Structure-Based DNA-Targeting Strategies with Small Molecule Ligands for Drug Discovery

Jia Sheng, **Jianhua Gan**, and **Zhen Huang**
Department of Chemistry, Georgia State University, Atlanta, Georgia 30303

Abstract

Nucleic acids are the molecular targets of many clinical anticancer drugs. However, compared with proteins, nucleic acids have traditionally attracted much less attention as drug targets in structure-based drug design, partially because limited structural information of nucleic acids complexed with potential drugs is available. Over the past several years, enormous progresses in nucleic acid crystallization, heavy-atom derivatization, phasing, and structural biology have been made. Many complicated nucleic acid structures have been determined, providing new insights into the molecular functions and interactions of nucleic acids, especially DNAs complexed with small molecule ligands. Thus, opportunities have been created to further discover nucleic acid-targeting drugs for disease treatments. This review focuses on the structure studies of DNAs complexed with small molecule ligands for discovering lead compounds, drug candidates, and/or therapeutics.

Keywords

nucleic acids; structure-based drug discovery; small molecule ligands; modification and derivatization; structures of DNA–ligand complexes

1. INTRODUCTION

Structure-based drug design (SBDD) has been used in the pharmaceutical industry for over 25 years as a guiding approach to identify lead compounds and develop new therapeutics. The success of SBDD mainly depends on the rapid advances in structural biology, which provides the detailed three-dimensional (3D) information of the drug targets and, more importantly, sheds light on the interactions between the targets and small molecule ligands. Based on the structures, novel small molecules can be designed by molecular modeling for additional screening. Combined with the co-crystallization studies, optimized compounds with better specificity and affinity can be further designed.[1] The biological macromolecules, including protein and nucleic acid, have naturally become the drug targets. Nucleic acids play important roles in living systems via participation in genetic information storage, replication, transcription, and translation directing protein synthesis. Catalytic RNAs also play critical roles in biological reactions as catalysts.[2–5] Thus, targeting nucleic acids can selectively disrupt gene expression for treating virus-caused diseases and cancers at the genetic level, that is, the nucleic acid level. Actually, it has already been established that nucleic acids are the molecular targets of many chemotherapeutic anticancer drugs used clinically. Compared to proteins, however, nucleic acids have traditionally gained much less attention in the SBDD field, probably because it is challenging to specifically recognize

nucleic acids by small molecules and it lacks structural information of nucleic acids in complex with lead compounds and drug candidates. Fortunately, over the past several years, the fields of nucleic acid chemistry and molecular and structural biology have made tremendous progresses. Many nucleic acid structures of various complexities have been determined, including more than 300 structures of ligand–DNA or ligand–RNA complexes deposited in the structural databases since 2004. The structural data provide the molecular mechanisms and fundamental functions of many nucleic acids and their complexes with ligands. Therefore, opportunities have been created for further design and development of nucleic acid-targeting drugs to treat genetic and acquired diseases. Herein we mainly highlight the recent advancements in structural studies of complexes of DNAs and small molecules (Table I) for potential drug discovery and investigation of DNA–ligand interactions.

2. STRATEGY THROUGH CHEMICAL BOND FORMATION

A. Pt-containing Compounds Forming Covalent Bonds with DNA

Cisplatin [or cis-diamminedichloroplatinum (II), Fig. 1A] has become one of the most widely used and effective anticancer drugs today to treat testicular, ovarian, cervical, head and neck, esophageal, and nonsmall cell lung cancers, since it was approved by FDA in 1978.[6–8] However, the chemotherapeutical treatment by cisplatin always causes severe side effects, including nausea, vomiting, and ear damage, because cisplatin attacks both cancer cells and normal ones. It is therefore important to elucidate the details of the cisplatin action modes in order to design new cisplatin analogs that can specifically target cancer cells. There are tremendous progresses in studying cisplatin mechanisms over the past three decades, including the exploration of its possible biological targets, the elucidation of its mechanisms, and the design of the novel derivatives. Although cisplatin can interact with many different components in cells, such as phospholipids, phosphatidylserine, DNA, and RNA,[9, 10] it is generally accepted that DNA is the primary target of cisplatin.[11] Cisplatin can form stable adducts with DNA either in a 1,2-intrastrand cross-links between two adjacent bases (GG or GA), or a 1,3-intrastrand cross-link between two guanines separated by another base.[12, 13] The resulting Pt-DNA adducts can hamper and inhibit a series of downstream biological processes, including replication and transcription, cell cycle arrest, and attempted repair of damaged nucleotides, which eventually lead to cell death.[14]

Extensive structural studies have been performed on cisplatin-DNA adducts by NMR, molecular mechanics calculation, and X-ray crystallography. The early crystallographic information of these adducts is mainly limited to short single-stranded DNAs, and it has been concluded that cisplatin reacted with DNA by covalently linking to the N7 positions of the adjacent G or A. The milestone in this research area appeared in 1995, when Lippard and his co-workers determined the first X-ray crystallographic complex structure of a double-stranded DNA dodecamer with cisplatin.[15] The 12mer DNA sequence is d(CCTCTG*G*TCTCC)• d(GGAGACCAGAGG), where the G*G* means the cisplatin cross-linked intrastrand GG dimer at N7 positions. As shown in Figure 1B and C, the base pairs are propeller-twisted, but retain hydrogen-bonding interactions. Very recently, the same group improved the resolution of the complex structure (PDB 3LPV) to 1.77 Å.[16] The higher resolution structure clearly shows the amine ligands and the cross-linked geometry of both platinum center and nucleobases, although their overall structures are virtually identical (Fig. 1D). The deoxyribose sugar puckers are also better resolved, allowing reexamination of the global structure of this platinum-modified DNA. In addition, this new structure reveals four octahedral $[Mg(H_2O)_6]_2^+$ ions associated with bases in the DNA major groove and 124 highly ordered water molecules participating in hydrogen-bonding interactions with either the nucleic acid or the diammine-platinum(II) moiety.

As shown in the Figure 1B and D, the major groove of the platinated DNA is compressed and the minor groove is widened, making the double-stranded DNA ready for structure-specific recognition by proteins, such as the high-mobility group domain (HMG). It has also been known for a long time that the platinated DNA duplex structure can attract HMG and other proteins.[17] To further investigate its molecular basis for this recognition, Lippard and co-workers accomplished another milestone by solving the X-ray crystal structure of a 1:1 cisplatin-modified DNA/HMG-domain complex, as showed in Figure 2.[18] It is revealed from the structure that domain A of the HMG1 protein binds to the widened minor groove of a 16mer DNA duplex containing the cisplatin adduct, and the DNA is probably further bent in order to better interact with the protein.

Besides HMG, it has been shown that two special polymerases (Pol η and Pol ζ) can also interact with cisplatin during cellular replication to bypass the platinum lesion, which reduces the therapeutic effect of cisplatin and contributes to tumor resistance.[19] Very recently, Carell and co-workers[20] reported a crystal structure of yeast Pol η pairing the Pt–GTG lesion with two nucleobases, which revealed the mechanism of the partial bypass reaction. As shown in Figure 3, the low-fidelity polymerase Pol η can place two nucleobases opposite the Pt–GTG lesion and the flipped-out central T of the Pt–GTG cross-link cannot be positioned in the active site, thus slowing down movement of the polymerase through the primer–template complex.

Additional understanding of how proteins like HMG and polymerases bind to cisplatin-modified DNAs has provided a platform for SBDD and optimization in order to develop better therapeutics. So far, over 3000 cisplatin analogues, including the Pt-containing prodrugs,[21] have been screened for further clinical trials to overcome certain side effects, such as high toxicity and intrinsic or acquired resistance.[22] In addition, special drug delivery systems have been developed to deliver cisplatin to tumor cells in more efficient ways.[23]

B. Organic Compounds Forming Covalent Bonds with DNA

In addition to the platinum compounds, other types of small molecules have been found to covalently bind DNA, including nitrogen mustard drugs (melphalan, uramustine, chlorambucil, and bendamustine, etc.), mitomycin C and psoralen. The detailed adduct formation and repairing mechanisms of these compounds in cells have been well summarized.[24] We focus on a few 3D structures to illustrate their modes of molecular recognition and interaction with DNA.

Nitrogen mustard compounds (Fig. 4A) have been used as effective anticancer drugs for a long time. Their cytotoxicity is mainly caused by the nonspecific DNA cross-linking, which prevents DNA duplex separation through the formation of a N7-dG/N7-dG interstrand cross-linking. To obtain more structural insight into this interaction, Stone, Egli, and their co-workers inserted the 3-aminopropyl-2′-dU and 7-deaza-dG into the Dickerson–Dew dodecamer.[25] The crystal structure of this modified DNA duplex (Fig. 4B) suggests a potential mechanism of interstrand *N* + 2 DNA cross-link formation by nitrogenmustard compounds without bending DNA.

Mitomycin C (Fig. 5A) is a potential antitumor drug that works through alkylation of guanine in the d(C-G)•d(C-G) steps of the DNA duplex.[26] Patel, Tomasz, and their co-workers solved a NMR solution structure of a 9mer DNA duplex containing this monoalkylated mitomycin C. As shown in Figure 5B, the mitomycin ring is located in the minor groove with its indoloquinone aromatic ring system at a 45° angle relative to the helix axis. As a result, conformational perturbation has been observed in this modified DNA structure, presumably through widening of its minor groove in order to stack the indoloquinone ring over the neighboring bases.[27] Interestingly, the mitomycin alkylated

DNA presents B-form sugar puckers and A-form base stacking patterns. The major metabolite of mitomycin C in cells, 2,7-diaminomitosene (2,7-DAM, Fig. 5C) has been identified and studied structurally to provide new insight into the interaction with DNA. The NMR structure of this drug–DNA complex (2:1 ratio) (Fig 5D) contains a self-complementary DNA dodecamer d(GTGG*TATACCAC) with G4 modified with mitosene at its N7 position. Surprisingly, 2,7-DAM is located in the major groove of DNA and oriented 3′ to the modified guanine, which explains why the overall conformation does not change significantly after the bulky modification.[28]

Psoralens, a class of photomutagenic and photochemotherapeutic agents, have been widely used for the treatment of vitiligo, psoriasis, and other cutaneous diseases. It is believed that they play these roles through interstrand cross-linking with DNA and RNA, specifically through the 5,6 double bond in pyrimidines, thereby blocking replication, transcription, and other DNA activities. 4′-(Hydroxymethyl)-4,5′,8-trimethylpsoralen (HMT, Fig. 6A) is one of the major synthetic psoralen derivatives that enhances its solubility in water and form higher yields of DNA adducts. Wemmer and co-workers reported a solution structure of HMT-monoadduct and cross-linked DNA duplex [5′-$(GCGTACGC)_2$-3′], as shown in Figure 6B. It has been observed that the HMT molecule spans across both the major and minor grooves by attaching with 5,6 double bonds in the two T4 bases, while maintaining the overall conformation. The aromatic rings of HMT have obvious stacking interactions with the surrounding four bases, which form van der Waals interactions with the HMT methyl groups. The cross-linking, base stacking, and hydrophobic interactions result in significant enhancement of the duplex stability. The X-ray crystallographic investigation of the interaction between HMT and DNA by Ho and co-workers revealed that the HMT-$d(CCGCTAGCGG)_2$ adduct can form a psoralen-induced four-way Holliday junction (Fig. 6C). Surprisingly, the HMT-$d(CCGGTACCGG)_2$ adduct with a single switched base pair forms a distorted junction (Fig. 6D).[29] This sequence-dependent interaction might also indicate a role of this important class of chemotherapeutics in initiating repair of psoralen lesions in mammalian DNA. In both structures, the assembly of four DNA strands forms a junction with two strands crossing over to connect the stacked helical arms. The two stacked DNA helical arms are related by crystallographic twofold symmetry, so that the two cross-linked strands define the asymmetric unit in the crystal. Both duplexes are highly distorted at the thymine bases linked to the six-member pyrone ring of the drug.

Aflatoxin B1 (AFB) is involved in mutation of the p53 tumor suppressor gene and the etiology of human liver cancer.[30] The metabolism of AFB includes oxidation to AFB-exo-8,9-epoxide by cytochrome P450.[31] This epoxide can react with duplex DNA efficiently to yield the N7 adducts of guanosine, a cationic adduct. The cationic species undergoes hydrolysis of the imidazole ring to form the AFB form amidopyrimidine adduct (AFB-FAPY, Fig. 7A).[32] Recently, Stone and co-workers solved an NMR structure of the DNA adduct containing the α form of this AFB-FAPY moiety (Fig. 7B).[33] This structure study indicated that the AFB moiety intercalates on the 5′-face of pyrimidine at the damaged nucleotides, causing obvious backbone torsion and overall duplex perturbation.

As discussed above, these covalent binders can cross-link to DNAs, causing modifications and perturbations in the DNA structures. The modified DNAs can no longer interact with their protein partners, thereby blocking the replication or transcription processes. This is probably the main mechanism of these covalent binders during the chemotherapy treatments. Due to relatively low selectivity, however, these agents are of high toxicity. Moreover, cells can develop different strategies to identify and repair the inter- or intrastrand DNA cross-links, which could play major roles in the drug resistance of certain cancers to chemotherapeutic treatments. In order to enhance the selectivity and reduce drug resistance, a clear understanding of the molecular mechanisms involved in the recognition

and repair of cross-linked DNA will be especially important. From a structural point of view, characterization of various types of DNA adducts can largely facilitate the study in this field. These structural studies can also provide direction toward molecular design and synthesis. For example, a synthetic N_4C-ethyl-N_4C interstrand cross-linked DNA was structurally characterized by Miller, Kielkopf, and co-workers as both a platform for drug design and a model system for DNA repair study. As shown in Figure 8, the detailed structure studies revealed that the ethyl cross-link in the CpG major groove does not significantly disrupt the B-form DNA helix and can selectively stabilize a preexisting conformation, although it can result in subtle differences in the roll of base pairs and loss of some divalent cation binding sites.[34] Moreover, Stone and co-workers solved two solution structures of DNA duplexes containing the cross-linked trimethylene moiety with the sequence contexts of GpC and CpG.[35] The structures indicated that both duplexes can maintain B-form geometry as well as the hydrogen bonds. However, the stacking between the cross-linked bases and the neighboring ones is quite different in these two structures (Fig. 9). The interaction in the GpC-containing duplex is greatly reduced, which is also consistent with the duplex stability result. The same research group also studied a DNA duplex structure with the hydroxytrimethylene interstrand linkage at the two N2 positions of guanosine using ^{15}N NOESY-HSQC NMR (Fig. 10), providing evidence for the stereochemical preference of this type of linkage and its thermal stability in duplex DNA.[36] Very recently, the same group also investigated a similar DNA structure modified with *trans*-4-hydroxynonenal (HNE) moiety (Fig. 11).[37]

3. TARGETING DNA WITH MINOR AND MAJOR GROOVE BINDERS

A. Minor Groove Binders

To disrupt the specific gene expression, the minor groove binding offers the highest sequence specificity between a small molecule and DNA. Classic minor groove binders are polyamides or heterocyclic dications, such as DAPI, berenil, Hoechst 33258, netropsin, distamycin, and pentamidine (Fig. 12). These groove binders were originally developed to prefer AT-rich regions and later further developed to expand to all A/T, T/A, G/C, and C/G pairs.[38, 39] Due to their capability to interact with DNA in a more specific manner, minor groove binders hold a great promise to treat the diseases at the DNA level. Actually, these minor groove-binding agents have been extensively studied as a class of potential therapeutics with antibacterial, antiprotozoal, antitumor, and antiviral activities.[40–42] Dickerson, Sundaralingam, Dervan, Neidle, Wilson, and their co-workers have pioneered this research area by revealing the 3D structures of DNA complexed with minor groove binders,[43–47] and some of the investigations in this research field have been summarized recently.[48–50] The shapes of the groove-binding molecules typically match the curve of the minor groove, thus allowing a perfect fit via interactions such as van der Waals contacts and hydrogen bonding. Here we listed some of the typical complex structures.[51–56] The structure of the DNA in complex with Hoechst 33528 is shown in Figure 13. In the structure, the ligand is clamped by the phosphate backbone of the DNA in the minor grove and forms extensive van der Waals contacts with the DNA. Although the hydrogen bonds (total of 2) do not play an essential role in the recognition between Hoechst 33528 and DNA, H-bonds do play an essential role in the cases of the netropsin–DNA and distamycin–DNA interactions (Fig. 14). In the netropsin–DNA structure (Fig. 14A), eight hydrogen bonds have formed between the ligand and DNA. In the distamycin–DNA structure (Fig. 14B), even more hydrogen bonds (total of ten) have been observed. In these structures, the ratios between the DNA and ligands are different. In the 1:1-binding mode, the minor groove of the DNA duplex is compressed, and the major groove is widened, which gives the access to other molecules binding to the major groove of the DNA duplex. In the 1:2-binding mode, the DNA minor groove binder works through the opposite way, that is, widening the minor

grove and compressing the major grove. Other similar drug–DNA complexes, such as imidazole-pyrole-hydroxypyrole polyamide,[57] benzimidazole,[58, 59] and tribenzimidazole[60], have been extensively discussed and summarized previously.

The classic polyamides, composed of amide monomers linked by peptide bonds, can bind many different DNA sequences, permeate the cellular membrane, access chromatin, and disrupt interactions between the target DNA and transcriptional factors, such as hypoxia-inducible factor, androgen receptor (AR), and glucocorticoid receptors (GRs).[61–63] Their hairpin derivatives containing two (*R*)-β-amino-γ-turns (Fig. 15A) have been demonstrated to have favorable DNA-binding affinities and better gene regulating ability.[64–66] The binding location and orientation of the polyamides have been widely studied through several complex structures.[57, 67–69] The high-resolution structures provide valuable insights into their molecular interactions with the DNAs and DNA–protein complexes, which serves as the foundation for further drug optimization. Recently, Dervan and co-workers reported a complex structure of an 8-ring cyclic Py-Im polyamide and a DNA duplex $[d(CCAGGCCTGG)]_2$ at 1.18 Å resolution (Fig. 15B). The determined structure shows that the overall duplex conformation has been dramatically perturbed. The minor groove is widened by 4 Å, while the major groove is compressed by ~4 Å .Moreover, the helix axis is bent toward the major groove by more than 18°, compared to the native counterpart.[66] These large distortions provide a molecular basis for supporting the idea of allosteric perturbation of the DNA helix by small molecules as minor groove binders, thereby chemically and selectively regulating gene expression.[66] In addition, this complex structure elucidates the source of sequence-specific recognition. The interactions between DNAs and ligands include hydrophobic packing, specific hydrogen bonding of the connecting amides to the groove floor before and after the turn, water-mediated hydrogen bonding of the α-amine to the groove floor, and a conformational pucker that minimizes steric interactions of α-amino substituents. From this structure, it is also clear that the exocyclic amine of the guanine base under the turn will cause a large steric interference with the β-methylene of the amino turn.[66]

To further address the issue of sequence recognition specificity, Dervan and co-workers reported another high-resolution complex structure (0.95 Å resolution) containing the cyclic polyamide with two antiparallel ImPyPyPy strands capped by (*R*)-β-amino-γ-turns (Fig. 16). In the complex structure, the DNA is a 10-mer DNA duplex $[(5'\text{-CCAGTACTGG-}3')_2]$, where the middle TA replaced the GC of the previous sequence.[70] Very similar to the previous structure, a large perturbation is observed following ligand binding. The minor groove is widened by more than 4 Å, while the major groove is also compressed by more than 4 Å. The narrow major groove is too small to accommodate the typical proteins, such as transcription factors. The helix is also bent toward the major groove by over 15°. To better understand the impact of the major groove compression on the binding of transcription factors, they further analyzed the previously reported structures of AR and GR in complex with ds DNA.[71, 72] From the structural comparison, it turns out that after ligand binding, the major groove is no longer compatible with AR and GR binding, which may be taken as a potential mechanism to control gene expression chemically. As shown in Figure 16C, the A/T pair forms two hydrogen bonds with two Py groups of the ligand, suggesting that Py/Py can selectively interact with T/A pair. Moreover, the structure information allowed the chemical modification to achieve more specific T/A pair recognition. As shown in Figure 17, Hp forms one extra hydrogen bond with T, due to the addition of OH group at the C3 position. The space-filling model also shows that the Hp/Py pair fits tightly with the T/A pair and will sterically overlap with the A/T pair.

Different from the prevention of DNA–protein binding interactions, some chemicals, following exposure to ionizing radiation or UV light, will result in the formation of cellular

DNA–protein conjugates, thereby interfering with both DNA replication and transcription.[73] One of the repair mechanisms involves the formation of DNA–peptide conjugates as substrates for nucleotide excision repair.[74, 75] Recently, Stone and co-workers linked the amino-terminal lysine of the peptide KWKK to the exocyclic amino group of dG in the DNA duplex (5′-GCTAGCG*AGTCC-3′•5′-GGACTCGCTAGC-3′) through a trimethylene linkage (Fig. 18A).[76] Strictly speaking, this work should be catalogued into covalent binding, since the small peptide ligand is covalently bound with DNA. But it was observed from the complex structure (Fig. 18B) that the amino acids are in the minor groove, which provides the 3D interaction information of the DNA and its ligand, and serves as a good model for designing novel minor groove binders. This study also indicated that the small peptide conjugation can stabilize the DNA duplex.

