (calcined at less than 1000 °C) is often selected as
11
12 the external MgO added to the slag. Ben Haha et al. [15] investigated the effect of MgO
13
14 content (internal) on the performance of AAS and revealed that the main hydration products
15
16 are calcium silicate hydrate (C-S-H) gel and hydrotalcite-like phases (Ht), which are more
17
18 voluminous than C-S-H, resulting in a less porous structure and higher strength.
19
20 Thermodynamic modelling showed that up to 7% MgO content would be totally incorporated
21
22 in Ht while higher content would produce brucite [15]. Gu [18] used reactive MgO to replace
23
24 40% slag with K₂CO₃ and sodium silicate as the activators and found that the strength was
25
26 only slightly lower than the control although no explanation was provided regarding the role
27
28 of the reactive MgO in the mix. In the work by Shen et al. [17], a commercial light-burnt
29
30 dolomite (mainly contains reactive MgO and MgCO₃) was added in the water glass-activated
31
32 slag and fly ash blends, and the results indicated that the hydration of reactive MgO
33
34 decreased the shrinkage ratio of the paste, and no interaction between MgO and other
35
36 components was observed in the microstructural analysis.
37
38
39
40
41
42
43
44
45
46

47 However, it is known that the characteristics of reactive MgO vary significantly [19],
48
49 depending on their raw material, calcination conditions and the type of impurities and their
50
51 content [20,21], which may affect their performance in the activation process. None of the
52
53 above studies investigated the hydration kinetics of reactive MgO-GGBS paste or the effect
54
55 of different types of reactive MgO on the hydration process. Furthermore, the evolution of the
56
57
58
59
60
61
62
63
64
65

1 hydration products requires more detailed research to elucidate the different roles that
2 external reactive MgO and internal MgO (in the glass network) play in the mixture.
3

4
5 Hence this paper presents an investigation of the hydration of MgO-activated GGBS pastes
6 using two commercially available reactive MgO samples. The hydration products were
7 investigated by X-ray diffraction (XRD) and thermogravimetry analysis (TGA). In addition,
8 the hydration kinetics was studied by chemical dissolution and quantification of the non-
9 evaporable water content (NEW). Finally, scanning electron microscopy (SEM) combined
10 with energy dispersive X-ray spectroscopy (EDS) was employed to study the microstructure
11 and the elemental composition of the hydrated phases. Based on the experimental results, the
12 effects of the reactivity and content of the reactive MgO on the slag activation process were
13 discussed.

28 **2. Materials and Methods**

29
30
31 Two commercial reactive MgO samples, namely MgO_{94/200} and MgO_{90/200}, obtained from
32 Richard Baker Harrison, UK, and hydrated lime from Tarmac and Buxton Lime and Cement,
33 UK, were used as the activators for a GGBS, obtained from Hanson, UK. Table 1 presents the
34 composition of the MgOs, hydrated lime and the GGBS used, which shows that the major
35 differences between those two MgOs are their CaO content (MgO_{94/200} has twice the CaO
36 content of MgO_{90/200}) and acetic acid reactivity [19] (smaller value indicates higher reactivity,
37 so MgO_{90/200} is more reactive). Since the chemical compositions of both MgO are similar, the
38 large difference in their reactivity values was attributed to their calcination conditions. With
39 the increase of burning temperature and/or burning time, the surface area and the crystal
40 lattice decreased and the particle size increased resulting in decrease in the reactivity of MgO
41 [22]. The BET surface area of MgO samples were determined from nitrogen adsorption-

1 desorption isotherms on a TriStar 3000 instrument. It is calculated from the table that the
2 GGBS has an initial Mg/Al of ~0.78.
3

4
5 MgO-GGBS pastes were used in which the added MgO content ranged from 2.5% to 20% by
6 weight of the total binder. The water to cement ratio (w/c) was set as 0.32 for all the pastes
7 based on the standard consistence (as per [23]) of 10% MgO_{90/200} and 90% GGBS paste to
8 ensure good workability. Standard consistence is defined as the water to solid ratio which
9 permits the Vicat plunger to penetrate to a level of 6 ± 2 mm from the bottom of the Vicat
10 mould. Pure GGBS and hydrated lime (Ca(OH)₂) activated GGBS pastes were also made for
11 comparison purpose. The nomenclature used for the mixes is X-Y, where X = M_h or M_l or C,
12 indicating the activator used (MgO_{90/200} with a higher reactivity, MgO_{94/200} with a lower
13 reactivity and Ca(OH)₂, respectively) and Y denotes the activator's percentage in the mix
14 (from 2.5% to 20%) while G refers to the pure GGBS paste. The contents of the raw
15 materials in each mix prepared are presented in Table 2.

