Structure and Aanalysis of the Eye of a Numerically Simulated Tropical Cyclone

By Yoshio Kurihara and Morris A. Bender

Geophysical Fluid Dynamics Laboratory/NOAA Princeton University, Princeton, New Jersey 08540, U.S.A. (Manuscript received 22 September 1981, in revised form 4 November 1981)

Abstract

A tropical cyclone has been simulated in a quadruply nested mesh model with finest grid resolution of about 5 km. At the center of the vortex, a compact eye was maintained. Azimuthal means as well as asymmetry of the eye and the eye wall structure are described. The asymmetric features within the eye wall moved cyclonically at a much smaller rotation rate than the cyclonic wind within the eye wall. Roles of the mean radial-vertical circulation, the eddy motions and the diffusion effect in the maintenance of the mean structure are analyzed. In the analysis, attention is given to the balance between the wind and pressure fields and also to the budgets of relative angular momentum, heat and water vapor. The eddy motions caused a cooling and moistening effect in the eye which counterbalanced a warming and drying effect due to the mean sinking motion.

1. Introduction

The eve is a frequently observed phenomenon in intense tropical cyclones, consisting of a relatively warm and cloud-free air column surrounded by an area of intense convection, usually called the eye wall. Asymmetric structure of the eye wall has been recognized since earlier aircraft observations (e.g., Simpson, 1952; Gentry, 1963; La Seur and Hawkins, 1963).

certain features concerning the formation, structure and maintenance of the eye of tropical cyclones. This includes the construction of model vortices containing an eye, through analytical than an actual eye, we hope the obtained results considerations usually combined with observational analysis (e.g., Jordan, 1952; Malkus, 1958; Kuo, 1959; Eliassen, 1971; Willoughby, 1979; Smith, 1980). Composite analyses of the inner core region of observed hurricanes were made by Shea and Gray (1973) and Gray and Shea (1973). Also, laboratory experiments to simulate the asymmetric features are investigated. The the eye were reported (e.g., Wui and Ye, 1979). Based on the results from his axisymmetric numerical model, Ooyama (1969) discussed the heat and water vapor are discussed in Section effect of the non-balanced boundary layer flow on the eye structure. In Jones' (1980) three- ment are made in Section 7.

dimensional, nested-mesh model with finest grid resolution of 10 km, an eye-like structure appeared.

One factor which remained uncertain or speculative at best in the above mentioned studies is the role of asymmetries in the dynamics of the eye. In this study, we present a fairly comprehensive and coherent picture of the eye structure including the characteristics of asymmetry. Quantitative estimates of various quanti-Much effort has been made to understand ties within the eye and the eye wall were made possible by the application of a quadruply-nested movable mesh model. Although the eye we analyze is a numerically simulated one rather will increase our knowledge of the eye dynamics.

> In the present paper, the numerical model used and the time integration of it are briefly described in Sections 2 and 3, respectively. The time averaged, azimuthal mean of the vortex structure is shown in Section 4. In Section 5, balance relation between the wind and pressure and the budgets of relative angular momentum, 6. Finally, some remarks on the present experi-

2. Brief description of the model

The numerical simulation model used in the present study is the eleven level primitive equation model constructed at the Geophysical Fluid Dynamics Laboratory, NOAA. The governing equations of the model and the computational schemes applied to it are identical to those explained in the paper by Kurihara and Bender (1980, see both text and appendices).

We used a quadruply nested grid system for making the time integration of the model. The outermost grid area defined a channel type domain, with cyclic condition assumed for its 33.2 degree longitudinal span and laterally open conditions placed at 5.2°N and 38.4°N. The grid resolution, or the meridional distance between grid points, was reduced at each nesting from 90 km to 30 km, then to 10 km, and finally to 5 km. Other information on the grid system is listed in Table 1. The inner three meshes, which were movable, were shifted during the course of the time integration so that the vortex remained in the center of these meshes.