It has been well known that alternating AT sequences, which may contain Hoogsteen base pairs and form coiled coil structures, are extremely abundant in most eukaryotic genomes. For example, the $(AT)_5$ sequence occurs over a million times in the human genome.[77] However very little structural data is available to help understand its cellular functions, probably due to the difficulty of crystallization. Subirana, Campos, and their co-workers have recently studied this type of sequence with minor groove-binding agents.[78] The X-ray complex structure (Fig. 19A and B) of a DNA duplex [$d(ATATATATAT)_2$] with pentamidine was found to be able to stabilize a left-handed coiled coil arrangement through formation of cross-links between neighboring duplexes (Fig. 19C). The DNA duplex exhibits a mixture of Watson–Crick and Hoogsteen base pairs (in the bottom base pair). Unlike the previous complexes, pentamidine is not entirely bound within the minor groove. Instead, only the central portion of pentamidine resides inside the groove, leaving the positively charged ends detached from the DNA and free to interact with phosphate groups from adjacent duplexes in the crystal. This novel binding mode has potential implications for the antiprotozoal and antibacterial activities of pentamidine as anti-HIV drug.

5-Formyluracil (fU) is one of the major damaged thymidine derivatives, and is caused by the attack of hydroxyl radicals, inducing pyrimidine transition during replication.[79] In order to obtain structural information regarding this mutagenesis, Takenaka and co-workers solved the X-ray structure of a DNA duplex [$d(CGCGGATfUCGCG)_2$] containing a fU-G wobble pair and complexed with the minor groove-binding dye Hoechst33258.[80] The main purpose of the ligand was to stabilize the DNA duplex and obtain high-quality crystals. Despite no direct interaction between the fU residue and ligand, the structure still provided a potential starting point in the design of drugs to treat fU-caused diseases. It was revealed that the overall duplex structure did not have any obvious changes compared to the unmodified DNA. However, analysis of minor groove widths indicated that the minor groove of the fU-G base pair is wider, compared with other base pairs in the same DNA duplex. The crystal structure clearly indicated that the widening is caused by the binding of the ligand. The complex structure and its comparison with the corresponding native Dickerson–Drew DNA (12mer) are shown in Figure 20A and B.

As one of the traditional design rules, most of the classical models for minor groove binding emphasize the importance of the ligand curves in order to fit the groove shape and achieve high binding affinity.[81–83] However, one famous exception is compound DB921 (Fig. 21A), which is a linear heterocyclic diamidine able to strongly bind the DNA minor groove much stronger than similar and curved compounds.[84] For example, the crystallographic analysis of DB921 bound to AATT indicates its indirect contacts with the base through bound water molecules, resulting in an induced structural change in DB921 by forming a curve that perfectly matches the shape of minor groove (Fig. 21B).[84] Wilson, Neidle, and co-workers have carried out systematic studies for the role of water molecules in recognizing both the ligand and DNA minor groove. This represents an alternative recognition concept and has a

great potential to guide novel drug design.[40] Very recently, through a series of biophysical and crystallographic investigations, the same groups of scientists have systematically modified the DB921 structure and further studied the role of bound water molecules bridging the DNA and ligand.[85] The complex crystal structure of dodecamer DNA $(CGCGAATTCGCG)_2$ with DB1055, which was derivatized from DB921 by shifting the amidine at the phenyl group to the *meta* position (Fig. 21C), has been presented and compared with the DB921-bound DNA structure. The structure confirmed that the ligand binds in the AT region of DNA minor groove in a typical interaction mode. Both amidine groups interact with the O2 atom of the neighboring cytosine bases through the hydrogen-bonding network formed by the two highly conserved water molecules in the minor groove. (Fig. 21D) These studies provide the structural basis for designing sequence-specific minor groove binders, which interacts with DNA through the water-mediated hydrogen binding.

It is also worth mentioning that in addition to the drug–DNA binary complex systems, Georgiadis and co-workers have developed a novel host–guest complex system for studying the drug–DNA interaction. They have used the N-terminal fragment of Moloney murine leukemia virus reverse transcriptase (MMLV-RT) as a host and a DNA 16mer $d(CTTAATTCGAATTAAG)_2$ as a guest.[86] As an example, they co-crystallized netropsin (Fig. 12) with this DNA–protein system and determined the structure at 1.85 Å resolution. The crystal asymmetric unit contains one protein molecule and half of the 16mer DNA bound with one netropsin molecule (Fig. 22). The guanidinium moiety of netropsin binds in the minor groove, while the amidinium is bound to the widest region of the enlarged minor groove. By comparing this structure to other netropsin–DNA structures, different hydrogen-bonding patterns were found, and the orientation of netropsin within the groove was attributed to the asymmetry of the minor groove in the AATT site.[86] This work not only revealed the possible antiviral mechanism of the DNA groove binders but also established a powerful platform to study ligand–DNA interactions, although the DNA length is the major limitation for complex crystallization.

Recently, this host–guest approach has been further applied to solve the crystal structure of a DNA duplex [$d(CTTAATTCGAATTAAG)_2$] in complex with CD27 [4,4′-bis(imidazolinylamino)diphenylamine], a potent antitrypanosomal agents, which binds to its preferred AATT site.[87] Although the therapeutic effects of this compound have been explored previously,[88] the further development and optimization of this compound series requires more detailed structural and binding information. In the structure determined at 1.75Å resolution (Fig. 23), a planar crescent shape of CD27 was observed upon binding to the DNA minor groove, although it was predicted to be highly twisted in its energy-minimal state. The crystal structure reveals that CD27 interacts with the DNA by forming bifurcated hydrogen bonds with AATT, which results in the minor groove widening and the formation of favorable van der Waals interaction. This induced fit with conformational changes in both the ligand and DNA has provided another rationalization and base for designing effective minor groove binders.

B. Major Groove Binders

Compared to minor groove binding, interactions between small molecules and the DNA major groove have not been extensively explored. There are also very few structural reports on complexes of DNA and major groove binders, probably due to the requirement of much larger molecules and the difficulties to conduct the complex structure studies. Carbohydrates represent a class of agents capable of binding the major groove due to their size and intrinsic distribution of hydrophobic and hydrophilic moieties in their molecular structures, although the majority of them still show significant binding with the DNA minor groove. To date, the

carbohydrate compounds that can bind within the major groove include neocarzinostatin, nogalamycin, and several aminoglycoside (neomycin) conjugates (Fig. 24).[89]

As a representative antitumor agent, the neocarzinostatin chromophore (NCS-chrom) and its derivatives have been studied for more than four decades.[90, 91] It has been well-known that this small molecule exists by forming a complex with a protein in its natural form and causes DNA damage by hydrogen abstraction from DNA strands through a diradical intermediate, while the drug itself forms the postactivated derivatives.[90, 92] However, the molecular recognition and mechanism of this complex system have yet to be clearly elucidated through structural investigation. The previous structure study revealed that this type of drug interacts with a specific sequence of DNA through both minor groove binding and intercalation.[93–95] Another interaction mode between NCS-chrom and DNA contains a bulge-forming structure, which leads to the single strand cleavage.[96, 97] In this bulge structure, the drug molecule works as a major groove binder and its ring systems fill the bulge cavity and interact with DNA aromatic bases.[98] To better understand the molecular interaction and mechanism of this unusual complex, Goldberg and co-workers analyzed and compared the detailed NMR structures (Fig. 25) of the NCSi-gb-bulge-DNA, bulge-free DNA, as well as the NCSi-glu-DNA.[98] As shown in Figure 25C, conformational changes in both DNA and ligand are observed. The NCSi-gb mainly binds at the major groove and the two ring systems of the drug are brought closer to each other in the complex. More interestingly, this binding promotes the formation of a bulge pocket and this was not found in the unbound DNA structure. The bulge formation represents the potential transition of DNA conformation.[98] On the contrary, NCSi-glu, which is generated by glutathione induced activation, binds with the DNA duplex in the minor groove (Fig. 25D). Considering that these two NCS derivatives have the similar composition and structure, the striking differences observed from their DNA complexes provided important insight into DNA recognition and specificity, which are valuable for drug design and discovery. Later on, the same research group designed a new spirocyclic helical ligand, which is similar to the NCSi-gb structure without the bulky cyclocrabonate moiety, and they solved the solution structure of a two-base bulge-containing DNA bound with this new ligand.[99] However, the structure revealed that this ligand binds to the minor groove. This example also indicates the flexibility of DNA recognition and interaction with small molecules and the importance in studying individual complex structures at high resolution.

Arya and co-workers pioneered the design and development of a novel neomycin-Hoechst 33258 conjugate (Fig. 26) for probing the binding effect of an aminoglycoside antibiotic (neomycin, Fig. 26A) on the B-DNA structure.[100–102] Neomycin is known to bind A-like conformations of nucleic acids including DNA and RNA, and is able to stabilize triplex formation. Since A-form DNA has a narrow major groove, it is suspected that neomycin binds in the major groove of these structures,[100] although no direct structure evidence is available. It is also known that neomycin itself cannot bind to the major groove of B-form DNA. Therefore, in order to examine whether this type of aminoglycoside can bind to the major groove of B-from DNA, Arya and co-workers covalently attached neomycin with a strong minor groove-binding moiety (i.e., Hoechst 33258, Fig. 26A), which has preference to bind AT-rich DNA sequences and is used to block the minor groove space.[103] Systematic biophysical studies, such as UV melting, isothermal fluorescence titration, differential scanning calorimetry, circular dichroism, and computational modeling, have indicated that the neomycin moiety interacts with the DNA major groove (Fig. 26B and C), while the Hoechst moiety binds to the minor groove. It is also worth mentioning that the linker connecting these two moieties can also be adjusted for better binding efficiency and sequence selectivity. Although X-ray crystallographic or NMR studies of these complexes are not yet available to confirm this binding model, the design of such dual-binding ligands

opens up great potential to develop novel conjugates for selective nucleic acid targeting and gene expression inactivation.

Recently, along this line of the covalent binder conjugation, the same group further included an intercalative moiety as a third party of the complex system.[104] For better comparison, they synthesized a neomycin-Hoechst 33258-pyrene conjugate (NHP, Fig. 27A) and studied DNA binding with this triple-recognition ligand. The computational modeling of the interaction between this ligand and a DNA duplex $(CGCAAATTTGCG)_2$ (Fig. 27B) clearly suggested a “clamp” model: the Hoechst moiety fits very well with the minor groove curve, and the neomycin moiety binds tightly and selectively with the major groove through hydrogen-bonding interactions. Moreover, the pyrene moiety intercalates into stacked base pairs by enlarging their distance at its binding site. Clearly, the high-resolution structure study will provide invaluable information to confirm the biophysical data and the binding model.

Other than the small molecule ligands, some typical additives in crystallization conditions can also bind DNA in the major groove. Lattman and co-workers reported these interactions during their study of transcriptional inhibitor P4N with the Sp1 consensus sequence.[105] The structural study revealed specific interactions between polyethylene glycol (PEG) molecules and the major groove of the Sp1-DNA recognition site. The DNA adopts the A-conformation and contains three curved PEG molecules. In addition, a cobalt hexamine ion per DNA duplex binds to the major groove. It is likely that these PEG molecules open the major groove by approximately 1 Å, compared to the modeled A-form DNA. The specific binding of these small ligands to the DNA major groove opens many opportunities to design novel small molecules for major groove recognition and interaction.

Although these DNA groove-binding agents hold the great promise in modulating specific gene expression, in terms of clinical applications, the successful use of these compounds is largely limited by cell uptake and nuclear localization. They are dependent on a wide range of molecular determinants, such as the Py/Im content of polyamide compounds, the number and location of charges, composition and the attaching position of linkers. Recently, various chemical modifications have been introduced into small molecule ligands, and some compounds have showed improved biological activity. For example, experimental data suggested that the polyamides derivatized with isophthalic acid (IPA) at the C-terminus have improved activities in He La (cervical cancer) and U251 (glioma) cell lines.[106] This enhanced potency by IPA modification was also observed in other cell lines.[107] A more recent study suggested that polyamide potency can also be enhanced by other modifications at the C-terminus, such as a C3-aliphatic linker tethered to an aromatic group through an oxime linkage. This modification resulted in approximately 20-fold enhancement of the potency of the polyamides targeting the androgen response element in LNCaP cells.[108] In general, the C-terminus modification may be a common strategy to overcome the problems in cellular uptake and nuclear localization. Solving these problems will significantly broaden the applications of the polyamides in biology and human medicine.

4. INTERCALATING INTO DNA

Intercalation is another binding mode of small molecule drugs with nucleic acids. It involves the insertion of a planar molecule between DNA base pairs, thereby interrupting DNA functions. Intercalators bind to the DNA duplex well, normally with association constants of 10^5–10^{11} M^{-1}. This is due to several favorable forces, including hydrophobic, ionic, hydrogen-bonding, and van der Waals interactions.[109] The intercalation decreases the DNA helical twist and lengthens the DNA.[110, 111] Traditionally, it has been thought that only molecules with fused-ring structures could be good intercalators. But it was later found that

the presence of basic, cationic, or electrophilic functional groups is often necessary for a compound to be a good intercalator, while the fused-ring structures are not always required.[112, 113]

DNA intercalators, such as adriamycine, daunomycin, daunorubicin, dactinomycin, echinomycin, and ditercalinium, have been extensively used as antitumor, antineoplastic, antimalarial, antibiotic, and antifungal agents, as well as the chemotherapeutic agents to inhibit the growth of cancer cells. Unfortunately, the requirement for a ligand to function as an intercalator is relatively low. Therefore, although thousands of different intercalators have been identified, most of them were eliminated from clinical application due to their high toxicity and nonspecificity.[114] Again, the structure-based research of these DNA–drug complexes is very important, not only for biochemical and biophysical studies, but also to shed new light on further design and optimization of novel compounds with better target specificity and low toxicity. So far, many crystal structures are available for typical intercalators. Herein we will discuss complex structures of DNA molecules with several important intercalators, such as daunomycin, adriamycine, echinomycin, and ditercalinium, as well as their derivatives.

Daunomycin, an anthracycline-type antibiotic, consists of a planar aromatic ring system, a fused cyclohexane ring, and an amino sugar moiety (Fig. 28A). It is a naturally occurring agent that is widely used in chemotherapy treatment of cancer. It is also the starting model for thousands of potential drugs.[115] Extensive studies, including high-resolution crystallographic and NMR investigations, have been performed to understand the structural, kinetic, and energetic contribution of this drug upon interaction with nucleic acids.[116–122] Most of these structure studies have revealed that two drug molecules intercalate between the GC steps with the sugar moiety placed in the minor groove in each duplex unit (Fig 28B), though the DNA duplexes are usually short (hexamers or octamers). Through sequence selectivity investigation by different biophysical methods, it was revealed that this ligand prefers a purine-pyrimidine step[123] and the DNA molecules are usually elongated or twisted after binding. A complementary computational modeling by Liedl and co-workers described a possible 1:1 binding mode in its complex with a 14mer DNA duplex.[124] By comparing the two binding modes with different ligand ratios, they found that the sugar ring was highly flexible in the minor groove. Furthermore, this intercalation increased duplex stability by reducing the flexibility of phosphate groups at DNA backbone.

Adriamycin is the closest derivative of daunomycin with only an extra hydroxyl group at the C14 position (Fig. 28C), but their biomedical functions are significantly different. Daunomycin is most effective in the treatment of leukemias, while adriamycin is more effective in solid tumor treatment.[118] Rich, Wang, and co-workers pioneered the structural determination of these anthracycline compounds in complex with DNA. To better understand a more detailed relationship between the structure and function, they also compared the binding of these two compounds to the same DNA duplex $d(CGATCG)_2$. Only very subtle differences were found in terms of the binding mode. However, additional solvent interactions were observed for the extra hydroxyl group in the adriamycin–DNA complex (Fig. 28D). Moreover, they found that the conformations of spermine in these two complexes were different. These changes may be the reason for the different clinical activities of these important drugs.

Ditercalinium, a dimer of 7H-pyridocarbozole (Fig. 29A), is a widely used synthetic anticancer drug that plays its role by binding to DNA through bis-intercalation and inducing DNA repair in both prokaryotic and eukaryotic cells.[125–127] This noncovalent binding with DNA is recognized by the cellular repair system as a covalent interaction, therefore activating the repair process until the cell death. This is a novel mechanism for cancer

treatment. Many chemical derivatives and their biomedical effects have been evaluated.[128–130] The complex structure (Fig. 29B) indicated that ditercalinium bis-intercalates at the two CpG steps of a short DNA $(CGCG)_2$, and the DNA retains an underwound and right-handed double helix with the linker of drug molecule located in the major groove. The positively charged nitrogen atoms of ditercalinium are located near the bottom of the DNA major groove, making charge–charge interactions with the DNA groove that prove to be another important factor in the complex stability.[131] Upon binding, the DNA is bent toward the minor groove at about 15°. These aforementioned structural properties provide further direction in the optimization of these types of drugs.

Echinomycin (Fig. 30A) is a quinoxaline antibiotic that also binds to DNA duplexes by bis-intercalation and interferes with both replication and transcription.[132] These types of compounds have great potential as anticancer agents.[133] Therefore, the investigation of the interaction between echinomycin and DNA will be very helpful for drug optimization and novel design. Several NMR structure studies have been reported for echinomycin-bound DNA complexes.[134, 135] Crystal structure studies of its closely related derivative (i.e., triostin A) bound DNA complexes were reported as well.[138, 139] In 2005, Sheldrick and co-workers reported three complex structures of echinomycin with different DNA sequences and revealed binding details for this compound. It was found that the complex structures of echinomycin and DNA are very similar to that of the triostin A-bound DNA structure.[140] It is shown in Figure 30B that one complex structure of DNA $d(GCGTACGC)_2$ bound two drug molecules intercalating between two CpG steps in each duplex. The main moiety of the drug is located in the minor groove, with the quinoxalines protruding into the major groove. Except for the Watson–Crick base pairs in the binding sites, all other base pairs are Hoogsteen base paired. In addition, the base stacking of the DNA is obviously extended, imposing more rigidity on the structure. Moreover, several hydrogen bonds between the drug and DNA have also been observed, which are consistent with previous studies. It is also worth pointing out that, from an energetic point of view, binding of the first intercalating group will increase the entropy, allowing the second intercalator to bind much easier than the first one. Therefore, bis-intercalators often bind much stronger than a single intercalator. Although only the Hoogsteen pairs were found outside the echinomycin binding site, a complex structure solved later by the same group (Fig. 30C) demonstrated that Watson–Crick base pairs can also exist outside and close to the bis-intercalation site.[141] Clearly, these structures indicate that the drug acts as a rigid body with a conformation independent of the presence of DNA and promotes DNA structure distortions. This and other structural investigations provide novel structures that can be investigated for drug discovery.

Generally speaking, the binding specificity of DNA intercalators is relatively low, which is the reason why most of the intercalators are too toxic to be used as drugs. Occasionally, new molecules with unexpected sequence preferences can still be discovered as candidates for novel therapeutic development. For example, cryptolepine (5-methyl indolo[2,3b]-quinoline, Fig. 31A), a naturally occurring indoloquinoline alkaloid isolated from the roots of *Cryptolepis triangularis* collected in Kisantu, has been found to have many pharmacological effects, especially as an antimalarial and cytotoxic drug as well as a potent topoisomerase II inhibitor.[142] This drug was found to intercalate preferentially with CpG-rich sequences and go to the cytosine–cytosine sites, instead of CG steps.[143] The crystal structure solved by Aymami and co-workers showed, for the first time, how a drug interacts with the d(CpC)-d(GpG) site of a DNA duplex $[d(CCTAGG)_2]$ in a base-stacking intercalation mode (Fig. 31B). This binding to nonalternating bases is unusual among the nearly 100 intercalator–DNA complexes, most of which have a CG intercalation site, a few with GC sites, and a few with TG sites. Revealed by the structure, the drug molecule is sandwiched between two consecutive C-G base pairs, with the six-member ring stacking between two cytosines and

the fused aromatic rings between two guanines. As a result, cryptolepine is slightly bent, with a 6.8° angle between the two aromatic rings, which probably formed due to the five-membered ring between the two aromatic functionalities. In addition, the positive charge interactions between the drug and DNA can enhance stability of the duplex. The intercalation parallel to the base pairs and the asymmetry of the drug molecule are both key factors for such a nonalternating site preference, which enhances its accommodation in nonalternating sites (CC)-(GG) by allowing a distinct stacking interaction with either (CC) or (GG), without hydrogen-bonding interactions.[144]

5. TARGETING DNA THROUGH MULTIFUNCTIONALIZED LIGANDS

On the basis of the discussed binding modes, it is rational to design small molecule ligands with multiple interacting elements, which will presumably improve the stability and specificity of the target recognition. Several compounds designed using this strategy have been examined.[49, 145, 146] Actually, most of the covalently bound complex structures always contain a second interacting element. Several previously discussed examples (e.g., the major groove binder, neomycin-Hoechst 33258-pyrene, in Fig. 27) also fit in this category. Other than those, very limited progress in structure study has been made in this area, including a few NMR solution structures with multiple binding modes. For example, Weisz and co-workers solved a complex structure containing a pyrrolo[2,1-c][1,4]benzodiazepine-benzimidazole hybrid (PBD-BIMZ) (Fig. 32A) that was covalently linked to a guanine base at its exocyclic 2-amino group in a DNA duplex [(5′-AACAATTGTT-3′)$_2$]. These hybrids have significant anticancer activity in a number of cancer cell lines. This NMR structure indicated that the ligand binds to one of the two symmetric guanine bases in a special configuration and is oriented in the minor groove with its benzimidazole moiety toward the 5′-end of the modified guanine (Fig. 32B). The overall DNA structure is still the B-form, and only the local region with the covalent binding site has certain helical distortions. In contrast, the terminal N-methylpiperazine ring appears to be more flexible with various conformations.[147] More recently, the same research group also solved the structure of a PBD-naphthalimide derivative in complex with the same DNA decamer (Fig. 32C) by ^{1}H and ^{31}P 2D-NMR. This bis-functional hybrid covalently links to a guanine within the minor groove and the naphthalimide moiety inserts between the A-T and A-T base pair step. The intercalation results in an opposite buckling of the base pairs at the intercalation site and duplex unwinding at adjacent internucleotide steps (Fig. 32D).[148]

Likewise, recently several other minor groove binders or intercalating agents have also been covalently linked with DNA at specific positions.[33, 149] It was revealed that this covalent bonding can greatly stabilize DNA–ligand interactions, and the duplex conformation can also be altered. More importantly, since most molecules only have weak preference for a specific sequence and binding to several alternative sites often happens, these combination modes thus provide a convenient way of “site-specific DNA-targeting.”[150–153] This combination of binding elements opens up huge opportunities for synthetic and medicinal chemists to design, synthesize, and evaluate a variety of novel compounds with multiple functions. This exploration will in turn stimulate structural studies in this field,[154] especially high-resolution crystal structural analysis, which will further provide insight into these combined binding modes and reveal more structural details.