33 Raw materials were mixed in a bench-top food mixer and cast into 40 mm cubic moulds. The
34 fresh AAS paste cubes were demoulded after 24 hours and then transferred into a deionised
35 water tank and cured for 7, 28, 56 and 90 days at a temperature of 20 ± 1 °C. The unconfined
36 compressive strength (UCS) of the samples, in triplicate, was then determined according to
37 [24] at a loading rate of 2400 N/s on a CONTROLS ADVANTEST 9 strength test machine at
38 each curing age. The crushed samples were ground and mixed with deionised water at a water
39 to solid ratio of 1 to determine the AAS paste pore water pH according to [25], which
40 reported that this method gave the pH values close to the directly squeezed pore water using
41 high pressure. Eutech pH 510 meter with accuracy of 0.01 was used throughout the study.

dried, the samples were further ground to pass through a 75 μm sieve. To evaluate the slag reaction degree, duplicate 0.5 g samples were dissolved in salicylic acid-methanol-acetone solvent and the remaining powders were filtered, dried and then ignited to 1000 $^{\circ}\text{C}$ as proposed by [26]. In this study, the commonly used Ethylenediaminetetraacetic acid (EDTA) method is replaced by the salicylic acid-methanol-acetone method to determine the slag reaction degree considering the high amount of Ht formed according to [26,27]. XRD measurement was carried out on the Siemens D5000 X-ray diffractometer using a scanning range from 5 to 60 (2θ), with scanning speed of 2 s/step and resolution of 0.05 $^{\circ}$ /step to identify the hydration products formed. TGA was conducted on PerkinElmer STA6000 equipment from 40 to 1000 $^{\circ}\text{C}$ with the increasing rate of 10 $^{\circ}\text{C}/\text{min}$. The TG curves were also used to calculate the value of NEW [6] for each sample, which is estimated from the weight loss between 50 and 800 $^{\circ}\text{C}$ after being normalised by the ignited weight of the sample. The slag reaction degree and NEW data were compared to evaluate the reaction kinetics of the MgO-GGBS blends. It was found that weight loss after 800 $^{\circ}\text{C}$ was negligible from the TGA results. SEM/EDS was performed on the JEOL 5800LV machine and roughly 30 points on each sample were picked for determination of elemental composition of the gel.

3. Results and Discussion

3.1. Unconfined compressive strength and pH development

Figure 1 shows the UCS development of the MgO-GGBS pastes together with corresponding $\text{Ca}(\text{OH})_2$ -activated GGBS pastes for comparison. For $\text{Ca}(\text{OH})_2$ -activated GGBS, the optimum activator addition was found to be 10%, which agrees well with [5]. The two types of reactive MgO samples showed different performances in activating the GGBS. Generally, the more reactive MgO ($\text{MgO}_{90/200}$) produced the higher UCS values for each curing age at the same level of MgO addition. Up to 56 days, the strength of the M_h -GGBS blends increase with the

1 MgO content up to 15wt%. The UCS for paste with 15% M_h addition reached approximated
2 40 MPa after 28 days, which was 50% higher than the corresponding $Ca(OH)_2$ -GGBS paste.
3
4 Further addition of MgO did not make any difference in terms of UCS. At 90 days, 10wt%
5
6 MgO addition gave the highest UCS value, probably because further addition of MgO caused
7
8 decrease of the GGBS content and cracks were observed to have formed due to the expansive
9
10 nature of the Ht (see XRD and SEM results).
11
12
13

14
15 On the other hand, the UCS values of M_l -GGBS blends were only slightly higher than the
16
17 inactivated GGBS up to 10wt% MgO addition. It should be noted that at 15% addition (i.e.,
18
19 M_l -15), there was a sharp UCS increase compared with lower additions approaching 30 MPa
20
21 at 28 days and the difference between those two types of reactive MgO was reduced. Further
22
23 addition to 20wt% (i.e., M_l -20) gave higher strength which was roughly the same as M_h -10. It
24
25 is clear that reactive MgO activated GGBS sufficiently in terms of UCS, while the optimum
26
27 addition level depended on the characteristics of the MgO.
28
29
30
31