In the present model, the hydrostatic balance is assumed and also a parameterization scheme is used to incorporate the effect of moist convection. Accordingly, an accurate simulation of transient features of individual convection elevortex system. We will make an evaluation on probably due to the β -effect (e.g., Adem, 1956). the effect of parameterization for moist convection later in Section 7.

3. Time integration of the model

The initial condition of the model was determined in a manner similar to | that described by Kurihara and Bender (1980). An initial circular vortex was specified by formula (3.1) in their paper for $\sigma \ge 0.9$ and the intensity of the vortex was decreased with height above $\sigma = 0.9$ by the factor $\sigma/0.9$. (σ is the pressure normalized by its surface value.) Numerical constants in (3.1) were set as $V_m = 12 \text{ m s}^{-1}$ (maximum wind speed), $R_m = 150 \text{ km}$ (approximate radius of maximum wind) and $R_0 = 1,167$ km (equivalent to 10.5 Fig. 1 Radial distribution of azimuthally averaged degrees latitude: radial extent of vortex). The

above vortex was placed at 19.8°N. The values of the constants $T_0(\sigma)$ and p_{*0} which appear in the above mentioned paper as well as the initial relative humidity were the same values as $T(5000, \sigma)$, $p_*(5000)$ and the initial humidity. respectively, described in the paper by Kurihara and Tuleya (1974). It is important to note that no zonal flow was present at the initial time and, hence, the evolution of the vortex occurred in a calm environment.

The time integration of the model proceeded to 48 hours with the time steps listed in Table I. During the integration, the sea surface temperature was fixed at 302K. Fig. 1 shows the time change of the radial distribution of the azimuthally averaged surface pressure. Rapid deepening of the vortex took place during the 24 to 36 hour period. A slow change in the central ments is precluded even though the grid resolu- surface pressure after hour 36 suggests that the tion was increased in this experiment. We vortex was at a nearly stationary state in the presume that, when an intense vortex having the later period. At hour 43.6, when the storm was scale of a tropical cyclone evolved in the model the most intense, the minimum surface pressure integration, the condition of hydrostatic balance and the maximum surface wind were 924 mb may be valid for such a vortex especially at its and 76 m s⁻¹, respectively. In the 48 hour period, quasi-stationary stage. The eye structure was the center of vortex moved 52 km to the west expected to appear as a central part of the above and 73 km to the north from the initial position,

cyclone, was persistently observed. (An eye-like at ten time levels from hour 37.1 to hour 46.55 structure was first noticed at hour 25 when the is presented. An area of moderate and heavy central pressure and the maximum surface wind rain, i.e., greater than 0.05 mm/126 s, which were 983 mb and 45 m s⁻¹, respectively.) In encircles the area of no rainfall indicates the Fig. 2, the distribution of the precipitation in- eye wall. Apparently, the eye that developed in tensity, together with that of surface pressure the present experiment was very compact. It may be compared favorably with the eye of intense hurricanes such as Hilda of 1964, Inez of 1966 and Camille of 1969. The dark shaded area of heavy rainfall within the eye wall in Fig. 2 takes a round shape but broken at one or two openings. This suggests that there exists a few positions of maximum rainfall intensity within the eye wall. Also, it should be noted that the contours of surface pressure are elongated, though very little, toward the areas of strong rainfall. In the present case, the positions of surface pressure minimum and the eye almost coincide with each other.

4. Mean structure of the eye and the eye wall

In this section, we investigate the time averaged, axially symmetric component of various fields in the central area of the vortex. To obtain the mean fields, we first computed the azimuthal averages of quantities at various radii for each of the time levels used in Fig. 2. To compute the azimuthal average, the grid point values were interpolated onto 40 equally spaced points along each circle through bilinear interpolation. The axisymmetric fields thus obtained at the ten time levels showed little fluctuation with time. Accordingly, the mean vortex defined from the average of these fields can be considered representative of the entire analysis period. The structure of the mean vortex is shown in Figs. 3 through 6 as a function of the pressure level (ordinate) and the radial distance from the storm center (abscissa). The heavy solid lines in the figures indicate the radial distribution of the mean surface pressure.