6. TARGETING THE DNA QUADRUPLEX

Telomere recognition and regulation have been recognized as an important potential strategy for cancer therapy. The 3′-end of eukaryotic DNA (telomere) contains 100–200 copies of a G-rich sequence, which can fold into G-quadruplex structures intermolecularly or intramolecularly. The formation of G-quadruplex structures can inhibit and regulate

telomerase activity, which is critical in maintaining telomere length in cancer cells during replication. Besides telomeres, G-quadruplex-forming sequences have also been found in the promoter regions of many other genes, such as *c*-MYC, chicken β-globin gene, human ubiquitin-ligase RFP2, and the protooncogenes: c-KIT, BCL2, VEGF, H-ras, and N-ras. Structural studies have clearly revealed the conformational diversity of these G-quadruplex structures. These structures or conformations are highly dynamic and sensitive to cations, proteins, flanking sequences, and even concentrations. Biological studies have further confirmed that small molecules stabilizing G-quadruplex structures can also inhibit telomerase activity as well as telomere-binding proteins, which are often overexpressed in most cancer cells.[155–157] Therefore, the G-quadruplex structures, as novel anticancer targets, have naturally become a focus of novel drug discovery.

Since G-quadruplex structures mainly contain stacked guanine tetrads with several planar layers, a large number of small molecules, especially compounds with electron-deficient aromatic systems (such as the amidoanthraquinone derivatives), have been examined for binding.[158] It has been demonstrated that molecules like daunomycin and distamycin A, which are known to intercalate into duplex DNA, are also capable of binding to these quadruplex structures. But whether the planar ligands are intercalated in the center of the G-quadruplex structure or stacked on the exterior needs to be further investigated.[159, 160] Despite their low selectivity, G-quadruplex recognition by anthracyclines (e.g., doxorubicin and daunomycin) has been biochemically investigated.[161, 162] Later on, Neidle and co-workers presented the first complex structure of parallel G-quadruplex and daunomycin.[163] The asymmetric unit includes a quadruplex molecule formed by four parallel d(TGGGGT) strands, and three end-stacking daunomycin molecules associated with three sodium cations (Fig. 33A). The G-quadruplex complex structure is very similar to the native counterpart. And the daunomycin moiety has interactions with the quadruplex grooves through hydrogen bonding and van der Waals contacts. This structure indicates that the complex might be more stable with the ligand stacking on the end compared to the intercalation, since the surface around the terminal is large.[164] These results are consistent with another complex structure containing a disubstituted acridine, where aG-quadruplex was formed by two strands of d(GGGGTTTTGGGG) and the ligand was also bound at the end of the G-quartet.[165] In addition, these binding modes provide clues on how the molecules may interfere with telomere modification and maintenance by related proteins.

Similarly, distamycin A is known to bind side by side to the minor groove of duplex DNA. The complex solution structure of a parallel quadruplex DNA [$d(TGGGGT)_4$] and distamycin A has been accomplished recently by Randazzo and co-workers. The structure shows that drug binding is also similar to DNA minor groove binding, and two drug dimers bind two opposite sites of the quadruplex structure (Fig. 33B).[166] Because the minor groove environment of quadruplexes differs from each other, this structure provides a fine starting point for designing quadruplex groove-specific binders. It was also found that the affinity between distamycin A and the G-quadruplex was enhanced approximately tenfold when the ratio of ligand to DNA was increased.

These studies also imply that DNA duplex-binding ligands should be reevaluated in G-quadruplex systems. In addition to the typical duplex DNA-binding agents, new types of compounds that can specifically bind to quadruplex DNA have been found and characterized by a series of biochemical and structural studies. These new compounds include BRACO 19, RHPS4, TMPyP4, and telomestatin (Fig. 34). These biochemical and structural investigations not only revealed more details about the interaction between the G-quadruplex DNA and ligands, such as the effects of external loop rearrangement, hydration patterns, and strands conformations, but also offered new platforms for further drug

discovery to target G-quadruplex structures and regulate gene expression. The progresses in this area have been summarized recently by Neidle.[167]

7. TARGETING UNMATCHED BULGE, DNA JUNCTIONS, AND PHOSPHATE BACKBONE

Besides the discussed binding modes, several other interesting “non-standard” interactions have also been observed between DNA and small molecules with therapeutic potential. A few examples of small molecules, which target the unmatched bulge, DNA junction, and phosphate backbone and have the DNA-complex structure information, are discussed here.

Mismatched and bulged DNAs can happen in hairpins or be caused by mutations of either of the paired bases, especially at extended triplet-repeat sequences in the genome of human diseases.[168] Therefore, specific recognition of these structures may result in novel therapies. Several studies have shown that these types of local topology of nucleic acids can indeed be recognized by small compounds, following the study of a complex structure of an aminoglycoside antibiotic and a small ribosomal RNA.[169, 170] Goldberg and co-workers solved a solution structure of a designed spirocyclic helical ligand (SCA-alpha2) (Fig. 35A) bound at the two-base bulge site in a DNA duplex [d(5′-CCATCGTCTACCTTTGGTAGGATGG-3′)$_2$].[99] SCA-alpha2 is a close mimic of the previously discussed NCSi-gb binder to the major groove. As shown in Figure 35B, the two rigid aromatic rings of the ligand stack on the DNA bulge bases and form a right-handed helical wedge that can penetrate the bulge-binding pocket and immobilize the two bulge residues (GT), which point toward the minor groove. The amino sugar anchors in the DNA major groove and points toward the 3′-bulge-flanking base pair.[99] These details suggest that both shape and space are important in designing novel ligand targeting the duplex bulge site. The same group also solved the complex structure of a DNA duplex containing a GT bulge (5′-CACGCAGTTCGGAC•5′-GTCCGATGCGTG) and DDI (NCSi-gb synthetic mimic, Fig. 35C). As shown in Figure 35D, the benzindanone moiety stacks with neighboring G and A bases in the bulge site. The dihydronaphthalenone and aminoglycoside moieties are aligned to each other and are positioned in the minor groove, preventing its intercalation into the bulge site. In this complex, the unpaired guanosine is intrahelical and stacks with the intercalating moiety of DDI, while the unpaired thymine is extrahelical.[171] Later, the ent-DDI (the DDI enantiomer, Fig. 35A) has also been examined in the same DNA duplex with the two-base bulge. It was found that ligand binding in the bulge area was opposite due to the opposite spirocycle chirality.[172] The complex structure formed by binding of the synthetic agent to the two-base bulged DNA reveals a binding mode that differs in important details from that of the natural product, explaining the different binding specificity for the DNA bulge sites. Both structures indicated a large conformation change of the DNA upon the complex formation. This information at the molecular level provides a platform for designing stereochemically controlled drugs that recognize bulged DNA.

A conventional strategy to recognize the mismatched bases is to use an intercalator to replace the mismatched base, while avoiding the phosphate backbone adjustment. For example, in a complex structure of a rhodium compound ([Rh(bpy)$_2$chrysi]$^{3+}$, Fig. 36A), there are several intercalating moieties (or ligands) capable of binding to a bulged DNA duplex. The ligand intercalates at the mismatch site, ejecting the mismatched base and replacing this pair with the aromatic four-ring system (Fig. 36B). The ejected bases can stay in both the minor and major groove.[173] This interaction mode can be expected to displace a protein (such as DNA repair enzymes), thus making the damaged DNA unrepaired.

Recently, a naphtyridine-azaquinoline (NA) derivative (Fig. 36C), containing two aromatic ring systems connected by a spacer, was found to bind to DNA with triplet-repeat

sequences, especially CAG repeats.[174] As shown in Figure 36D, the two intercalating moieties of the ligand simultaneous pair with the mismatched A and the adjacent-G. Both of the A and G nucleobases are still located in the duplex structure, while the C paring with the adjacent G was pushed away from the original position. It is also observed that the spacers of the ligand molecules are parallel to each other in the major groove. Using this structure as a starting point, it is possible to design compounds that can mimic base pairs and recognize the mismatched DNA structure.

It is well known that DNA can form other higher ordered structures, such as the three-way junction and Holliday junction, under certain conditions. Three-way junctions have been found to be present in diseases, such as Huntington's disease[175] and myotonic dystrophy[176], in viruses and in replicating DNAs, especially during the rapid growth of cancers. Small molecules have been developed to target three-way junctions.[177, 178] Similar to bulge DNA targeting, these compounds usually contain two intercalating groups connected by a rigid linker, which forces the compounds to adopt elongated conformation. Recently, a complex structure of three-way junction bound to a small molecule was determined (Fig. 37A). In the structure, the ligand forms extensive interactions with the DNA. Its arms wrapped around the central iron atoms and form π–π stacking interactions with the central DNA bases. The shapes of the ligand and the DNA central cavity are complementary to each other. The DNA in the structure adopts an open and Y-shaped conformation with three arms extended away from the ligand-binding cavity. The DNA minor grooves interact with the pyrimidine rings of the ligand, which dominate the interactions between the DNA and ligand. The DNA major grooves are open for accepting more interactions to form tighter and more specific binding.

Moreover, homologous recombination is a biological process for repair of a collapsed replication fork, which involves strand invasion, branch migration, and resolution of the Holliday junction formed by two adjacent duplexes.[179] Homologous recombination-deficient cells are sensitive to poly(ADP-ribose) polymerase (PARP) inhibitors.[180, 181] Inhibition of Holliday junction resolution may lead to general PARP1 sensitivity in replicating tumor cells. Recently, one Holiday junction structure in complex with an acridine derivative has been determined.[182] In this structure (Fig. 37B), the two acridine moieties of the ligand functionalize as intercalators. The spacer has an appropriate length, which places the two acridine moieties at the correct distance for insertion at two distant sites. In addition to the four direct hydrogen bonds, π–π stacking interactions were also observed between DNA and ligand. These unique interactions in the structure can guide and facilitate design of new ligands that specifically bind the Holiday junction. To develop Holiday junction-specific binders, it is essential to avoid the molecular scaffold that binds duplex DNA. It is expected that more effective Holiday junction inhibitors will be discovered, when more Holiday junction structures complexed with ligands become available.

To target DNA with high specificity, most of the work in this area focuses on the nucleobases, which of course play the central role in the function of DNA through both hydrogen bonding and base stacking. Targeting other parts of the DNA structure (e.g., ribose and backbone) for specificity has not attracted much attention. In principle, it is also essential to target these components, since each DNA sequence presents a unique array of nucleobases, sugars, and backbone phosphates with subtle differences, which can result in high specificity in the DNA recognition. A recent study by Williams and co-workers described the targeting of the phosphate backbone by a novel type of platinum compound through a binding mode named "phosphate clamps."[183] In the complex structure of the ligand and DNA at 1.2 Å high resolution, a double-stranded Dickerson dodecamer DNA [$(CGCGAATTCGCG)_2$] is recognized by a cytotoxic platinum (II) complex (Triplatin NC). This Pt-compound, without the covalent bonding potential, consists of three cationic Pt(II)

centers and hydrogen-bonding functionalities linked by a flexible hydrophobic linkage. As shown in Figure 38, this ligand associates with the backbone by binding with the phosphate oxygen atoms, and presents its hydrophobic linkages over the minor groove. Interestingly, the ligand appears to prefer O2P over O1P atoms. Recognition of the subtle differences on the backbone may offer a new potential to target DNA sequence specifically, especially in combination with other recognizing elements.

8. TARGETING DNA BY TRIPLEX FORMATION

As another type of DNA-major groove binder, single-stranded DNA can also bind to a DNA duplex sequence specifically through Hoogsteen or reverse Hoogsteen-type interactions. These are called triplex-formation oligonucleotides (TFOs).[184] This research subject has been extensively reviewed recently.[185, 186] As this review focuses mainly on the interactions of nucleic acids and small molecules, we will just briefly discuss the TFO strategy here. The binding of TFOs can block the DNA major groove and prevent access of other molecules, such as proteins, thereby inhibiting transcription.[187] The resulting overall conformation of the triplex is similar, but different from the B-form. DNA triplex structures can form either intermolecularly through binding of an exogenously applied oligonucleotide to a target duplex sequence,[188] or intramolecularly by the naturally existing endogenous mirror-repeat sequences.[189] Currently, the intermolecular triplexes have gained much more attention because of their potential clinical applications in treating cancer and other human diseases. The only requirement of this binding mode is the existence of purine-rich tracts in the target duplex in order to gain high-binding affinity and specificity.[190, 191]

In theory, the TFO should be a good strategy target DNA, but there are several practical drawbacks preventing them from being a useful therapeutic tool, such as nuclease sensitivity, tendency to form self-associating structures, poor discrimination of DNA from RNA, triplex instability, and difficult cellular uptake.[144] However, a lot of research efforts have been made in order to overcome these drawbacks and make it feasible for therapeutic use, including the introduction of chemical modifications such as threose nucleic acid (TNA), peptide nucleic acid (PNA), and locked nucleic acid (LNA). Furthermore, detailed structural studies of these systems have facilitated advancement in this area. Since the TFO naturally exists in biological systems, therefore, the TFO itself can also serve as a therapeutic target for novel drug development. Actually, most of the previously mentioned DNA intercalators can also bind and stabilize the triplex system due to their planar structure,[192] though the selectivity is expected to be low. Moreover, Arya and co-workers have presented an alternative method to recognize the DNA triplex using aminosugar compounds. For example, neomycin, a major groove binder, can stabilize both the TAT triplex and base-mixed DNA triplexes without affecting the DNA duplex. This selectivity was attributed to its potential and shape complementarity to the triplex Watson–Hoogsteen groove, which was supported by biophysical and computational studies.[193] Based on that, intercalator–neomycin conjugates have also been developed, similar to the major groove binders. Among them, pyrene–neomycin[194] and BQQ–neomycin[195] are the two most effective conjugates. These principles of dual recognition should be applicable to design ligands that can bind any nucleic acid target with high affinity and selectivity. The associated structure is yet to be determined, which will demonstrate the proposed binding modes and serve as a platform for further ligand design and drug development.

9. PERSPECTIVES

Drug discovery is a very complicated process and involves many different steps, such as target selection, target site identification, lead compound selection, and optimization. Integrated efforts are required from structural biology, computational modeling, and

biophysical studies. The majority of currently marketed drugs target proteins, such as G-protein-coupled receptors, nuclear hormone receptors, and other proteins involved in disease pathway. Due to the accessibility of proteins, drug design, and discovery have being predominantly focused on this class of macromolecule since the beginning. The therapeutic potential of other macromolecules, such as nucleic acids as drug targets, has been largely ignored mainly due to their apparent chemical composition and similarity. For example, only about 2% of drugs targeted DNA and RNA molecules in 2003. Over the past few years, significant advances have been made in the nucleic acid research field both functionally and structurally. Functionally, it has been realized that besides genetic information storage and transfer, nucleic acids also play critical roles in many other biological processes, such as cell growth, development, and neoplastic transformation. Structurally, it has been revealed that in addition to forming duplex structures, nucleic acids can fold into higher ordered structures such as triplexes, quadruplexes, riboswitches, and ribozymes. When combined with proteins, nucleic acids can assemble into much more complicated structures, such as the ribosome.

Nucleic acids functioning as the primary molecular targets of some clinical drugs, such as anticancer drugs and antibiotics, have been experimentally confirmed. It is also clear that small molecule drugs can affect the function of nucleic acids through different mechanisms, such as altering the nucleic acid conformation or competing with the endogenous molecule regulators of nucleic acids. Unfortunately, many drug candidates have failed before or during the clinical trails due to their low sequence specificity or high toxicity. Thus, to speed up the process of drug discovery, scientists have developed many different strategies, including virtual screening, molecular modeling, and SBDD. Compared to other methods, SBDD, which depends on the availability of the target structure, especially the high-resolution crystal structures, is more rational. By summarizing many different DNA–ligand complex structures, we show in this review that small molecules can interact with nucleic acids through various interactions, such as hydrogen bonding, stacking, van de Waals interaction, salt bridge, solvent network, and shape complementary. These interactions and principles will undoubtedly stimulate the design of novel drugs targeting nucleic acids. Moreover, on the basis of extensive structure and function studies, it is expected that the proper arrangement and combination of multiple interacting elements will significantly increase target specificity as well as affinity.

Compared with determined protein structures, the number of determined nucleic acid structures is very limited (approximately 4% of protein structures), which is one of the main reasons for the lagging development of drugs targeting nucleic acids. Structure determination of nucleic acids is hindered by two main bottleneck problems, including crystallization and phase determination. Similar to protein, the phase problem of nucleic acid structure determination can be solved by molecular replacement, multi wavelength anomalous dispersion (MAD) and single wavelength anomalous dispersion (SAD) methods. Conventionally, heavy metal atoms such as iodine or bromide atoms are either soaked or chemically introduced into the nucleic acid structures for SAD and/or MAD.[196–198] Recently, our laboratory has pioneered and developed a novel technology, the selenium derivatization of nucleic acids (SeNA).[50, 199–207] Our experimental results have shown that the Se atom can be stably introduced to various positions of nucleic acids and significantly facilitate structural and functional studies of nucleic acids and protein–nucleic acid complexes. SeNA has great potentials to facilitate phase determination as well as the crystallization of nucleic acids, their small molecule complexes, and their protein complexes. Drug discovery to target nucleic acids has advanced significantly over the past several years in treating various human diseases, such as cancer, inflammation, and viral infections. Despite the many challenges (such as toxicity and sequence nonspecificity) that remain to be solved, continuing research on nucleic acid structure and function will rapidly advance our understanding of nucleic acid–ligand interactions as well as novel drug

discovery. It is clear that nucleic acid targeting is an emergent area in both therapeutic and diagnostic development.

Biographies

Jia Sheng obtained his MS degree in organic chemistry in East China University of Science and Technology (Shanghai, China) with Prof. Limin Wang, where he studied the rare-earth catalyzed organic reactions. He went to USA in 2005 and obtained his Ph.D. degree in bioorganic chemistry at Georgia State University (Atlanta, Georgia) in 2009, under the supervision of Prof. Zhen Huang, where his focus was nucleic acid derivatization with selenium and tellurium for macromolecule structure and function studies. He is currently a research scientist in the same lab with Prof. Zhen Huang, further expanding the research in

nucleic acid-small molecule interactions and protein–nucleic acid complex structure determination.

Jianhua Gan obtained his Ph.D. degree, in 2002, in organic chemistry in Shanghai Institute of Organic Chemistry, Chinese Academy of Sciences, under the supervision of Prof. Zongxiang Xia, where he studied the protein crystallography. In 2003, he went to USA and joined Prof. Xinhua Ji's group in National Cancer Institute (NIH, USA), studying the function and structure of ribonucleases III. Currently, he is a research scientist in Prof. Zhen Huang's lab at Georgia State University, focusing on nucleic acid–protein interaction and structure determination.