32
33 The variation of the pH of the pore water with time and MgO content is depicted in Figure 2.
34
35 Although the 7 days pH values varied significantly and seemed not to be affected by the MgO
36
37 reactivity or content, all the 28 day pH values dropped to below 12 for those samples
38
39 containing less than 10% MgO in the M_h -GGBS blends and less than 15% MgO in the M_l -
40
41 GGBS blends. It was found that although the CaO content in M_l is twice than that in M_h , that
42
43 the relative small content of this impurity did not make much difference to the whole system
44
45 pH, which could be due to the relatively fast reaction between $Ca(OH)_2$ and silica in the slag
46
47 to form C-S-H. The pH values of the $Ca(OH)_2$ -GGBS blends were all over 12 regardless of
48
49 the curing time, which explains their higher early strengths than MgO-GGBS blends with low
50
51 MgO addition levels.
52
53
54
55
56
57
58

59 **3.2. Slag reaction degree**

60
61
62
63
64
65

1 The evolution of slag reaction degree with the MgO content at different curing ages is plotted
2 in Figure 3. It shows that an increase in the curing time and MgO (both internal [15] and
3 external) content increased the slag reaction degree. At 7 days, the slag reaction degree was
4 extremely low for all blends and changed marginally with reactive MgO content (the high
5 value for M₁-5 is attributed to experimental error). At 28 and 90 days, the slag reaction degree
6 approximately increased proportionally to the reactive MgO content. In all ages, slag in M_h-
7 GGBS blends showed higher reaction degree compared to that in M₁-GGBS blends. It should
8 be noted that the slag reaction degree for C-10 reached 24.8% at 28 days, which is much
9 higher than that of MG blends. The higher slag reaction degree in Ca(OH)₂ activated system
10 is attributed to the higher pH as discussed above; however, it is surprising that higher strength
11 was achieved when MgO content was over 15%. It is claimed by Ben Haha et al. [15] that
12 higher MgO content (internal) in slag cement will increase the quantity of Ht-like phases
13 which is more voluminous resulting in lower porosity. In order to confirm that the higher
14 strength of MgO-GGBS blends comes from better pore filling effect of its hydration products,
15 10% of each activator (i.e., Ca(OH)₂ and M_h) was mixed with slag in different w/c.
16

17 The strength result is presented in Figure 4 in which it is obvious that in the short term (less
18 than 28 days), Ca(OH)₂ activated slag showed higher strength regardless of w/c used while
19 M_h activated slag exhibited its advantage only after 90 days. At w/c = 0.32, the UCS of the
20 M_h-GGBS blend was approximately 50% higher as that of Ca(OH)₂-GGBS blend, and the
21 discrepancy was lessened by increasing w/c. At w/c = 0.5, there was almost no difference
22 between these two activators in terms of UCS at 90 days. It is hypothesised that at lower w/c
23 ratio, the hydration products of MgO and GGBS were more effective by filling the pores
24 while higher initial w/c results in larger pore volume in the cement matrix, the contribution of
25 this pore filling effect to strength is mitigated.

3.3. Hydration Products

3.3.1. XRD

Figure 5 presents the XRD patterns for the M_h -GGBS and M_l -GGBS blends respectively with 10 and 15% MgO addition. The broad and diffuse peak at $25-35^\circ 2\theta$ reflects the short range order of the $\text{CaO-Al}_2\text{O}_3\text{-MgO-SiO}_2$ glass structure of the GGBS. For both reactive MgO activated GGBS paste, the characteristic peak for MgO was identified regardless of the curing time and MgO addition indicating the incomplete hydration of both reactive MgO. For M_h -GGBS blends, C-S-H can be identified as a broad peak at $2\theta = \sim 29.5^\circ$. In addition, various peaks for tobermorite-14 Å phase were detected. Gehlenite hydrate phase at $2\theta = \sim 25^\circ$ was identified for all the mixes. The decreasing intensity of gehlenite hydrate with the increase of MgO content is consistent with the modelling results by Ben Haha et al. [3]. Newly formed peaks of Ht at $2\theta = 11.7$ and 22.3° were found in the M_h -10 blend after 7 days, and the peak height increased with curing time and MgO addition level indicating that more Ht formed with more MgO present and longer curing times. Calcite peaks were detected due to the impurity in the raw material and the carbonation of hydration products by exposure to the air. For M_l -GGBS blends, the abovementioned peaks for, tobermorite-like C-S-H, gehlenite hydrate and calcite were also found with relatively lower intensity suggesting lower hydration degree. In addition, Ht was only detected for the 15% M_l addition level at 28 days in the XRD pattern indicating that with the addition of the more reactive MgO, Ht is more easily formed. The XRD results agreed well with previous studies that Ht and C-S-H are the main products of alkali-activated slag when Mg is present [15,28–30]. It also suggested that Ht made a significant contribution to the strength gain as reported by [15,30]. It should be noted that in all mixes tested, no brucite was observed, suggesting that all the brucite was consumed by the reaction with GGBS, which contradicts with the modelling result by Ben Haha et al. [15].