Fig. 3 shows the height-radius distribution of the mean azimuthal wind. A vertical, dashdotted line indicates the radius of maximum azimuthal wind. It is located approximately at 20 km radius between 850 and 500 mb levels, tilts slightly outward above 500 mb and is found horizontal dash-dotted line in Fig. 3.

lation system. The large area of upward motion ture anomaly is 15K at the center at the 300 mb is connected to the upper level outflow of the level. A weak negative anomaly exists at the outer circulation system. The mean sinking 100 mb level outside the 10 km radius. According motion within the eye is estimated to be about to Fig. 6, the upper half of the eye is particularly 0.03 mb s⁻¹. In the distribution of ϖ (figure not dry. A region of high mean relative humidity shown) an area with mean upward velocity extends to upper levels within the eye wall. The exceeding 0.18 mb s⁻¹ was observed between the contour for 65 per cent runs near the top of the 350 and 800 mb levels at around 18 km radius, boundary layer in the outer area, but reaches to i.e., 2 km inside of the radius of the maximum almost the 100 mb level in the eye wall. The contour pattern suggests that the mean location of the outer boundary of the eye wall may be chosen at about 35 km radius.

Asymmetry of the vortex

We already noticed in Section 3 the existence of asymmetry in the structure of the eye wall. Analysis of the asymmetric or eddy component of an intense vortex is most appropriate when a zonal flow is absent as in the present case, since the definition of asymmetry becomes ambiguous in the presence of a zonal flow. As seen in Fig. 2. the asymmetric component appears to rotate within the mean vortex. Accordingly, its typical feature can more easily be depicted from the analyses of the fields at one appropriate time level. In this section, various fields at hour 46.55 are presented.

Fig. 7 shows the distributions of the horizontal wind and the vertical velocity, ω , at levels $2(\sim15 \text{ km})$, $4(\sim8.3 \text{ km})$, $6(\sim3.3 \text{ km})$ and 10(~0.2 km), respectively. The asymmetry of the horizontal wind is most evident at level 2, i.e., the outflow level. The field of ω exhibits a pattern of spiral shape, especially at middle levels. While the negative (positive) ω corresponds to upward (downward) motion at the levels 2, 4 and 6, the large area of negative ω at the level 10 reflects the movement of an air parcel toward the lower pressure area. From the comparison of Fig. 7(c) and Fig. 2(j), it may be suggested that the precipitation intensity within the eye wall is correlated well with the vertical velocity at the middle levels.

The positions of the strong upward motion and, hence, the large rainfall intensity moved around the vortex center. The analysis of such movement was made. The results indicate that it takes 77 minutes on the average to make one counter-clockwise rotation. On the other hand, the rotation rate for the wind within the eye wall is, when estimated from the mean azimuthal wind of 60 m s⁻¹ at the 20 km radius, 35 minutes for one rotation. Accordingly, the rotation of the asymmetry within the eye wall relative to the

eye and the eye wall

In this section, we investigate the role of asymmetry as well as that of mean radial-vertical circulation in the maintenance of the mean where structure of the vortex. For the above purpose, we perform budget analyses of various quantities for a period during which transient features, such as the fluctuation in the distribution of vertical motion within the eye, are considered minimal. In the present time integration, such a relatively steady period is found after hour 45.435. All the results presented in this section represent the average of budgets at five time levels within a 10.5 minute period after the above time level.