Zhen Huang obtained his BS degree from Sichuan University in 1984, under the supervision of Prof. Shuling Chen, and his MS degree from Peking University in 1987, under the supervision of Prof. Zhong Wen. He obtained his Ph.D. degree from Swiss Federal Institute of Technology at Zurich (ETH) in 1994, under the supervision of Prof. Steven A. Benner. In the same year, he joined Department of Genetics at Harvard Medical School as Research Fellow, under the supervision of Prof. Jack W. Szostak. He was hired by Brooklyn College, the City University of New York, in 1998, as Assistant Professor, and was promoted to Associate Professor in 2004. In the same year, Dr. Huang was recruited to Chemistry Department at Georgia State University, and was promoted to Full Professor of Chemistry & Chemical Biology in 2009. His current research interests are in medicinal chemistry, anticancer research, synthesis and structure-and-function study of selenium-derivatized DNAs and RNAs, nucleic acid X-ray crystallography, structure and function studies of protein–nucleic acid complexes, development of novel RNA microchip technology for pathogen direct detection and gene expression profiling, nucleic acid-based cancer diagnosis, nanomedicine, and drug discovery.

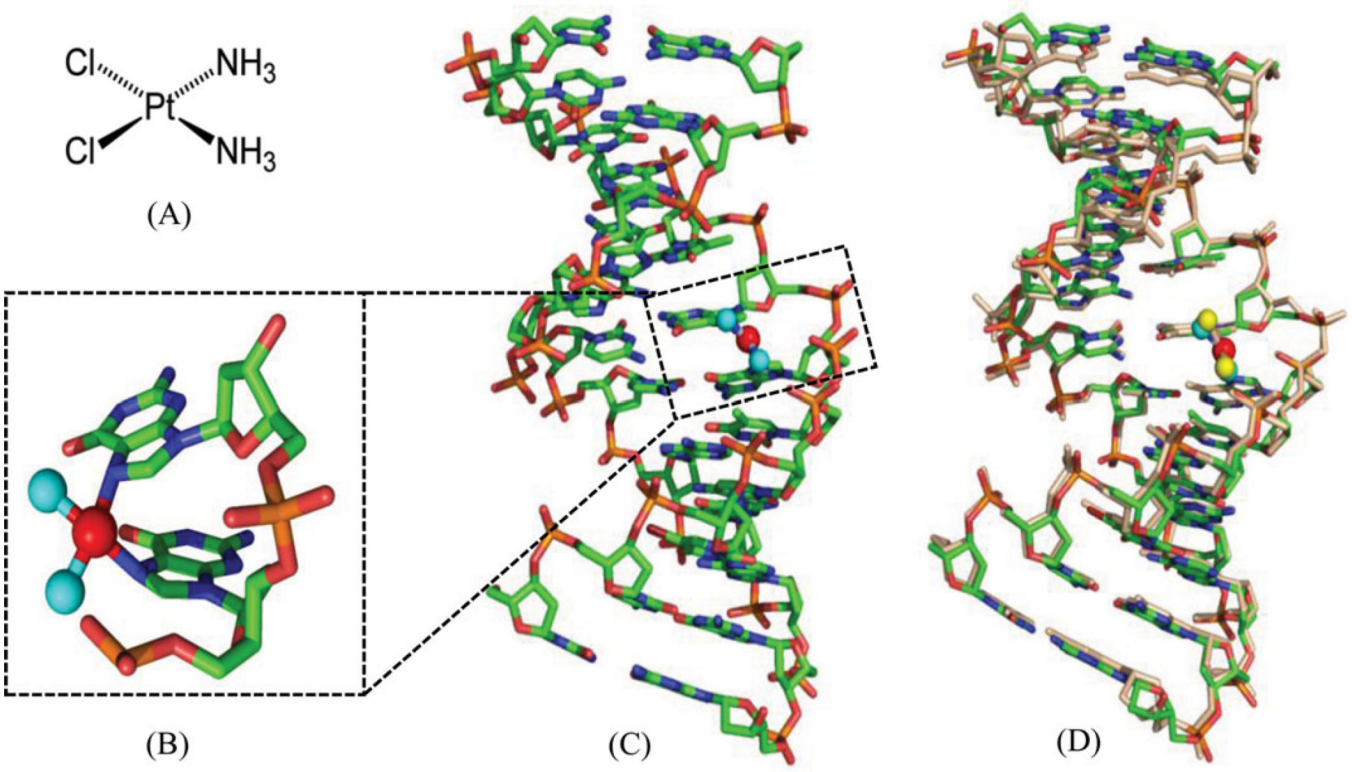

Figure 1.

(A) Chemical structure of cisplatin. (B) Overall structure of DNA duplex (5′-CCTCTG*G*TCTCC-3′ and 5′-GGAGACCAGAGG-3′) in complex with cisplatin (PDB ID: 1AIO). (C) Close view of G*G* platination sites. The base pairs are propeller-twisted, but retain the hydrogen-bonding interactions. (D) Superimposition of the low-resolution structure (PDB: 1AIO) and high-resolution structure (PDB: 3LPV) of DNA duplexes modified with a 1,2-cis-$\{Pt(NH_3)_2\}^{2+}$-d(GpG) cross-links. The DNA is shown as sticks, the N and Pt atoms are shown as the cyan and red spheres in 1AIO, and the yellow and red spheres in 3LPV, respectively.

Figure 2.
Overall structure of the HMG in complex with platinated DNA duplex (PDB ID: 1CKT). The protein is shown in cartoon mode and the DNAs are shown in sticks with the cis-[$Pt(NH_3)_2${d(GpG)-N7(G8),-N7(G9)}] intrastrand adduct with the N and Pt atoms in spheres.

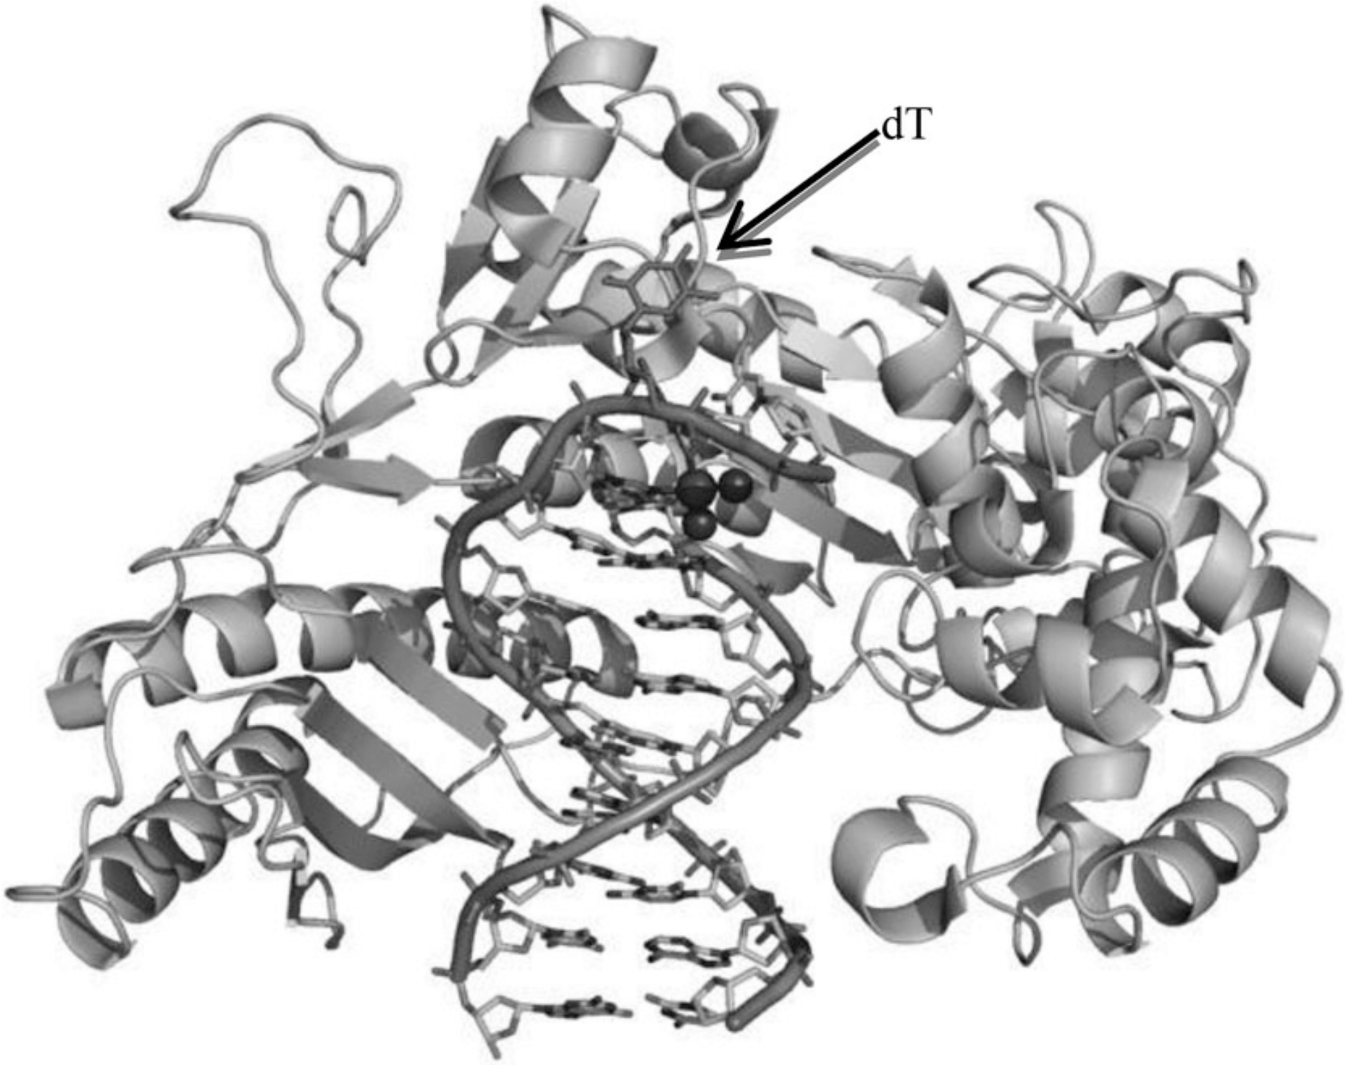

Figure 3.

The overall crystal structure of Pol η in complex with a DNA primer and template containing a cisplatin–(1,3-GTG) lesion (PDB ID: 2WTF). Protein is shown as cartoon. DNAs are shown as sticks outlined with cartoon backbone. Pt and N atoms are shown as spheres. The central flipped-out dT is indicated by arrow.

Figure 6.

(A) Chemical structure of 4′-(hydroxymethyl)-4,5′,8-trimethylpsoralen (HMT). (B) NMR structure of DNA-8mer [5′-$(GCGTACGC)_2$-3′] complexed with HMT, with two psoralens alkylating two thymidines (PDB ID: 204D). (C) Crystal structure of the Holliday junction induced in the HMT-$d(CCGCTAGCGG)_2$ complex. (D) Crystal structure of the distorted junction induced in the HMT-$d(CCGGTACCGG)_2$ complex.

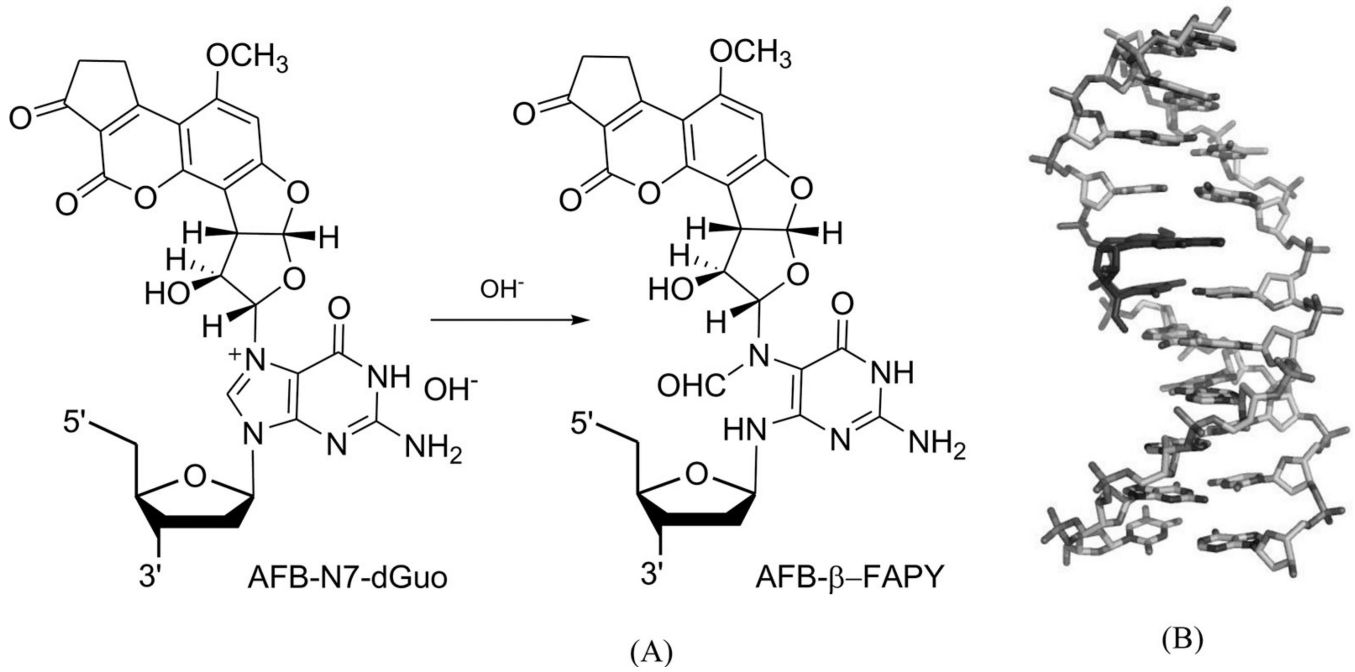

Figure 7.

(A) Structures of the FAPY adduct following the base-catalyzed ring opening of the AFB-N7-dG cationic adduct. (B) Overall structure of a AFB-FAPY-G containing DNA duplex {5′-d[CTAT(AFB-FAPY-G)ATTCA]-3′ and 5′-d(TGAATCATAG)-3′ (PDB ID: 2KH3)}.

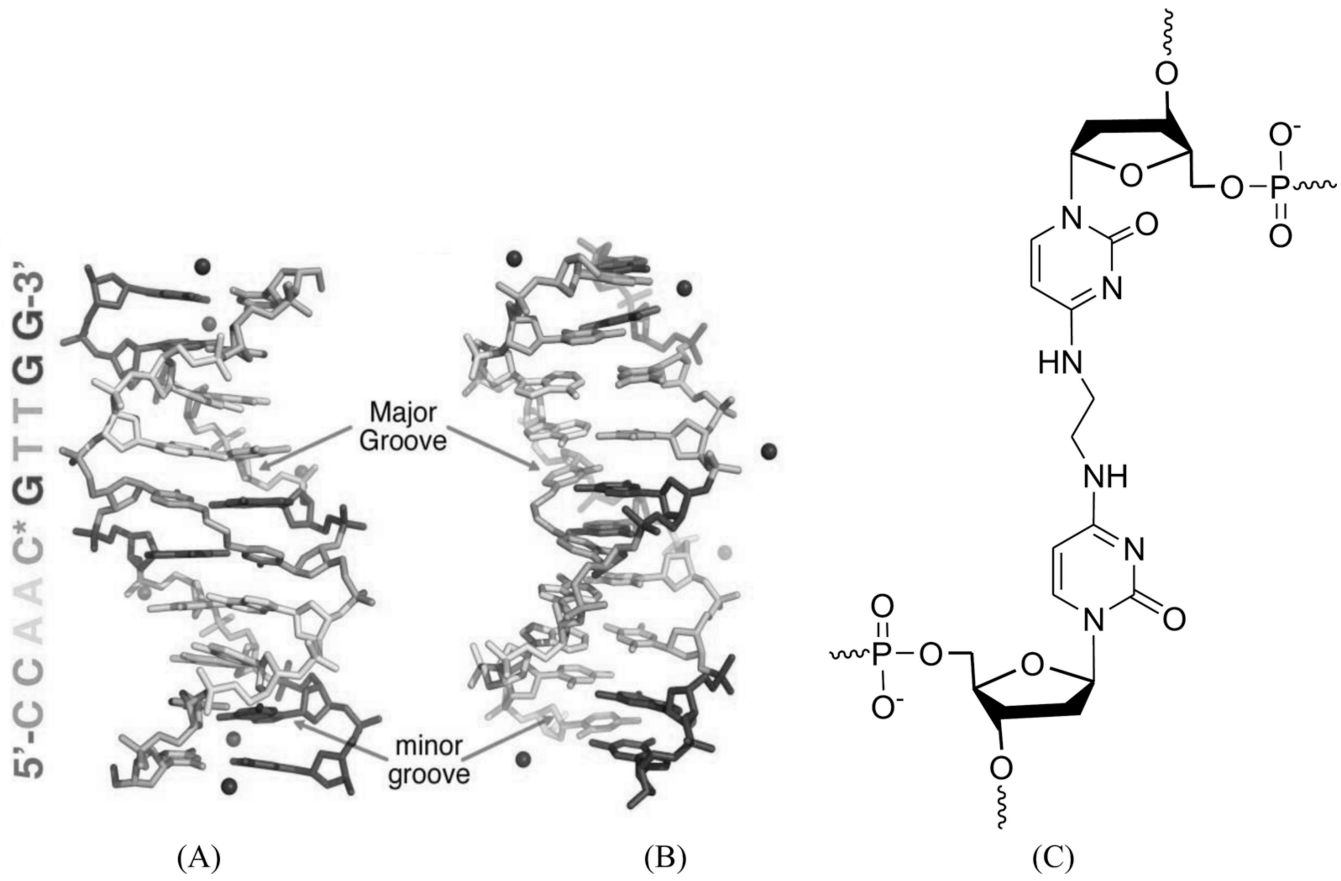

Figure 8.

(A) and (B) Overall X-ray crystal structure of DNA [d(CCAAC*GTTGG)$_2$] bound by the N4C-ethyl-N4C interstrand cross-link between the cytosines of the central CpG (*). The ethyl cross-linked cytosine bases are in the middle of duplex. (PDB ID: 2OKS). (C) Chemical structure of the N4C-ethyl-N4C interstrand cross-link.

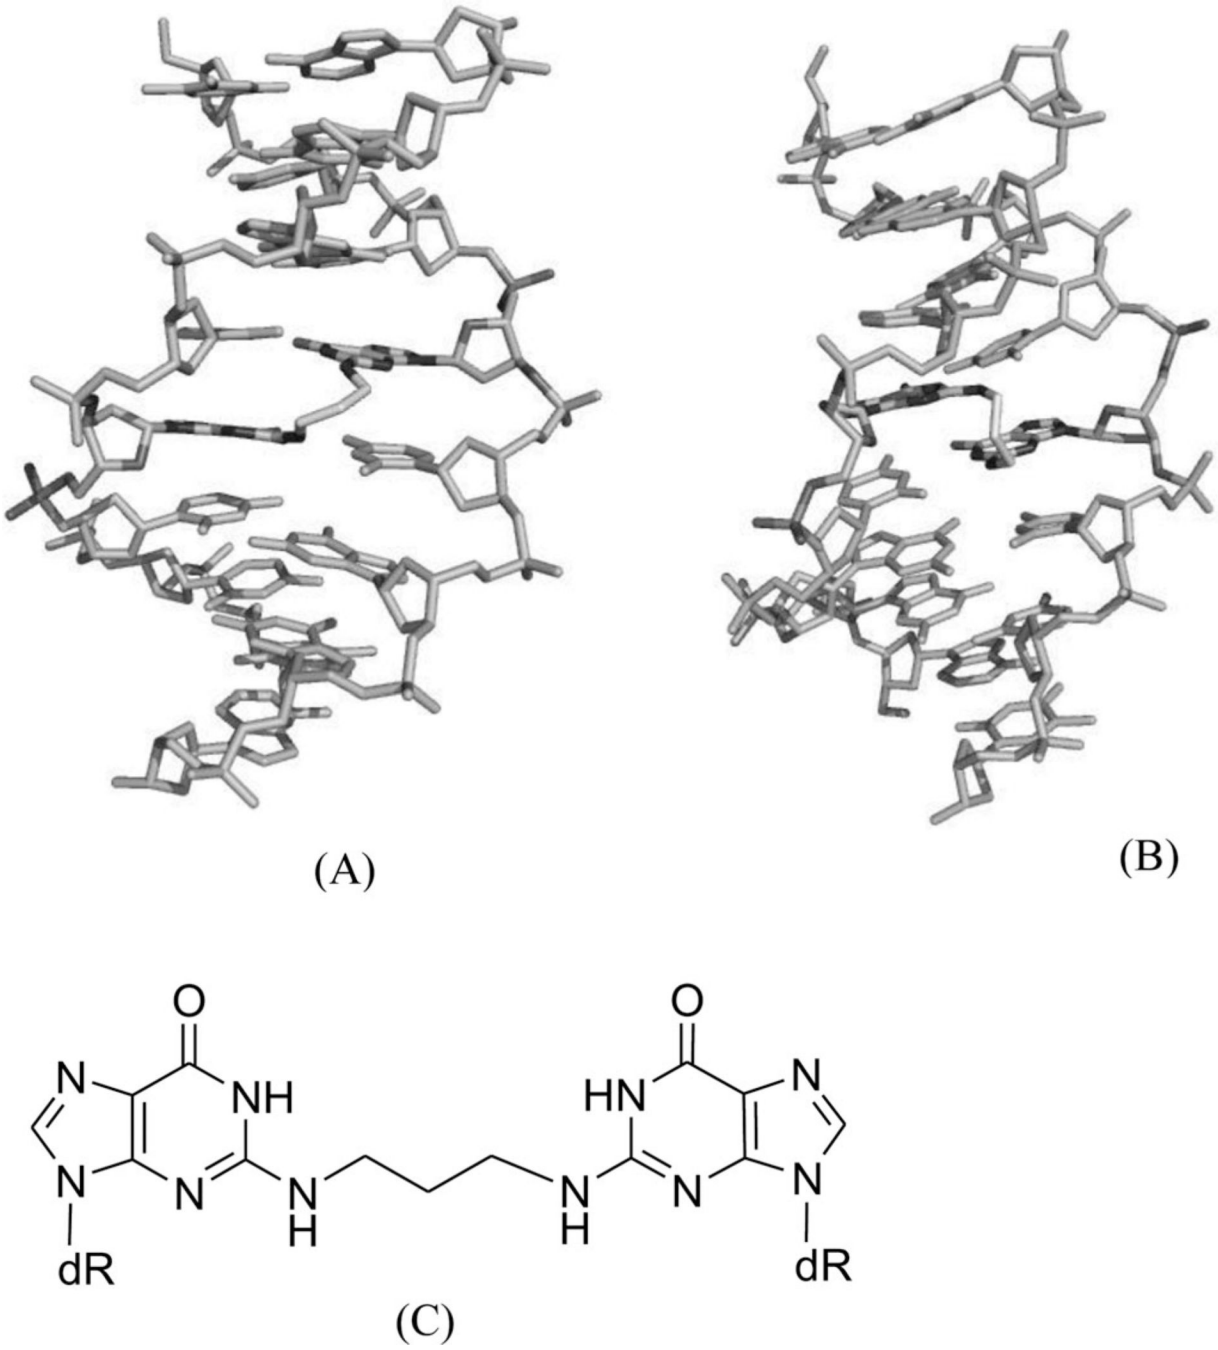

Figure 9.