1 The absence of brucite also simplified the data interpretation in the TG curves (see next
2 section) since the decomposition temperatures of brucite and Ht overlap [31,32].
3

4
5 According to [33–36], the mechanism of alkali-activation includes the destruction of the
6 prime material into low stable structural units, their interaction with coagulation structures
7 and the creation of condensation structures. In the MgO-GGBS blends, the first steps consist
8 of a breakdown of the slag bonds: Ca-O, Mg-O, Al-O-Al, Si-O-Si and Al-O-Si [7] and the
9 simultaneous dissolution of MgO. Afterwards, Mg ion either reacts with Si-O or Al-O to
10 form M-S-H or Ht in the blend and Ca reacts with Si-O and Al-O to form C-S-H and C-A-S-
11 H. The existence of M-S-H by the reaction of MgO and silica fume at ambient temperature
12 was confirmed in numerous papers [37–39]. However in this study, due to the low
13 crystallinity of M-S-H [40], it is hard to be distinguished by XRD.

26

27 28 **3.3.2. TGA**

29
30
31 TG and first derivative of TG (DTG) signs are direct and very fast measurements of the
32 weight loss and its rate of occurrence during analysis, by which different materials are
33 identified based on their thermal characteristics [41]. The DTG curves of M_h-GGBS and M_l-
34 GGBS blends with varying MgO addition are shown in Figure 6. From the DTG curves, three
35 major humps involving several tiny peaks were observed as described below:
36
37
38
39
40
41
42
43
44

- 45 1. At temperatures up to 250 °C, this involves the dehydration of C-S-H, and possibly
46 M-S-H [39,42]. The small shoulder at ~80-130 °C could be attributed to AFm,
47 gehlenite hydrate [41,43] or Ht [44].
48
49
50
51
- 52 2. The temperature range of 300 to 550 °C includes mainly the decomposition of Ht
53 since brucite was found to be totally consumed by the reaction with slag from the
54 XRD analysis. In addition, the tiny peak at around 530 °C was attributed to the loss of
55 coordinated water in M-S-H [39,45].

3. The temperature range of 550 to 800 °C is the decomposition range of various carbonate-containing phases including magnesium carbonate, calcite [46] and Ht [47], originating from the raw material and the carbonation due to exposure to the air.

Although several authors [48,49] tried to quantify each hydration phase by thermal analysis, it is claimed that the quantification of the amount of each phase is not possible since there are too many overlaps in each temperature range [30]. Therefore the weight loss is divided into three main stages without differentiation between the phases. The first weight loss between 50 and 250 °C, in this study is denoted as Δm_1 and the second hump at 250-550 °C denoted as Δm_2 . In addition, the NEW was calculated by the weight loss between 50 and 800 °C. Herein all the weight losses were divided by the final ignited mass.

Table 3 lists the evolution of Δm_1 , Δm_2 and NEW with the increase of reactive MgO addition and curing time. There is a clear trend of an increase of all three variables for the MgO-GGBS blends with the increase of MgO content as well as the curing time, which is attributed to the higher hydration degree thus more hydration products formed. Generally, with the same amount of reactive MgO addition, M_h -GGBS blends give higher values for all of the three variables. The TG data agreed well with the UCS results considering that an increase in the hydration products causes strength gain due to filling of pores occupied by water previously.