In making the budget analyses, we ignore the asymmetry and the time variation of the surface pressure for simplicity. Also, since the budgets are calculated within a radius of 80 km from the storm center, we can assume that the Coriolis parameter, f, is constant; $f=5.09\times10^{-5}$ s⁻¹. The analyses are made using a cylindrical coordinate system with the σ -coordinate in the vertical. The notations used are: r (radius from storm center), u (radial wind, positive outward), v (azimuthal wind, positive counterclockwise), $\dot{\sigma}$ (vertical σ velocity, $d\sigma/dt$), ω (vertical p-velocity, dp/dt), T (temperature), R (mixing ratio of water vapor), ϕ (geopotential of a pressure surface), p_* (surface pressure), R_g (gas constant) and c_p (specific heat of the air at the constant pressure). The overbar notation represents the azimuthal average of a quantity along a certain fixed radius. The azimuthal averages at each radius were calculated from the grid point values using the same procedure described in section 4. Deviation of a quantity from its azimuthal average is denoted by a prime. We define the operator M which expresses the advection of a quantity \bar{x} by the mean circulation:

$$M(\bar{x}) = -\bar{u}(\partial \bar{x}/\partial r) - \bar{\dot{\sigma}}(\partial \bar{x}/\partial \sigma).$$

The operator E denotes the effect of eddy trans-

$$E(x) = -\frac{1}{\bar{p}_{*}} \left[\frac{\partial \bar{p}_{*} r u' x'}{r \partial r} + \frac{\partial \bar{p}_{*} \dot{\sigma}' x'}{\partial \sigma} \right].$$

We evaluated $\overline{u'x'}$ by $\overline{ux-ux}$. In obtaining \overline{ux} , the interpolation of grid point values onto the points along each circle was made with respect to the product ux itself. Computation of $\overline{\dot{\sigma}'x'}$ was similar.

a. Balance of forces in the radial direction

We examine a state of balance between the 6. Maintenance of the mean structure of the mean azimuthal wind and the mean pressure field. The equation for \bar{u} may be written as

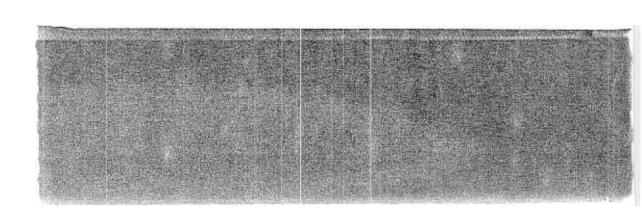

$$\frac{\partial a}{\partial t} = UA + UB + UC + UD \tag{1}$$

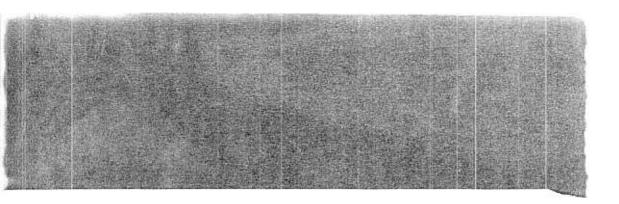

- UAimbalance from the gradient wind balance $[=(f+\bar{v}/r)\bar{v}-\partial\bar{\phi}/\partial r]$
- inertia effect due to the mean circulation $[=M(\bar{u})]$
- effect of the eddies $[=E(u)+\overline{v'v'}/r]$
- effect of horizontal and vertical diffusion.

The mean azimuthal wind, v, is super-gradient if UA is positive, whereas it is sub-gradient if UA is negative. In the present vortex, UA is near zero everywhere except for the boundary layer and the upper level outflow layer. This means that the gradient wind is a good approximation for \bar{v} at the place where \bar{u} is small. (The gradient wind relation may still be valid even when \bar{u} is large, if the actual wind and the radius of curvature of flow are properly considered for each air parcel. However, in this paper, we discuss the gradient wind balance only in terms of UA.)

The distributions of the budget components of (1) in the boundary layer are shown in Fig. 11. The center area (r<7.5 km) is excluded because of numerical difficulties related to the singularity at the center. The sign of UA indicates that v within about the 30 km radius is super-gradient except for the shallow layer outward of the 15 km radius where it is subgradient. As reflected in the distribution of UA +UB, the inertia effect of the mean circulation tends to cause deceleration of \bar{u} , leading to the reduction of the super gradient imbalance. The radial flow \tilde{u} becomes steady provided that UA +UB is counterbalanced by the terms UC and UD. This is approximately the case as seen in Fig. 11. The role of asymmetry, i.e., UC, is not negligible particularly at the small radii.