(A) Overall NMR structure of the CG-containing DNA duplex [(5′-TCCG*CGGA-3′)$_2$; PDB ID: 2KNL)] with the N2G-trimethylene–N2G interstrand cross-link in the middle of the duplex. (B) Overall NMR structure of the GC-containing DNA duplex [(5′-AGGCG*CCT-3′)$_2$; PDB ID: 2KNK] with the N2G-trimethylene–N2G interstrand cross-link in the middle of the duplex. (C) The chemical structure of the N2G-trimethylene–N2G interstrand cross-link.

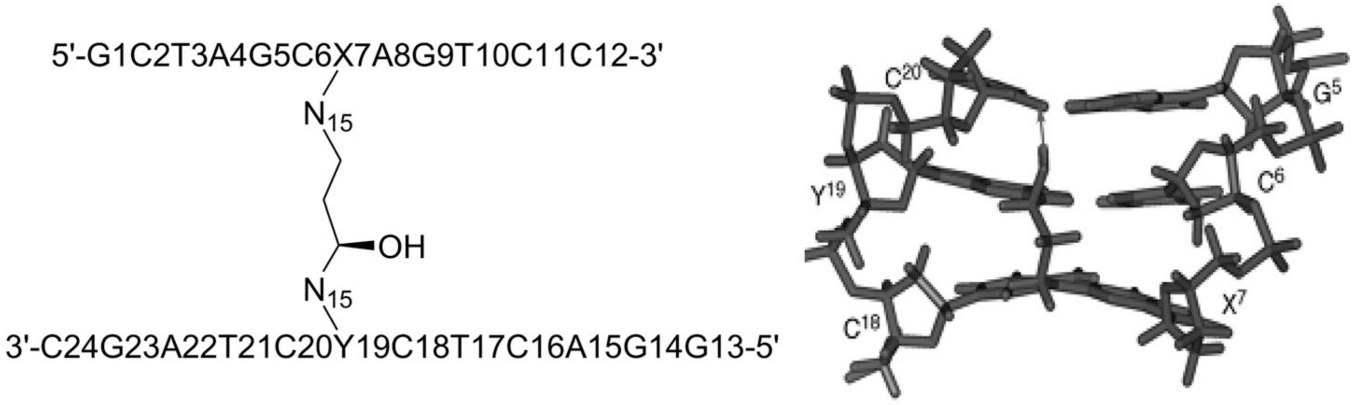

Figure 10.
(A) The N_{15}-labeled DNA duplex cross-linked with hydroxytrimethylene. (B) Local 3D structure of the cross-linked DNA duplex.

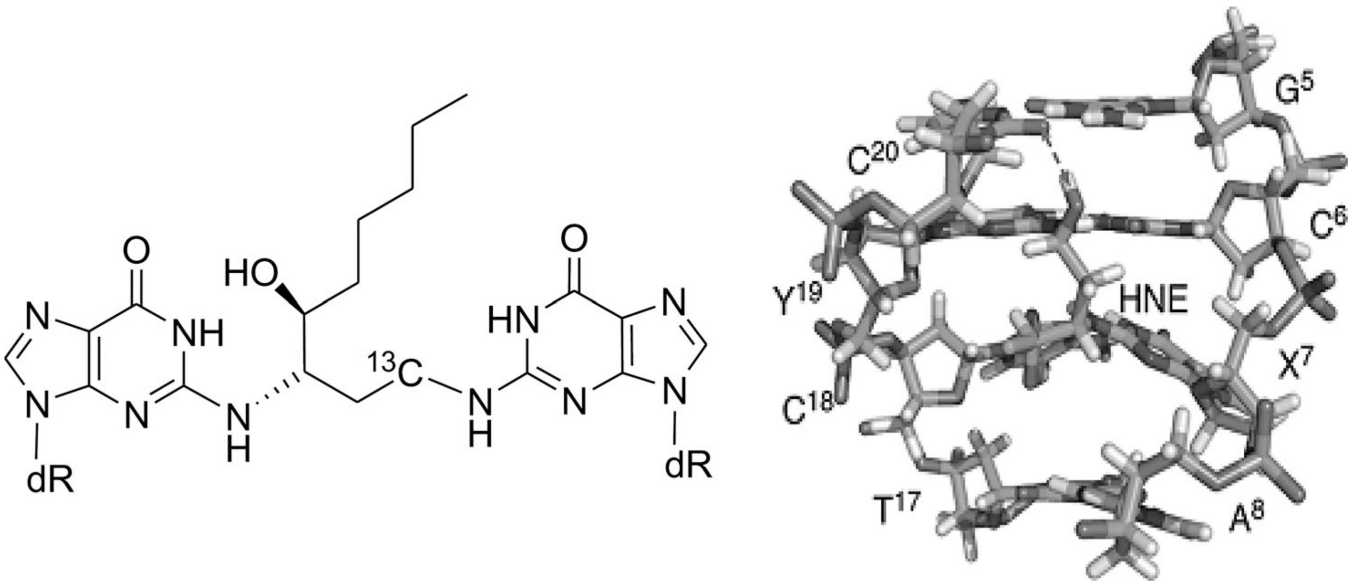

Figure 11.
(A) The DNA duplex linked with the trans-4-hydroxynonenal (HNE) moiety. (B) Local 3D structure of the cross-linked DNA duplex.

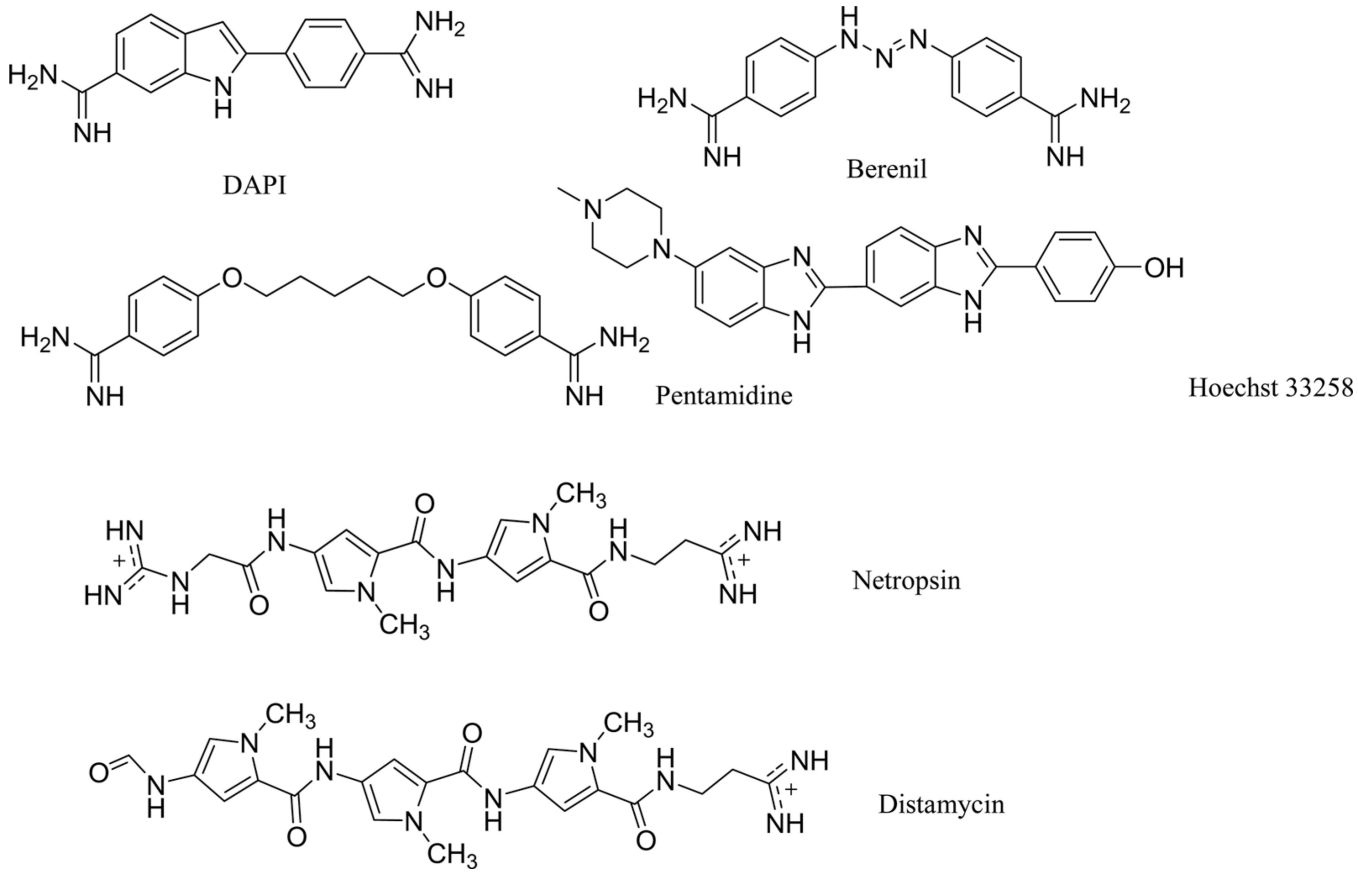

Figure 12.
Chemical structures of the typical DNA minor groove-binding agents: DAPI, berenil, pentamidine, Hoechst 33258, netropsin, and distamycin.

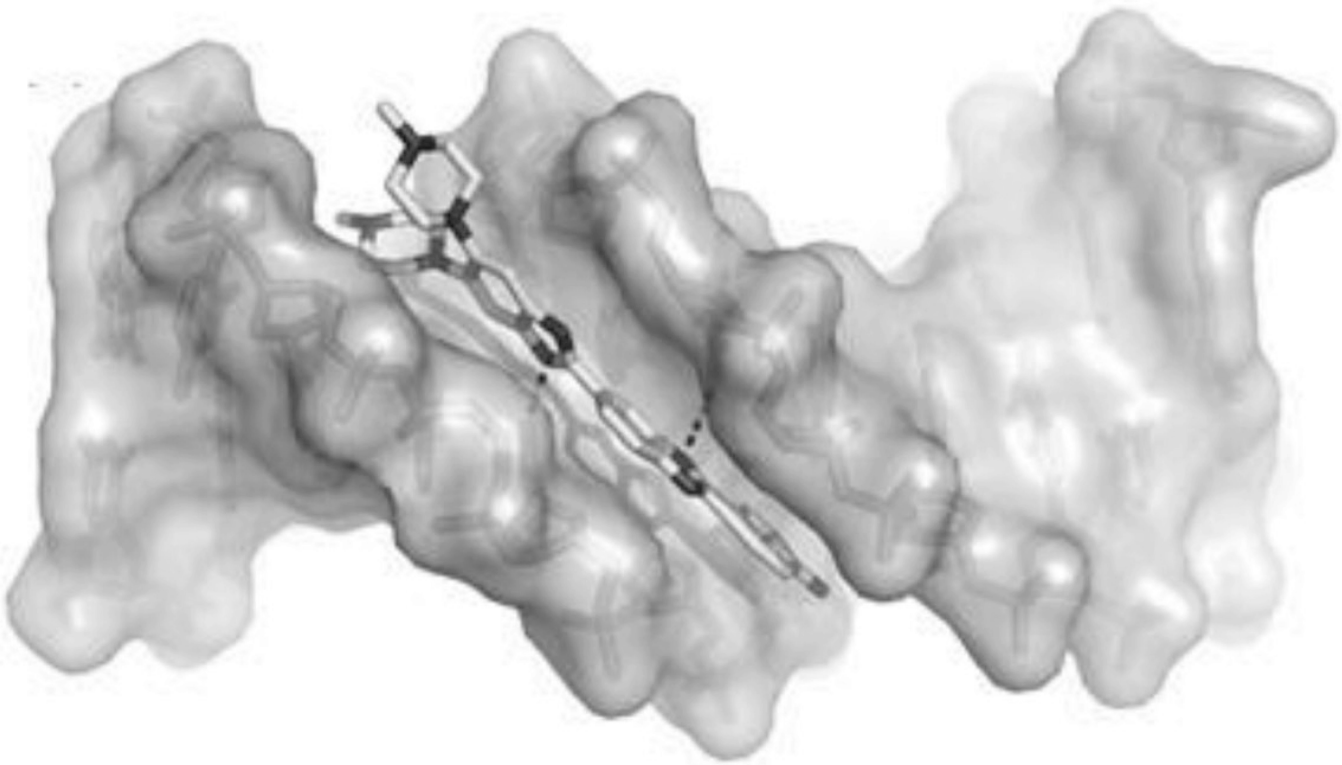

Figure 13.
Overall structure of the Hoechst 33258 (structure showed in Fig. 12) in complex with DNA [5′-d(CGCGAATTCGCG)$_2$-3′] (PDB ID: 8BNA). The DNA is shown in the surface view. Hoechst molecule is shown as sticks. The two hydrogen bonds are indicated by the black dashed lines.

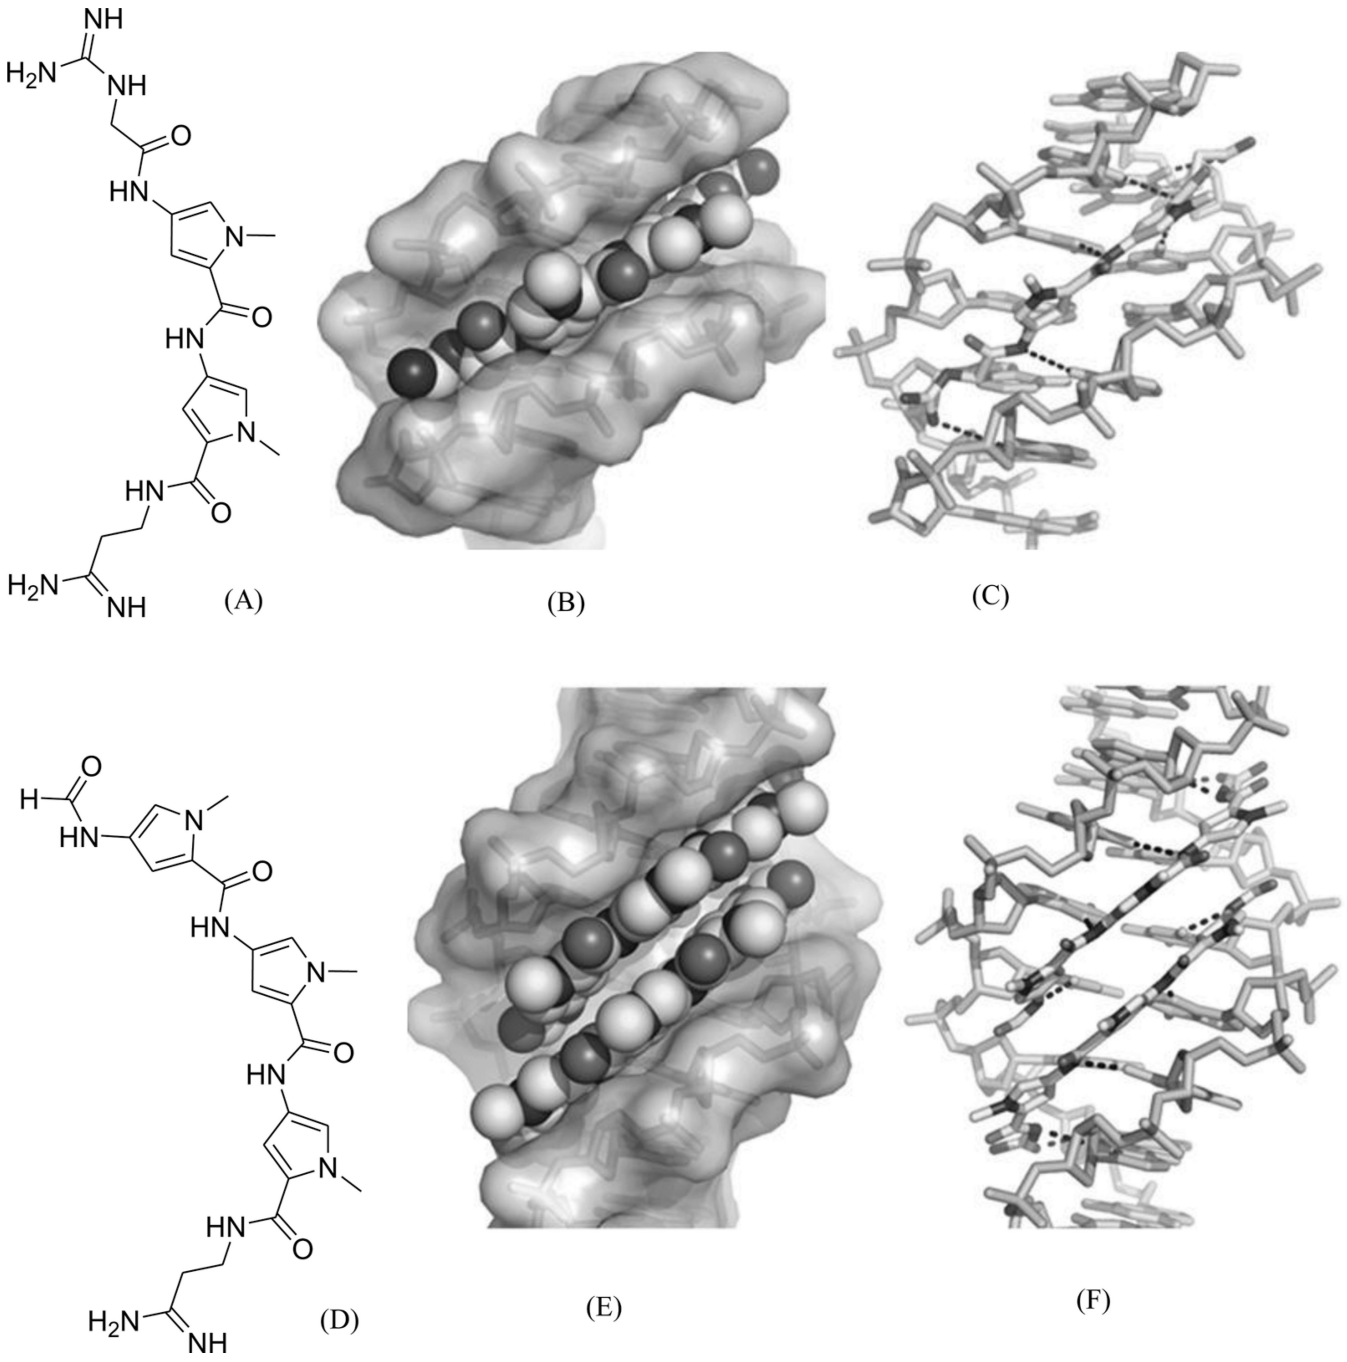

Figure 14.

(A) The chemical structure of netropsin (left) and its crystal structure in complex with DNA [5′-d($C^{5\text{-Br}}$CCCCIIIII)$_2$-3′; PDB ID: 358D]. (B) The chemical structure of distamycin (left) and its crystal structure in complex with DNA [5′-d(GTATATAC)$_2$-3′; PDB ID: 378D]. The structures are presented in two different formats to show the van der Waals interaction (middle) and hydrogen bonding (right, indicated by black dashed lines). Some H-bonds are obscured at the current view angle.