Non-evaporable water content is often used as a measurement of the hydration extent of plain Portland-cement pastes [50] and also blended cements with slags [3,6]. The approximate linear relationship between NEW and slag reaction degree is presented in Figure 7. The imperfect fitting is attributed to the varying composition and stoichiometry of the hydration products. The correlation between NEW and UCS is depicted in Figure 8, which shows an approximately linear relationship in the short term (7 and 28 days, in this study), which is in

1 agreement with [3,51]. However, at 90 days, the linear relationship is not satisfactory due to
2 (a) the evolution of the hydration products and the change of the stoichiometry, e.g., the
3 change of the incorporated water content in the C-S-H and Ht structure [52]; and (b) the
4 formation of the cracks resulted from expansion of the hydration products, i.e., although the
5 hydration is still progressing, the strength gain stops due to cracking in the cement matrix.
6
7
8
9
10

11 **3.3.3. Microstructural and elemental analysis**

12 SEM images of M_h -GGBS blends with 5, 10, and 15% MgO additions are shown in Figure 9.
13 At 5% addition, the irregular slag particles were loosely stacked, which explains its low
14 strength. Significant changes are observed in M_h -10 and M_h -15 blends, showing a much
15 denser microstructure with irregular slag particles connected by gels. The C-S-H aggregates
16 were distributed on the surface (Figure 9 (d) and (f)). In addition, small cracks were visible
17 for both M_h -10 and M_h -15 blends (Figure 9 (d), (e) and (f)) due to the expansive nature of
18 hydration products and the low water to cement ratio used in this study. Fibrous Ht was
19 detected in M_h -15 blend growing on the C-S-H gels (Figure 9 (f)), which agrees with the
20 XRD results. According to the modelling of [15], Ht phases are more voluminous than C-S-H
21 gels, resulting in a matrix with lower porosity in an adequate quantity; however, it is found
22 that when too much reactive MgO is present in the blend, the over-expansion causes volume
23 instability and may be detrimental to the strength. This is probably the reason why after 28
24 days, there is almost no strength gain for MgO_h -GGBS blends at over 10% reactive MgO
25 addition (Figure 1(a)).

49 To determine the elemental compositions of the hydration products, EDS were performed on
50 resin-impregnated polished samples. Roughly 30 points on the gel were picked up for each
51 sample at a magnification of 2500. Figure 10 plots the Mg/Ca vs. Al/Ca ratios of the gels in
52 the M_h -GGBS blends hydrated for 7 and 28 days. Extrapolating the straight line to Mg/Ca = 0
53 gives a positive number, indicating that the C-S-H gel also contains a proportion of
54

60
61
62
63
64
65

1 aluminium either in solid solution within the C-S-H structure or in an AFm form finely
2 intermixed with it [29]. There is a linear relationship between the two ratios with the points
3 lying on a line with Mg/Al ratio of 1.08 for blends with 5% reactive MgO content regardless
4 of the curing time. With the increase of reactive MgO content, it is clear that the data points
5 locate mostly above the fitted line indicating that the Mg/Al ratio increases. Due to the large
6 variation of the data, it is not possible to generate a linear relationship between reactive MgO
7 content and the Mg/Al ratio, which revealed the heterogeneity of the Ht composition, giving
8 support for inconsistent changes of the NEW data with curing time as mentioned above. It
9 should be noted that the result is contrary to the findings regarding the effect of internal MgO
10 on the Mg/Al ratio according to [15], who found that the Mg/Al ratio barely changed with
11 increased MgO content in the slag composition.

27 **3.4. Discussion**

28
29
30
31 The hydration chemistry that involves MgO and other cementitious materials was
32 summarised by Bakharev [53]. In PC paste, brucite is the most favoured product, while in the
33 presence of fly ash, silica fume and/or slag, brucite is usually accompanied with hydrotalcite
34 and M-S-H gel [53]. In alkali-activated slag paste, Ben Haha et al. [15] revealed that the main
35 hydration products are C-S-H gel and Ht, where a higher content of MgO in slag composition
36 produced more Ht. However, those studies only investigated dead burned MgO from PC or
37 MgO in the glass network from the slag composition instead of reactive MgO as an additive
38 in the mix.
39
40
41
42
43
44
45
46
47
48
49
50

51 Recently, the hydration between reactive MgO and conventional cement additives were
52 studied extensively. In the reactive MgO and silica fume blend, it was found that M-S-H was
53 the major hydration product [37,39]. Vandeperre et al. [54] studied the microstructure of the
54 reactive MgO and pulverized fly ash (PFA) blends and observed brucite and a very small
55
56
57
58
59
60
61
62
63
64
65