The state of balance in the outflow layer is illustrated in Fig. 12. As shown by UA, D within about 20 km radius is subgradient and v between 20 and 40 km is supergradient. The effect of UB is to reduce the supergradient imbalance above 200 mb level. In UB, the horizontal and vertical advection of \bar{u} are found to be equally important. It is clearly seen that the balance of forces at the upper levels is almost

389

complete with the addition of UC to UA + UB. i.e., $vr + (f/2)r^2$. If the former coincides with a The eddy effect, UC, is mainly due to the hori- contour of the latter quantity, it means that the zontal eddy transport of u' at radii greater than budget of angular momentum is complete without 20 km, while it is largely due to the vertical the terms MB, MC and MD. Otherwise, these transport at the smaller radii. The diffusion terms play a role in the maintenance of the effect, UD, is not important at the upper levels for the steadiness of the mean circulation.

b. Budget of mean relative angular momentum The equation for the mean relative angular momentum takes the following form,

$$\frac{\partial r\bar{v}}{\partial t} = MA + MB + MC + MD \tag{2}$$

where:

MA change due to the advection of absolute angular momentum by the mean radial-vertical circulation $[=M(r\bar{v})-$

MBeffect of eddy flux of relative angular momentum [=E(rv)]

MC change due to horizontal diffusion

change due to vertical diffusion.

In Fig. 13, the stream function for the mean radial-vertical circulation is superimposed on the distribution of the absolute angular momentum,

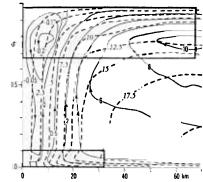

Fig. 13 Height-radius distribution of ~10 min average (at ~45.4 h) of mean absolute angular momentum (dashed lines, in 105m2s-1) and mean stream function (solid lines, in 107m2 mb s-1). The boxes show the domains for which Figs. 14 and 15 are prepared, respectively.

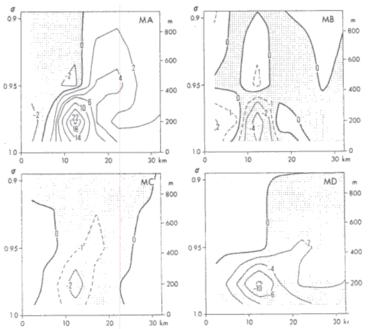

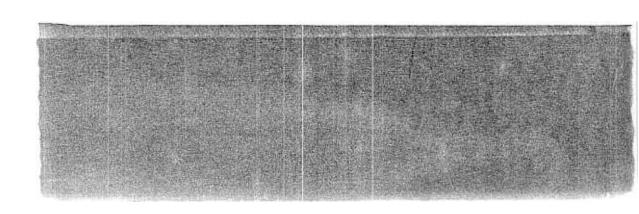

Fig. 14 Height-radius distribution of ~10 min average (at ~45.4 h) of the budget components of relative angular momentum, i.e., the terms in eq. (2), for the boundary layer (all units 102m2 s-2). Areas with negative values are shaded.

In the present case, an appropriate contribution balanced by the effect of eddies, MB. The condomains indicated in Fig. 13.

The distributions of the budget components in the boundary layer are shown in Fig. 14. The mean inflow brings larger momentum into the bottom part of the eye wall area, whereas the outward advection within the eye causes the decrease of momentum. In general, the vertical advection tends to reduce the above changes due to the horizontal advection. The resultant effect is found in the distribution of MA. It is evident from the figure that an apparent sink of momentum within the eye, negative MA, is mostly compensated by the momentum supply due to eddies, MB. The apparent source in the eye wall region, positive MA, is balanced by MD and, to a lesser but significant degree, by MB and MC. Thus, the angular momentum field of the the mean vortex, together with that of the mean mean vortex is kept steady.