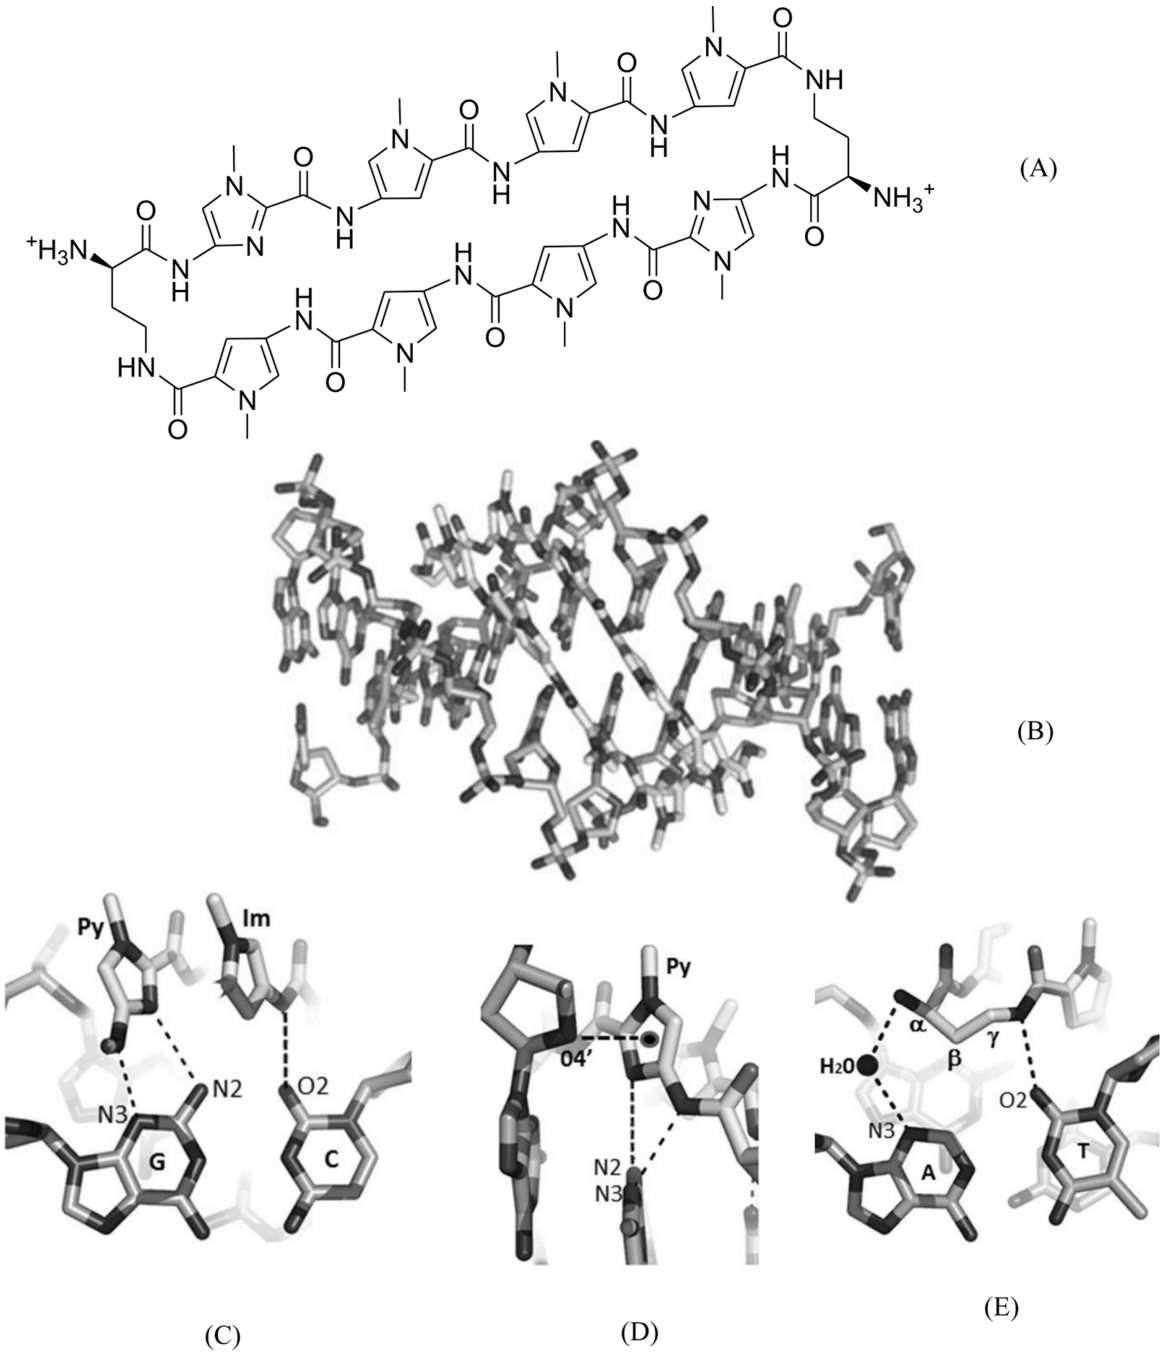

Figure 15.

(A) Chemical structure of the 8-ring pyrole–imidazole cyclic polyamide. (B) Overall structure (PDB ID: 3I5L) of the DNA duplex [d(CCAGGCCTGG)$_2$] complexed with the Py-Im ligand (in the middle). (C) The hydrogen-bonding interactions between the Py/Im and G/C pair. (D) The hydrophobic packing between the O4′ atom and the amide ring systems. (E) The direct and water-mediated hydrogen-bonding interactions between the turn and the A/T pair.

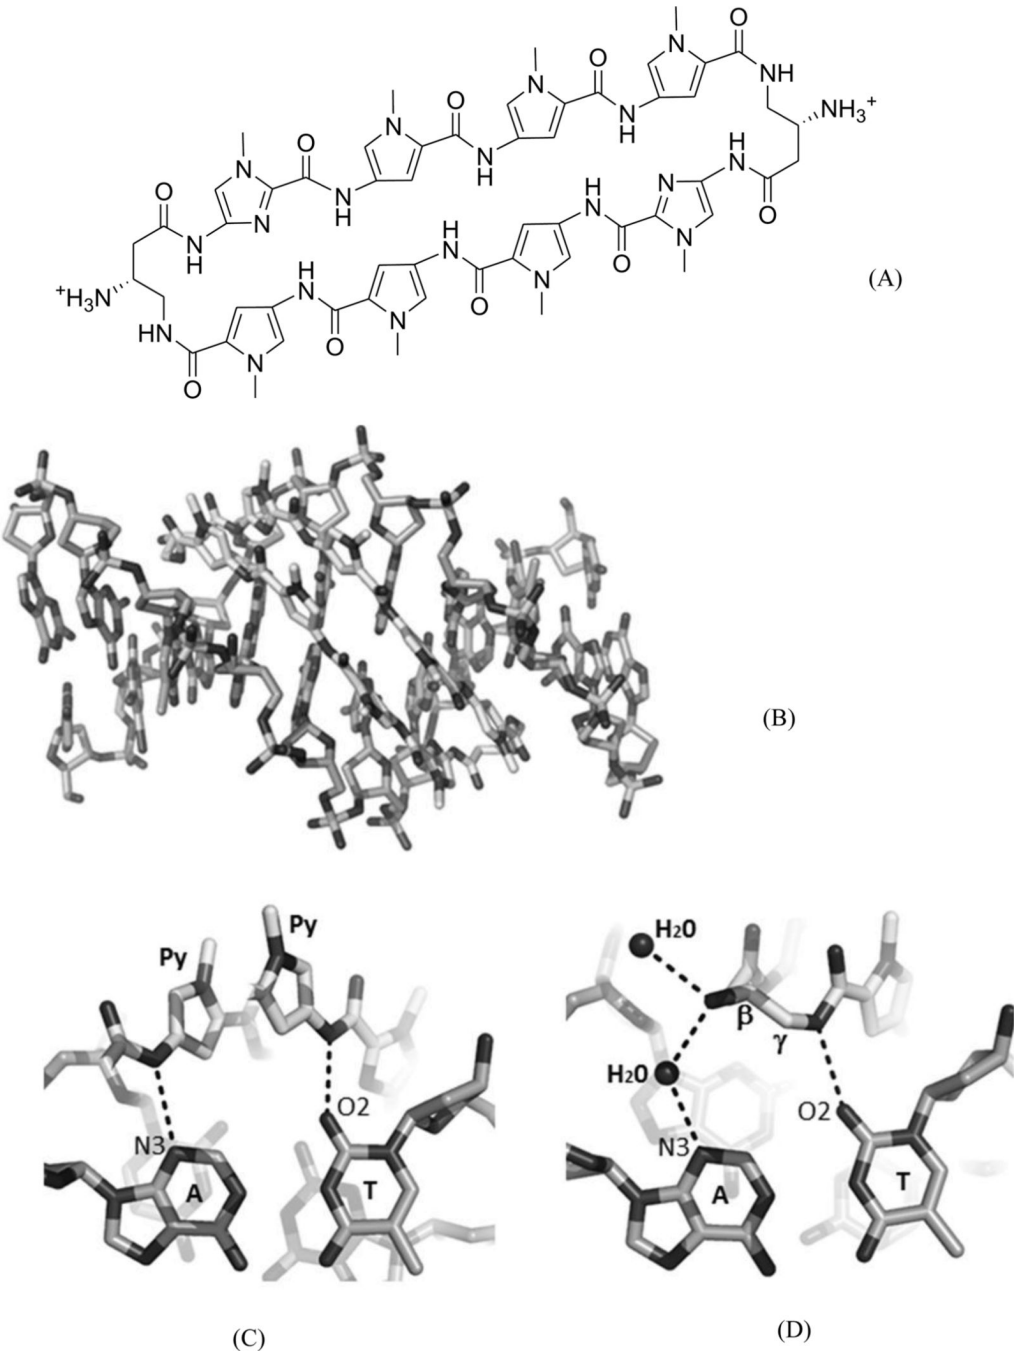

Figure 16.

(A) Chemical structure of the 8-ring pyrrole–imidazole cyclic polyamide. (B) Overall structure of the DNA duplex [d(5′-CCAGTACTGG-3′)$_2$] complexed with the ligand (0.95 Å resolution and PDB ID: 3OMJ). (C) The hydrogen-bonding interactions between the Py/Py and A/T pair. (D) The direct and water-mediated hydrogen-bonding interactions between the turn and the A/T pair.

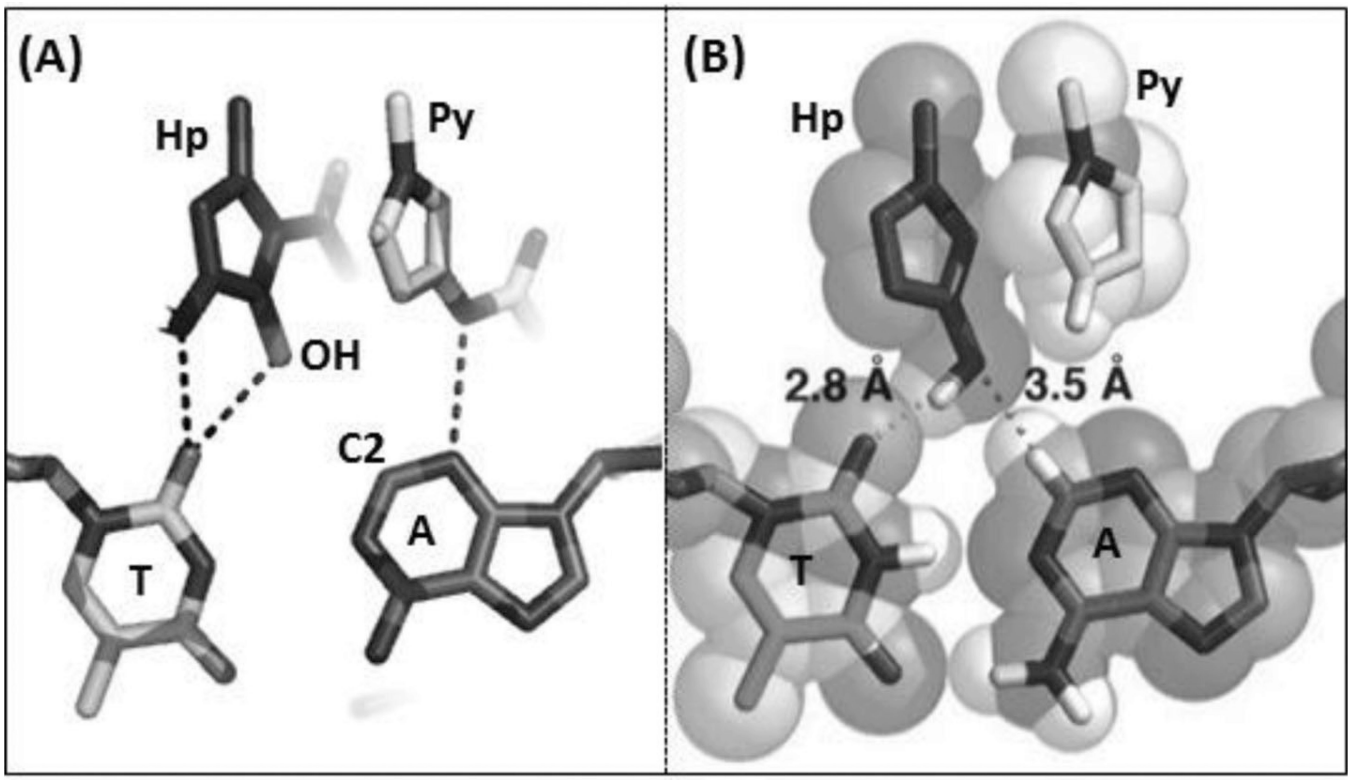

Figure 17.
(A) The hydrogen-bonding interactions between the HP/Py and T/A pair observed in the DNA duplex (5′-CCAGTACTGG-3′)$_2$ complexed with ImHpPyPy (PDB ID: 407D). (B) The space-filling model showing the tight fitting between the Hp/Py pair and T/A pair.

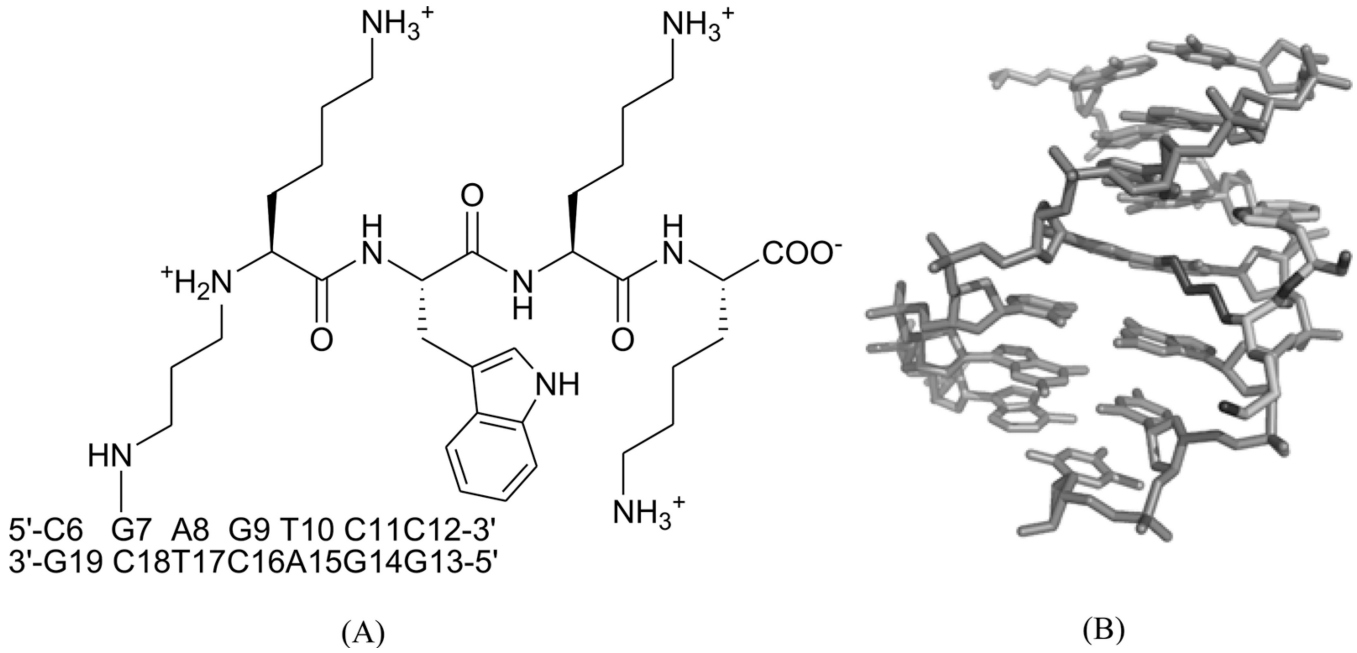

Figure 18.
(A) Chemical structure of the DNA–KWKK conjugate. The trimethylene moiety was named as residue X25. (B) An expanded view of the average structure of the peptide-conjugated DNA duplex (PDB ID: 2KV6). The peptide is in the middle.

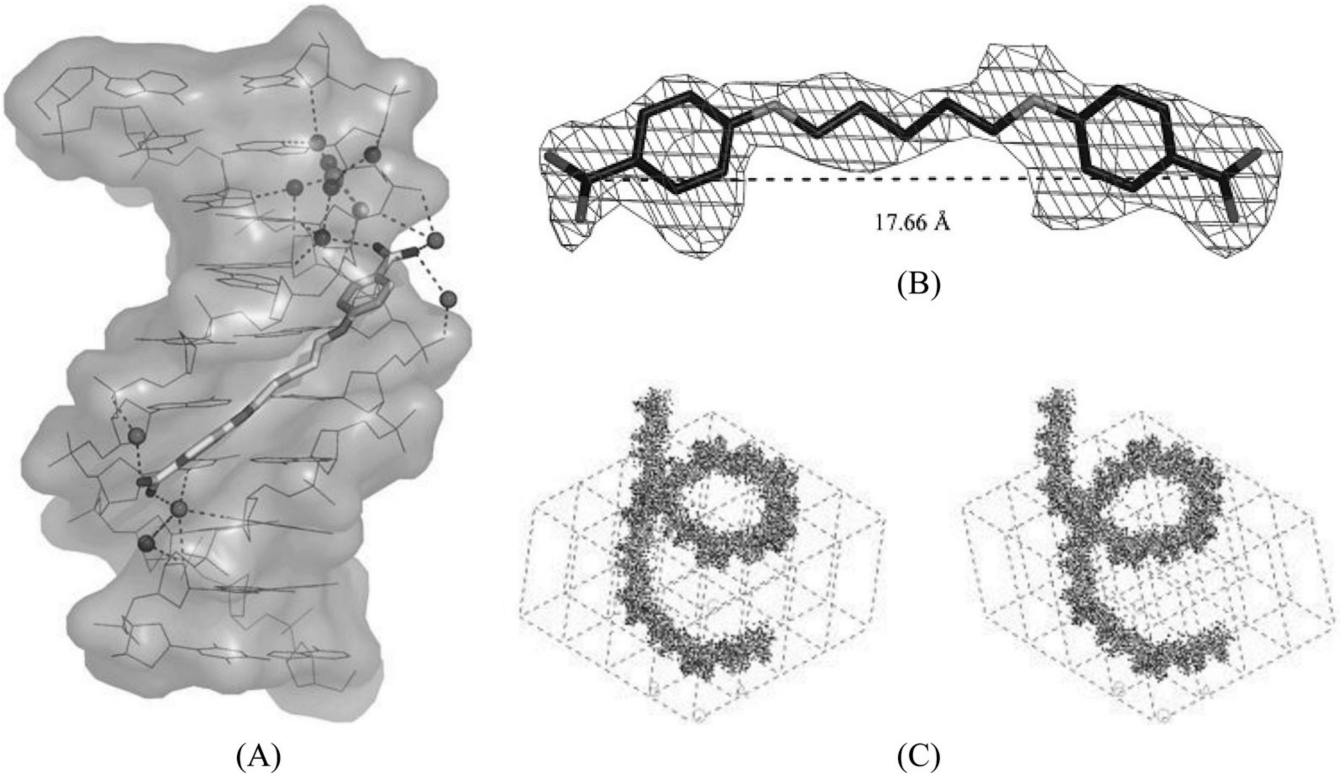

Figure 19.
(A) Complex structure of pentamidine bound with the DNA duplex [d(ATATATATAT)$_2$]. (PDB: 3EY0). The drug is in the minor groove at the center of sequence. The water molecules interact with the DNA and drug through hydrogen bonding (dashed lines). (B) Structure of pentamidine and its electron-density map (2Fo-Fc, contoured at 1 σ level). (C) Stereo view of one and a half turns of the coiled coil structure.