1 quantity of hydrotalcite from by XRD, which was consistent with results in [55], who
2 reported the formation of Ht on hydrating mixtures of alumina with reactive MgO.
3
4 Combining the hydration mechanisms of conventional alkali-activated slag (i.e., glass
5 network of CaO-MgO-Al₂O₃-SiO₂) [33–36], the hydration mechanisms of reactive MgO-
6
7 GGBS can be proposed.
8
9

10
11
12 In contact of water, MgO dissolves as follows [56]:
13

15
16
17
18
19 The dissolution of MgO provides an alkaline environment followed by the breakdown of the
20 covalent bonds (Si-O-Si and Al-O-Si) in GGBS particles [57]. Impermeable coatings of
21 aluminosilicates deposit on the surface of the slag grains within a few minutes of exposure to
22 water, hindering further hydration reaction [4]. If the pH is not high enough, there will not be
23 sufficient OH⁻ to break the Si-O and Al-O bonds for the formation of the hydration products.
24
25 Song et al. [4] claimed that the pH should be over 11.5 to initiate the activation process, while
26
27 in another study, the value is reported as 12 [58]. The results in this study seem to confirm the
28
29 latter value and also demonstrated that 10-15% reactive is able to maintain the pH value
30
31 above 12 to activate GGBS effectively.
32
33
34
35
36
37
38
39
40
41

42 Afterwards, Mg²⁺ either reacts with Si-O or Al-O to form M-S-H or Ht. From the XRD
43 results, it was found that no brucite was left even with up to 20% MgO_{90/200}. Therefore, the
44 overall hydration reaction of reactive MgO and GGBS blends was summarised as:
45
46
47
48
49

51
52
53
54
55
56 The formed Ht has a significant effect on the mechanical performance of reactive MgO-
57
58 GGBS blends since it occupies more space than C-S-H resulting in less porosity compared to
59
60
61
62
63
64
65

1 the corresponding Ca(OH)₂-GGBS blends. Preliminary study showed that by increasing the
2 MgO_{90/200} content to 50% or by using a highly reactive MgO (reactivity value = 10 s, at 20%),
3
4 brucite was also detected in the blends since in that case, the consumption rate of Mg²⁺ by
5
6 slag was lower than the dissolution rate of MgO. Consequently, the pore water will soon be
7
8 supersaturated by Mg²⁺ and OH⁻ and Mg(OH)₂ nucleation and growth set immediately:
9
10

12
13 In this study, up to 20% MgO_{90/200} did not produce any brucite since the dissolved Mg²⁺ was
14
15 soon consumed by the slag and was not able to achieve the supersaturation state.
16
17
18
19
20
21

22 The composition of the Ht in various cement systems has been studied by many researchers.
23
24 For the cases of MgO contained in slag composition, it is claimed that the slag (initial
25
26 Mg/Al=1.51) hydration produce the same form of Ht (Mg/Al ≈ 2.30-2.55) no matter what
27
28 system it has been put into: unactivated, PC blend or hydrated lime-activated [29]. Contrary
29
30 to that, Ben Haha et al. [30] found Mg/Al ratio of the hydration products were 1.24, 1.38 and
31
32 2.02 when the initial Mg/Al in the raw material (by increasing Al content) were 0.49, 0.60
33
34 and 1.29, respectively, while MgO content has no effect on the Mg/Al ratio [15]. Yi et al. [13]
35
36 investigated the Ca(OH)₂ activated slag (initial Mg/Al = 0.86) and found the Mg/Al ratio in
37
38 the hydration products was ~1.1. On the other hand, when reactive MgO was added, Yi et al.
39
40 [13] reported a Mg/Al ratio of ~2.0 when reactive MgO content was 10% and 20% in the
41
42 MgO-GGBS mixture although the variation of the data was relatively large. In this study,
43
44 note that the initial Mg/Al is ~0.78 in the slag used here. It is found that 5% of reactive MgO
45
46 addition generates the Ht with Mg/Al ratio of ~1.1, which is consistent with Yi et al. [13] and
47
48 Ben Haha et al. [30]. The Mg/Al ratio increased with the increase of reactive MgO content in
49
50 the mix; however, this ratio varies in a wide range indicating the heterogeneous composition
51
52 of the Ht formed when using reactive MgO compared to that formed by internal MgO.
53
54
55
56
57
58
59
60
61
62
63
64
65