The budget of relative angular momentum in the outflow layer is illustrated in Fig. 15. In this layer, the vertical advection of the angular ascending motion within the eye wall causes momentum causes the apparent source within the eye wall. The apparent sink at the large radii represented by TA, has to be nullified by TB+ results from the horizontal advection. Such TC+TD in order to maintain the stability of the advection effects of the mean radial-vertical mean vortex.

relative angular momentum of the mean vortex. circulation, MA, are almost entirely counterof MB, MC and MD is required at the two tributions of MC and MD are small by an order of magnitude.

c. Heat budget

The equation for the mean temperature is written as

$$\frac{\partial \bar{T}}{\partial t} = TA + TB + TC + TD \tag{3}$$

change due to the mean radial-vertical circulation $[=M(T)+(R_g/c_p)(T\bar{\omega}/p)]$

change due to eddy motion [=E(T)+ $(R_q/c_p) (\overline{T'\omega'}/p)]$

change due to horizontal and vertical diffusion

TD change due to condensation-convection. The distribution of potential temperature of stream function, is shown in Fig. 16. Since the air is stably stratified as seen in the figure, the mean sinking motion in the eye and the mean warming and cooling, respectively. This effect,

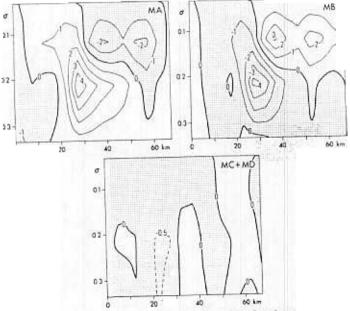

Fig. 15 As in Fig. 14 except for the outflow layer

The role of eddies, TB, is to remove the heat from the eye at all levels to enable a nearly

The analysis results of the heat budget for the stationary state in the eye to be maintained. It domain indicated in Fig. 16 are presented in Fig. is found that the horizontal eddy flux is a major 17. The above mentioned effect of the mean contributing factor in TB. The role of TB is also circulation is reflected in the distribution of TA. seen in the outflow layer. The diffusion TC serves mainly to supply heat into the boundary layer. The apparent heat sink, i.e., the negative TA, within the eye wall is compensated to a large degree by the diabatic heating effect, TD. The quantity TD is related to the conversion of latent energy into total potential energy. In the present model, such a conversion integrated within the 67.5 km radius is 2.415×10^{14} W. On the other hand, the conversion of total potential energy into mean kinetic energy, which is expressed by $-\bar{u} \partial \bar{\phi}/\partial r$, integrated for the same domain is 13.51×10¹²W, and the conversion into eddy kinetic energy, $-v' \cdot V \phi'$ (v and V are the horizontal wind and the gradient operator, respectively), is only 0.63×10¹²W. Accordingly, the heat engine efficiency in the inner region of the present vortex, which is given by the ratio of the conversion of potential to kinetic energy against the conversion from latent to potential energy, is approximately 6%.