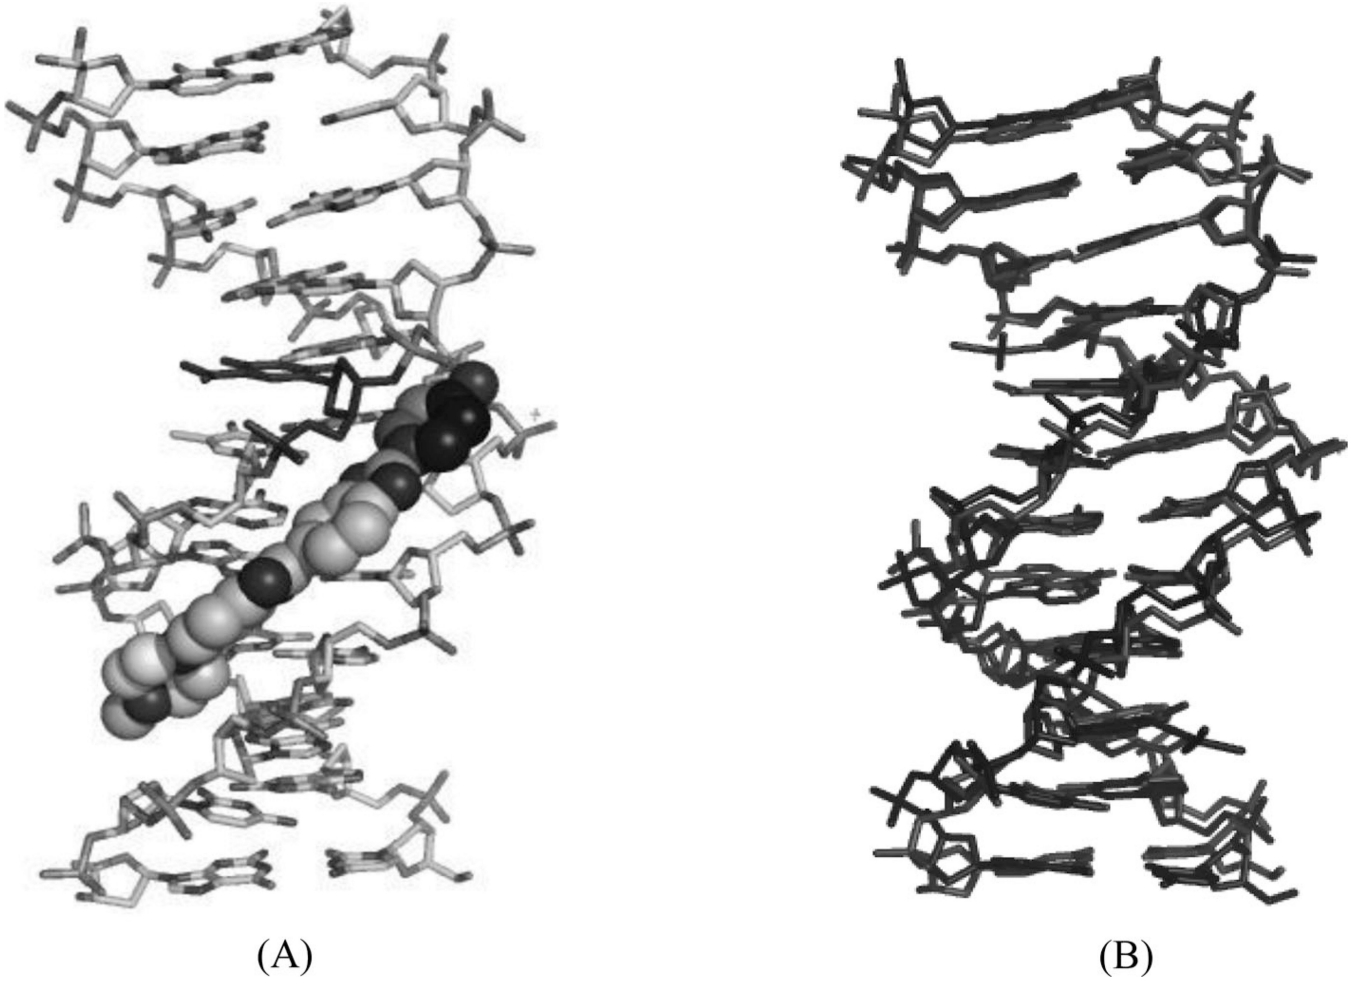

Figure 20.

(A) Overall crystal structure of the DNA duplex [d(CGCGGATfUCGCG)$_2$] bound with Hoechst33258 (PDB ID: 3AJK). (B) Superimposition of the ligand-bound DNA duplex (the ligand is not shown.) with the native Dickerson–Drew DNA 12mer [d(CGCGAATTCGCG)$_2$] (PDB ID: 5BNA). The rms is 0.28 Å.

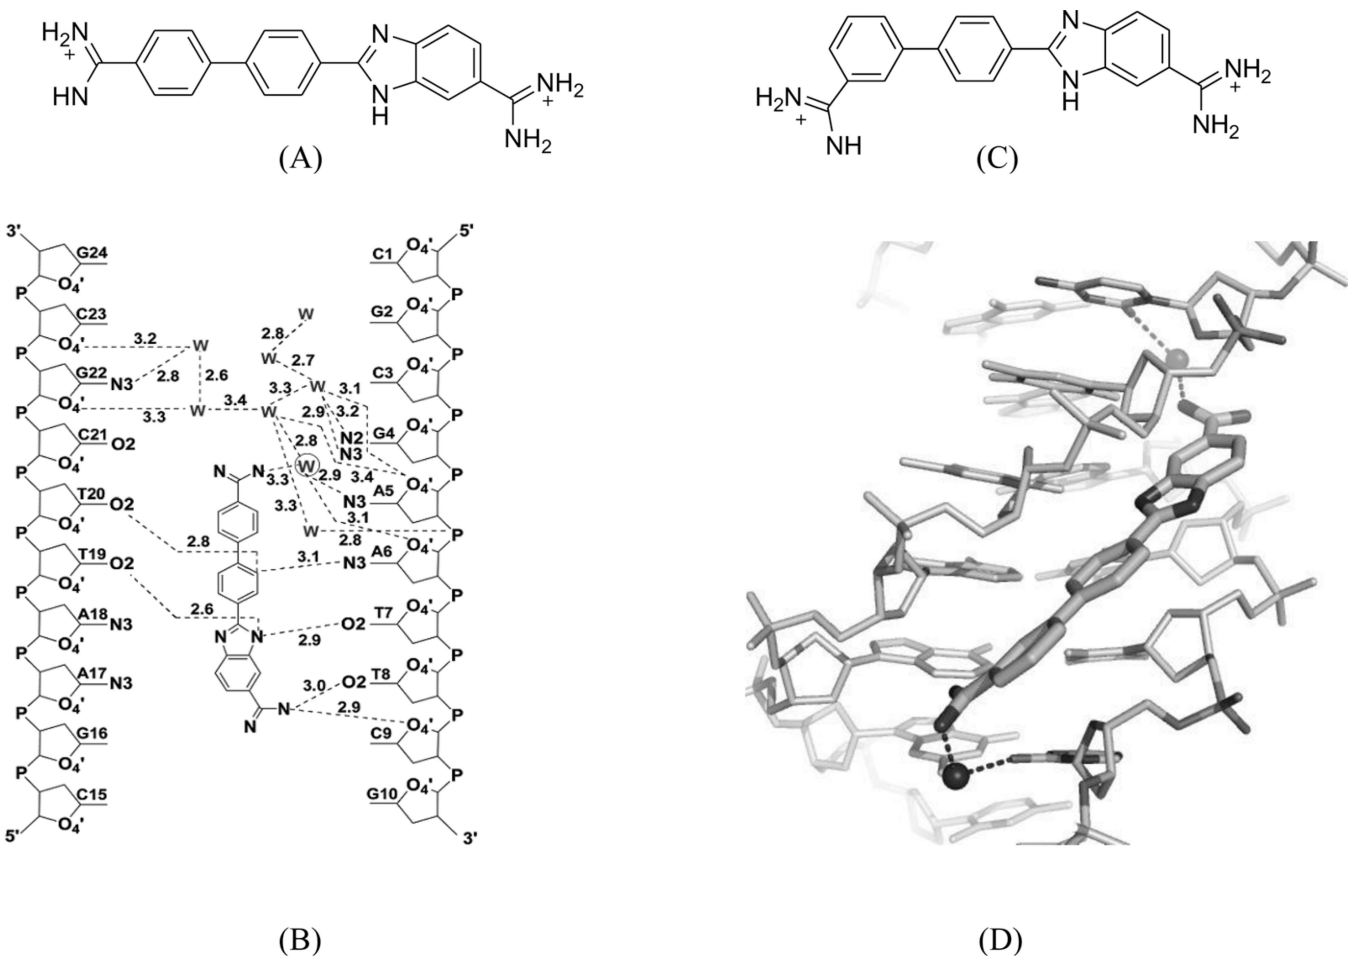

Figure 21.

(A) Chemical structure of DB921. (B) Water network observed in the structure of DNA in complex with of DB921 (PDB: 2B0K). (C) Chemical structure of DB1055. (D) Local hydrogen-bonding interaction in the DB1055-DNA complex structure. Water molecules are shown as spheres. (PDB: 2I5E).

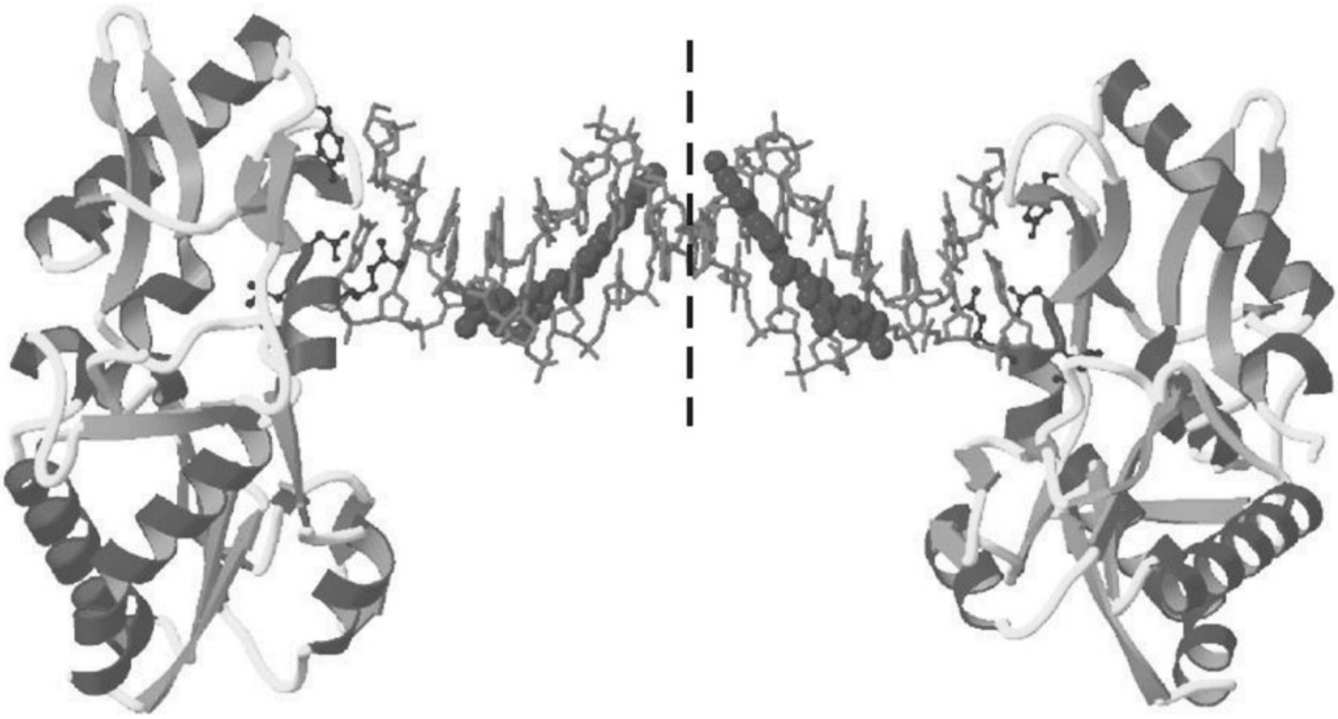

Figure 22.
The crystal structure (PDB ID:1ZTT) of an RT fragment–DNA–netropsin complex. The DNA sequence is 5′-d(CTTAATTCGAATTAAG)-3′. Netropsin is shown as spheres.

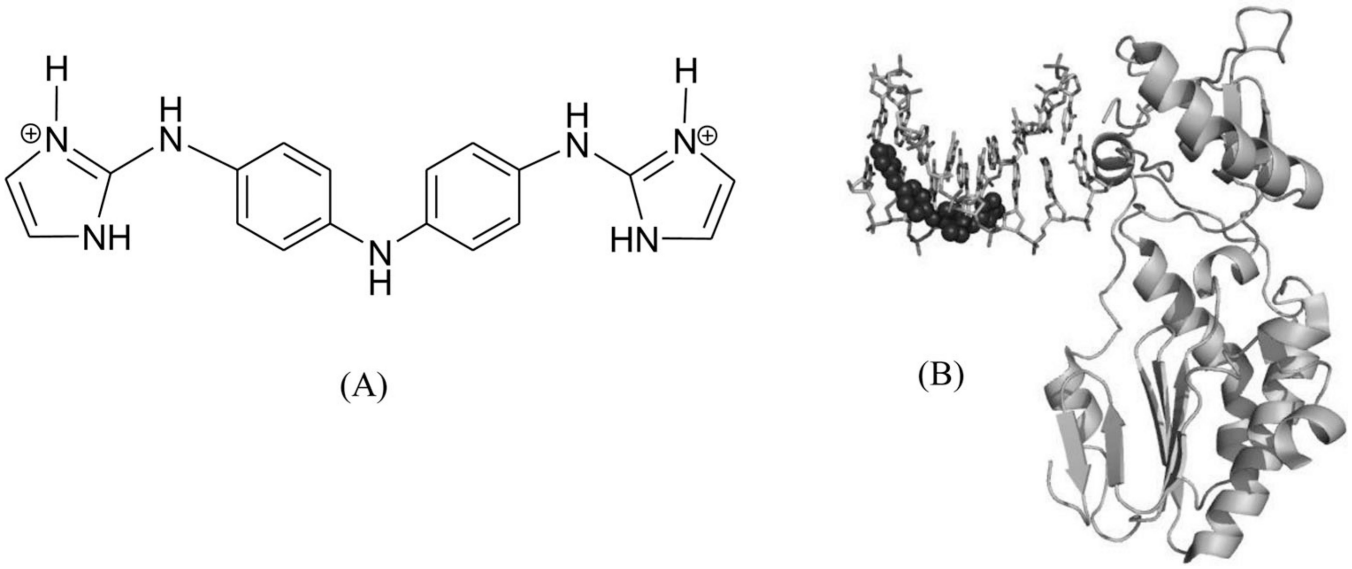

Figure 23.
(A) Chemical structure of CD27. (B) The overall structure (PDB ID: 3FSI) of a RT fragment in complex with DNA duplex and CD27. The DNA duplex is $d(CTTAATTCGAATTAAG)_2$.

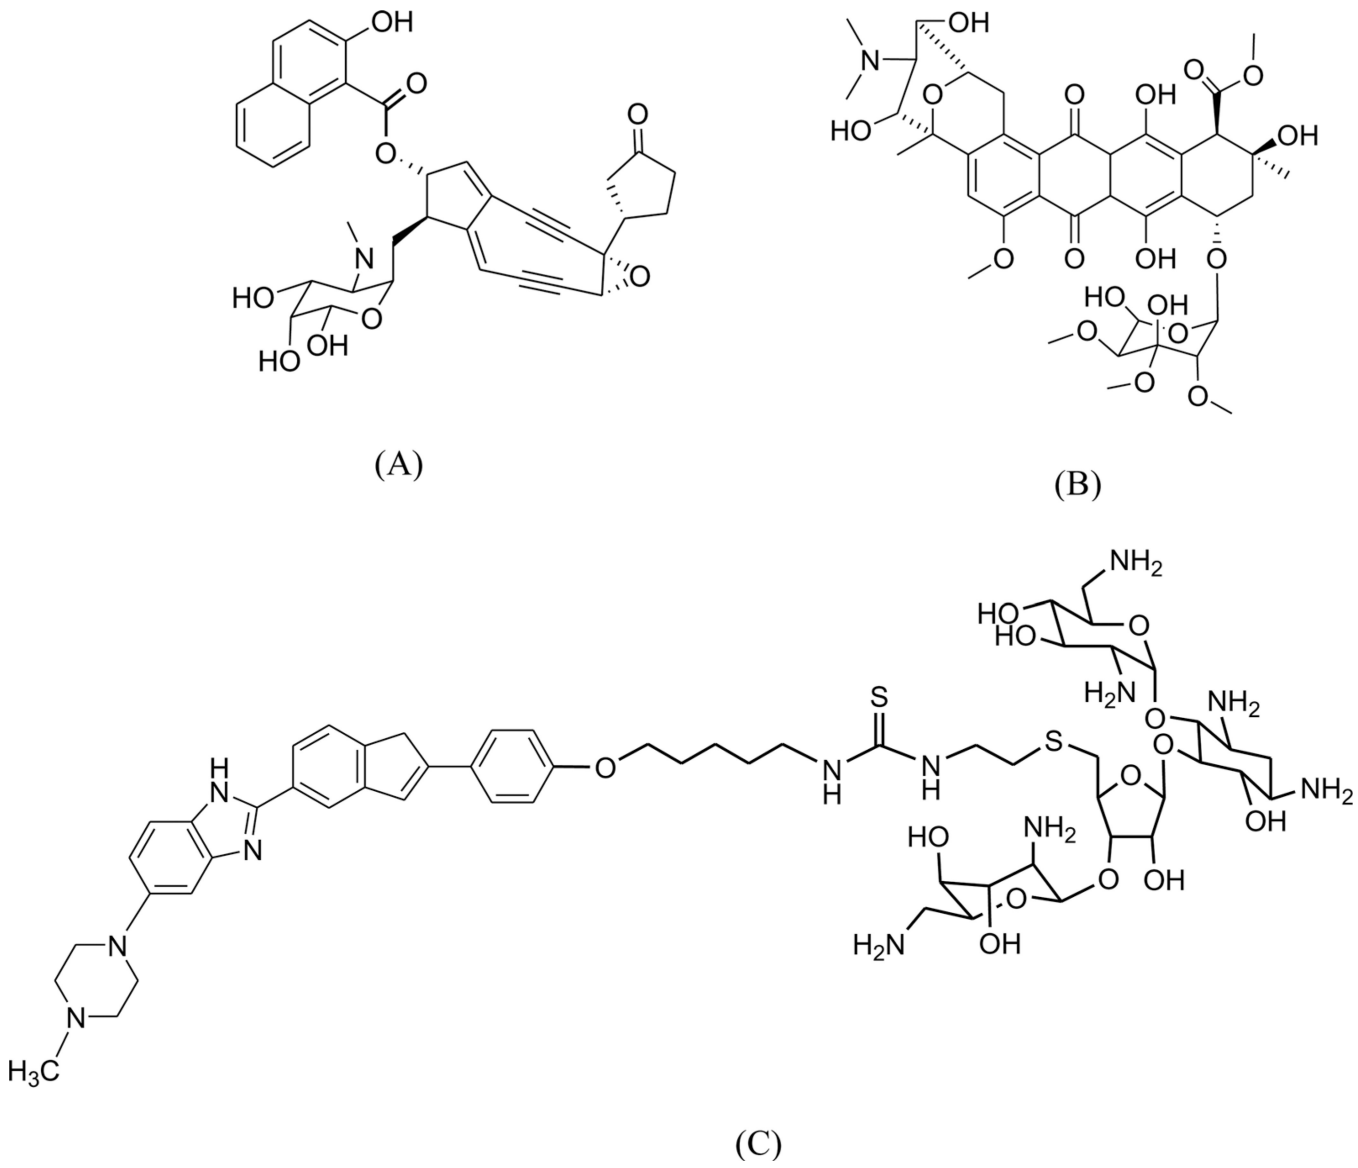

Figure 24.
Chemical structures of neocarzinostatin (A), nogalamycin (B), and a neomycin-groove binder conjugate (C).