1 Therefore, we conclude that the Mg/Al of the Ht is highly dependent on the initial slag
2 composition and the content of reactive MgO added. In the absence of added reactive MgO,
3
4 when the initial Mg/Al (Mg from slag) is 0.49-0.86, the Mg/Al of Ht was found to be 1.1-
5
6 1.38, while increasing the initial Mg/Al to 1.29-1.51 generates Ht with a Mg/Al of 2.02-2.55.
7
8 When reactive MgO was added, the quick dissolution of reactive MgO generated more
9
10 available Mg²⁺ in the short term; however, 5% addition did not change Mg/Al of Ht much,
11
12 which could be due to the combination of Mg in other phases such as M-S-H [37,39]. More
13
14 than 10% reactive MgO produced Ht with a highly heterogeneous nature showing a wide
15
16 range of Mg/Al ratio.
17
18
19
20
21

22 **4. Conclusions**

23
24
25 By comparing the UCS, pH values and porosity of MgO-GGBS blends, using two different
26
27 reactive MgOs, and also with Ca(OH)₂-GGBS blends and studying their hydration products
28
29 by means of XRD, TGA and SEM/EDS, reactive MgO is found to activate GGBS effectively.
30
31
32 The following conclusions can be drawn:
33

- 34
35 1. The reactivity of MgO affects the performance of MgO-GGBS blends, such that the
36
37 more reactive MgO gives higher UCS values and more hydration products in the same
38
39 curing time.
40
41
- 42
43 2. The pH is found to be the major controlling factor in the activation process, which is
44
45 affected by the reactivity and content of reactive MgO.
46
47
- 48
49 3. Although reactive MgO dissolves less slag in the same curing time compared to
50
51 Ca(OH)₂ due to lower pH, it is found that higher strength can be achieved at the low
52
53 w/c, which is attributed to better pore filling capacity of the hydration products.
54
55
- 56
57 4. The main hydration products are hydrotalcite-like phases (Ht) and calcium silicate
58
59 hydrate (C-S-H), with the content increase with the increase of MgO addition and
60
61 curing time.
62

- 1
2
3
4
5
6
7
8
9
10
11
12
13
14
15
16
17
18
5. The non-evaporable water (NEW) content is found to be a useful indicator of the extent of hydration and there is an approximately linear relationship between NEW and slag reaction degree. Besides, UCS is also positively correlated with NEW in the short term until excess hydration products cause microcracks in the matrix.
 6. The composition of Ht depends on the reactive MgO content. GGBS activated by 5% reactive MgO produces Ht with Mg/Al ratio of ~1.1 while more than 10% reactive MgO addition generates heterogeneous Ht with Mg/Al ratio spreading in a wide range above 1.1.

Table 1 Physical properties and chemical compositions of MgO, Ca(OH)₂ and GGBS, from suppliers' datasheets

Label	MgO _{94/200}	MgO _{90/200}	Ca(OH) ₂	GGBS	
Chemical composition (wt%)	MgO	94	93.2	-	8
	CaO	2	0.9	-	40
	Ca(OH) ₂	-	-	96.9	-
	CaCO ₃	-	-	1.4	-
	SiO ₂	1	0.9	-	37
	Fe ₂ O ₃	0.7	0.5	-	-
	Al ₂ O ₃	-	0.22	-	13
	Mg(OH) ₂	-	-	0.5	0.4
	Na ₂ O	-	-	-	0.3
	K ₂ O	-	-	-	0.6
	SO ₃	-	-	0.02	2.5
Reactivity* (s)	976.0	100.4	-	-	
Specific surface area (m ² /kg)	4400	9005	1529	493	

* measured in the laboratory using the acetic acid test [19]

Table 2 Mix design of MgO-GGBS pastes

Paste Nomenclature	Weight percentage /%			
	MgO _{90/200}	MgO _{94/200}	Ca(OH) ₂	GGBS
G	0			100
M _h -2.5	2.5			97.5
M _h -5	5			95
M _h -7.5	7.5			92.5
M _h -10	10			90
M _h -15	15			85
M _h -20	20			80
M _l -2.5		2.5		97.5
M _l -5		5		95
M _l -7.5		7.5		92.5
M _l -10		10		90
M _l -15		15		85
M _l -20		20		80
C-5			5	95
C-10			10	90
C-15			15	85

Table 3 Calculated weight loss from TG curves

Paste Denotation	Weight percentage /%								
	7d			28d			90d		
	Δm_1	Δm_2	NEW	Δm_1	Δm_2	NEW	Δm_1	Δm_2	NEW
G	1.47	1.23	3.35	1.75	1.79	4.40	3.03	1.90	6.84