d. Budget of water vapor

The budget of the mean mixing ratio of the

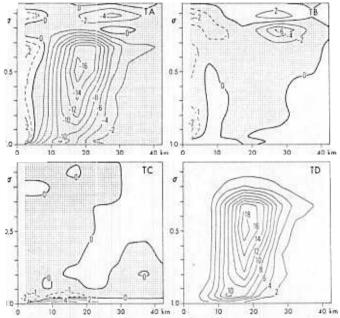

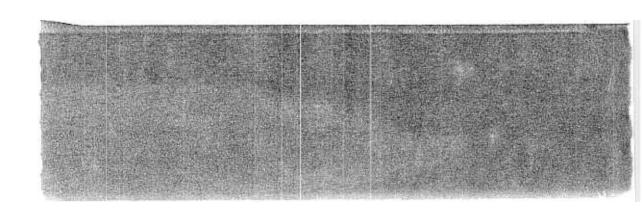

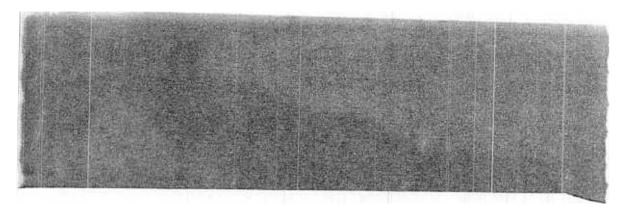

Fig. 17 Height-radius distribution of ~10 min average (at ~45.4 h) of the heat budget components, i.e., the terms in eq. (3), (all units 10-3 K s-1). Areas with negative values are shaded.

393

water vapor is analyzed using the following 7. Summary and remarks equation.

$$\frac{\partial \bar{R}}{\partial t} = RA + RB + RC + RD \tag{4}$$

where:

change due to the mean radial-vertical RAcirculation [=M(R)]

change due to the eddy motion [=E(R)]

RCchange due to horizontal and vertical diffusion

RDchange due to condensation-convection.

The distributions of each term in the above equation are shown in Fig. 18. The mean sinking in the eye has a drying effect, resulting in the negative RA, while the upward motion within the eye wall causes moistening, i.e., positive RA. to mention that Kurihara and Tuleya (1974), The above mentioned drying effect in the eye is using a model similar to the present one except largely offset by the moisture supply by the for the horizontal resolution and the treatment eddies, RB. Horizontal mixing by eddies is found of vertical mixing, obtained a larger vortex than to be a predominant factor in RB. The diffusion the present one in an integration which started effect, RC, serves to increase the mixing ratio in from an initial vortex with a much larger radial the boundary layer including that region contained within the eye. The effect of condensation, evolved from the initially rest state in a high RD, balances the positive RA within the eye resolution, axisymmetric, deep convection model wall.

Using a quadruply nested mesh model with a finest grid resolution of about 5 km, a quasistationary tropical cyclone is simulated. At the center of the vortex, a compact eye is maintained. The radius of the eye is about 6.5 km below 600 mb and increases to 8 km at 200 mb. Within the eye, a weak mean sinking motion exists, free from rainfall. The temperature anomaly of the eye is 15 K at 300 mb. Note that the above vortex is maintained in a calm environment. One of the problems to be studied in the future is to find the factors which determine the size and intensity of a quasi-stationary vortex. In this respect, it may be informative extent. On the other hand, the vortex which (Yamasaki, 1977) was much smaller than the

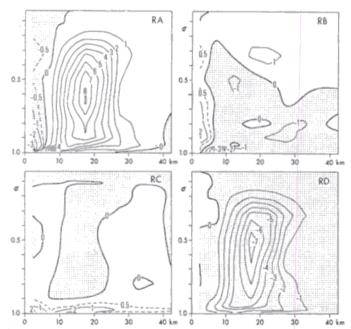

Fig. 18 Height-radius distribution of ~10 min average (at ~45.4 h) of the water vapor budget components, i.e., the terms in eq. (4), (all units 10-3 g kg-1 s-1). Areas with negative values are shaded.

present one. We speculate that relatively weak in the previously mentioned Yamasaki's model winds beyond a certain radius, either due to lack (1977) exhibited short period oscillation as well of basic flow or small size of vortex, will reduce as small scale radial-vertical variation. the evaporation rate and, hence, may weaken the convective activity in the outer domain.

than the wind within the eye wall.

the effect of diffusion. The frictional effect is also important in the boundary layer. If a basic flow is present, the balance of forces within the vortex is affected. According to the analysis a good approximation to the actual wind in the free atmosphere.

In the budget of relative angular momentum, the effect of the mean circulation is offset by either or both of the effects due to eddies and diffusion. The eddies supply angular momentum to the bottom part of the eye and remove angular momentum from the surrounding boundary layer.

The warming and drying in the eye due to mean sinking motion are counterbalanced by the cooling and moistening effect of the eddies. This effect is apparently caused at each level by the exchange of the air between the warm, dry eye and the relatively cool, moist eye wall. It should be noted here that the heat and moisture budgets presented in this paper are obtained from a rather simple model. The analysis results may have to be modified if the effects which are absent in the present model, such as the evaporation of falling raindrops and the suspension of cloud droplets, play significant roles in the budget.

The budget analyses in the present study were made for a particular ten minute period. The eddies represent the deviation from the axisymmetric field at each of the time levels. The local sum of the budget components for certain quantities at one arbitrary time level is not necessarily small, indicating fluctuation of the mean fields. We note here that the axisymmetric fields Eliassen, A., 1971: On the Ekman layer in a

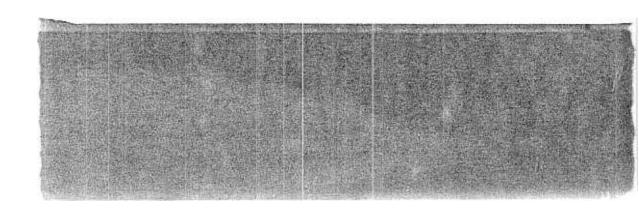

As mentioned in Section 2, a parameterization scheme for the moist convection (Kurihara, 1973) Asymmetry in the vortex structure is evident is incorporated in the present model. In order in various fields. Areas of anomalous rainfall to examine the degree of impact of the parameteriintensity and ascending motion are observed at zation on the structure of a mature vortex, a a few locations within the eye wall. The asym- supplemental integration was performed. In this metric features within the eye wall move case, the parameterization scheme was removed cyclonically with a much smaller rotation rate from the model at hour 37.1, after the eye was established, and the integration was continued Except for the boundary layer and the upper for about an 8.5 hour period. The vortex strucoutflow layer, the mean vortex is in gradient tures from the two models, with and without the wind balance. In the above two layers, a state parameterization effect, were then compared with of balance is achieved with the inclusion of the each other. It was found that the overall strucinertia effect of the mean radial-vertical circu- tures are about the same. This suggests that, in lation, the stress effect of the eddy motions and case of the grid resolution of 5 km, a large part of the heat and moisture fields within the eve wall area at the mature stage of the storm are determined by the explicit motion and that the contribution of the sub-grid scale convection is by La Seur and Hawkins (1963), the radius of rather small. (Convection in the outer area in curvature of the flow will vary around the storm the two integrations was too weak to make a in this case, although the gradient wind is still definite evaluation of the parameterization effect.) It also appears that the asymmetric features may be strongly dependent on the mean vortex structure, rather than the sub-grid scale convection. The ground for this conjecture is that the patterns of asymmetry in two numerical models, namely the present model and the model by Kitade (1980), are quite similar to each other in various respects despite the use of different parameterization schemes.

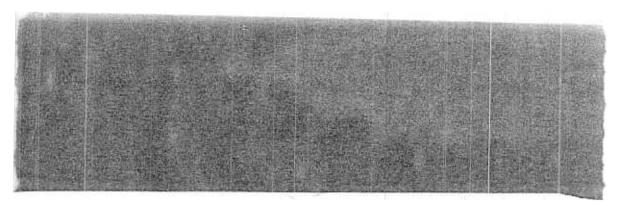

Acknowledgements

The present authors would like to express their appreciation to J. Smagorinsky for his continuous encouragement, and to R. E. Tuleya for many helpful advices during this study. They are grateful to R. E. Tuleya, Q. C. Zeng and P. Sardeshmukh for valuable comments on the earlier version of the manuscript. Gratitude is also expressed to J. Kennedy, J. Conner, P. Tunison, W. Ellis and M. Zadworny for their superb assistance in the preparation of the manuscript.