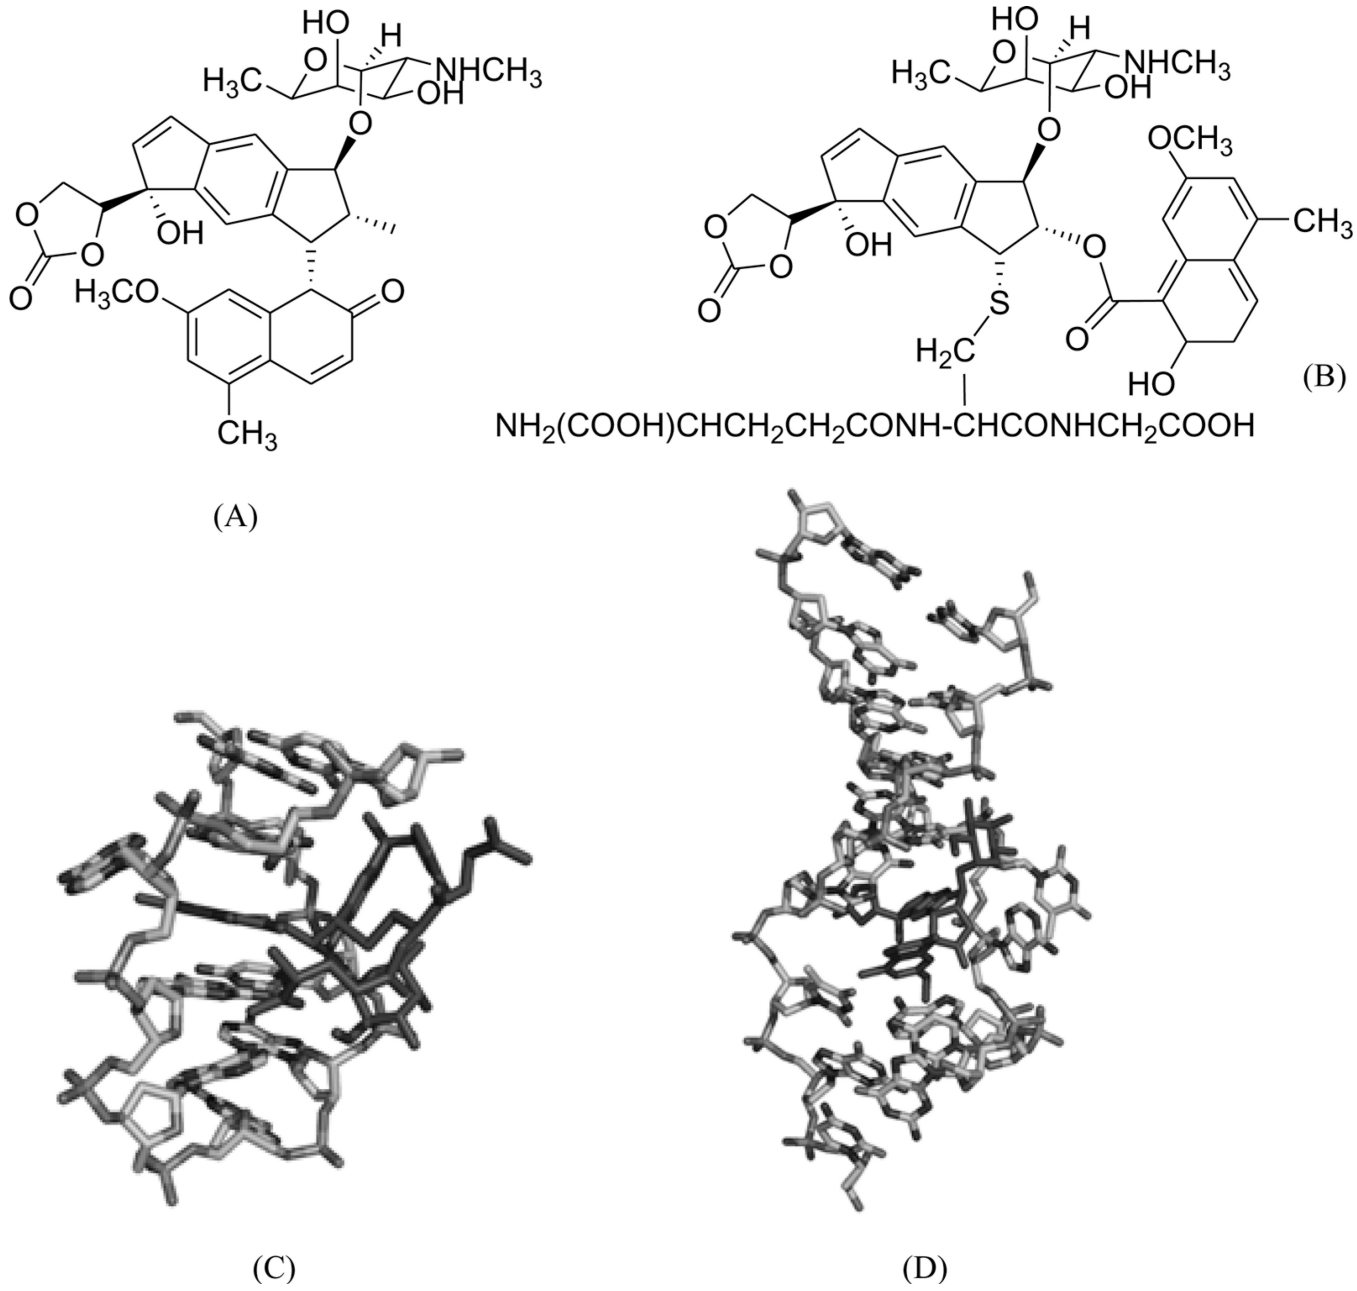

Figure 25.

(A) Chemical structure of NCSi-gb, formed by the postactivated NCS-chrom under basic conditions. (B) Chemical structure of NCSi-glu in presence of a thiol agent. (C) Induced formation of a DNA bulge structure (PDB ID: 1KVH) by binding of NCSi-gb on the DNA major groove. (D) Complex structure (PDB ID: 1MP7) of a DNA duplex bound by NCSi-glu.

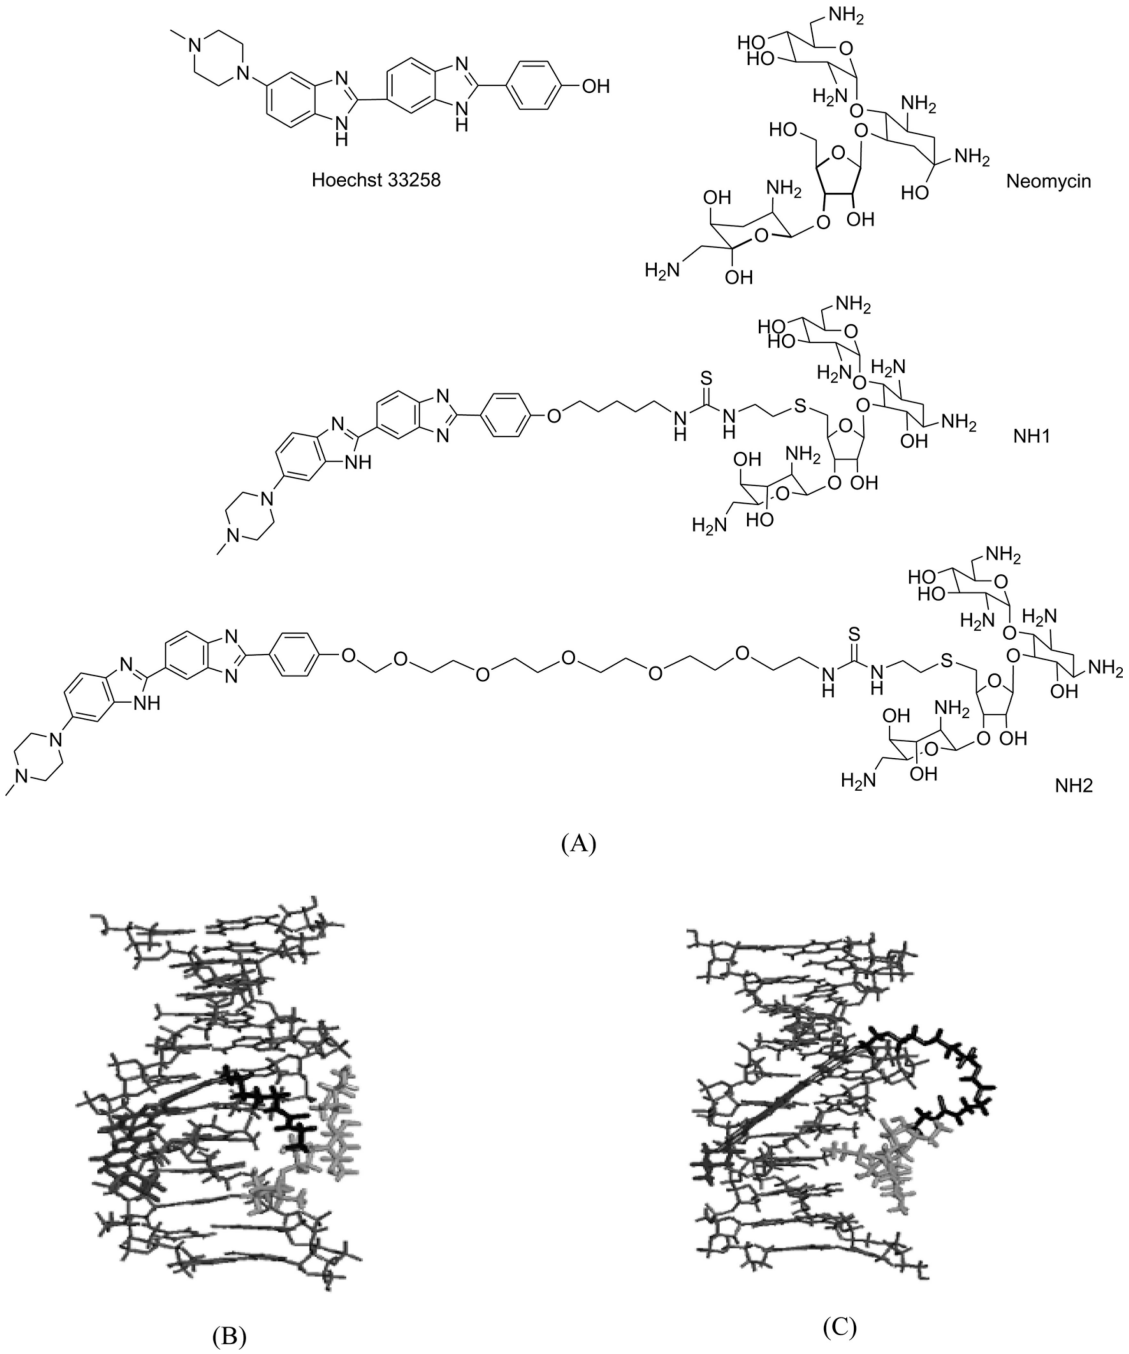

Figure 26.

(A) The chemical structure of Hoechst 33258, neomycin, and their two conjugates (NH1 and NH2). (B) and (C) Computation models of NH1- and NH2-bound DNA duplex $(CGCAAATTTGCG)_2$.

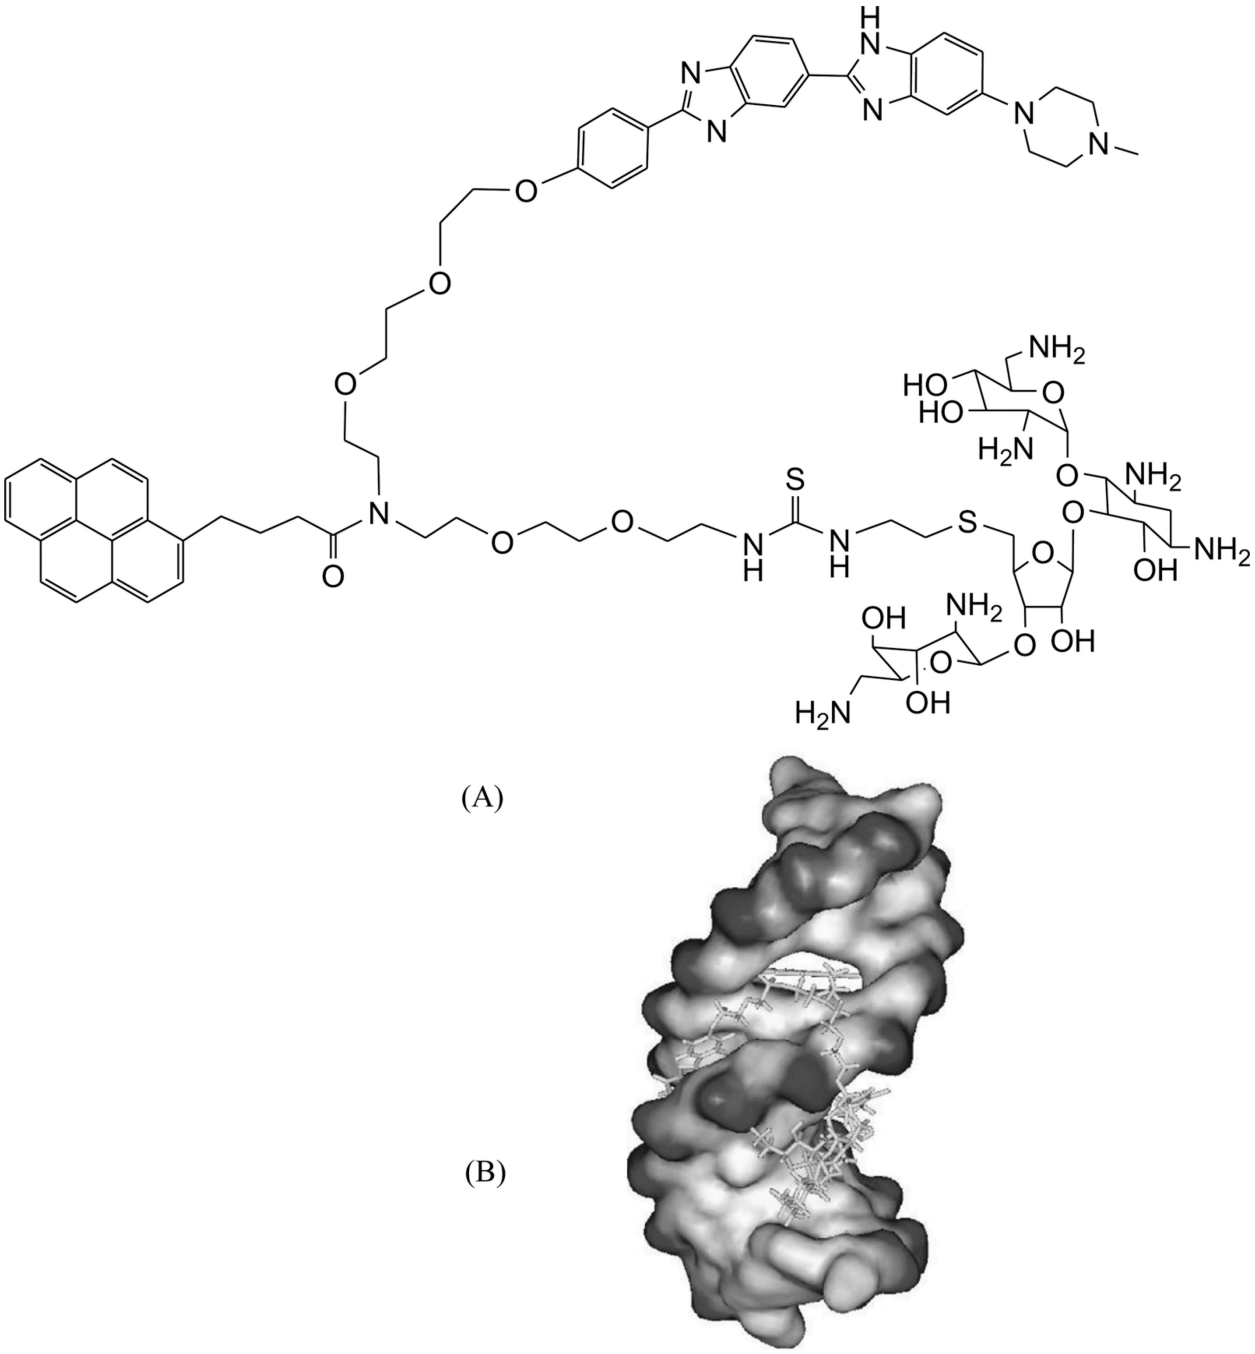

Figure 27.
(A) The chemical structure of the NHP conjugate containing the neomycin, Hoechst 33258, and pyrene moieties. (B) Computer model of NHP binding to a DNA duplex $(CGCAAATTTGCG)_2$.

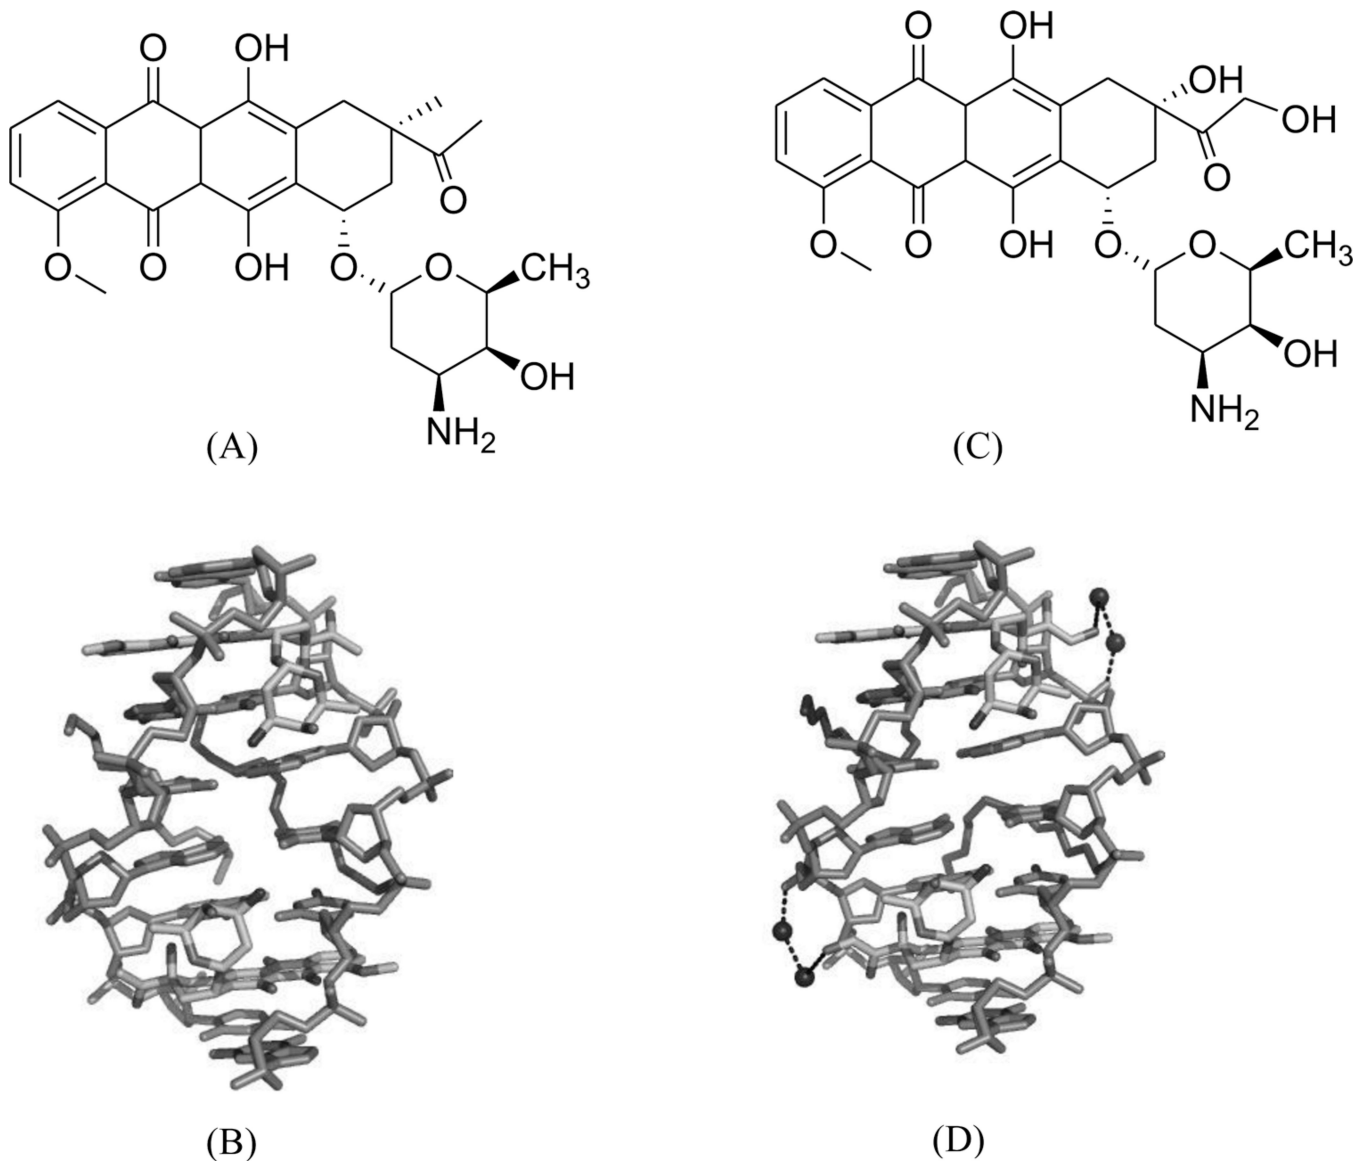

Figure 28.

(A) Chemical structure of daunomycin. (B) Overall structure (PDB ID: 1D10) of the daunomycin–DNA complex (2:1 ratio). The duplex is a B-form DNA/RNA chimera (dC)(rG)d(ATCG). (C) Chemical structure of adriamycin. (D) Overall structure (PDB ID: 1D12) of the adriamycin–DNA complex (2:1 ratio). The DNA duplex is 5′-d$(CGATCG)_2$-3′. Water molecules are shown as spheres.

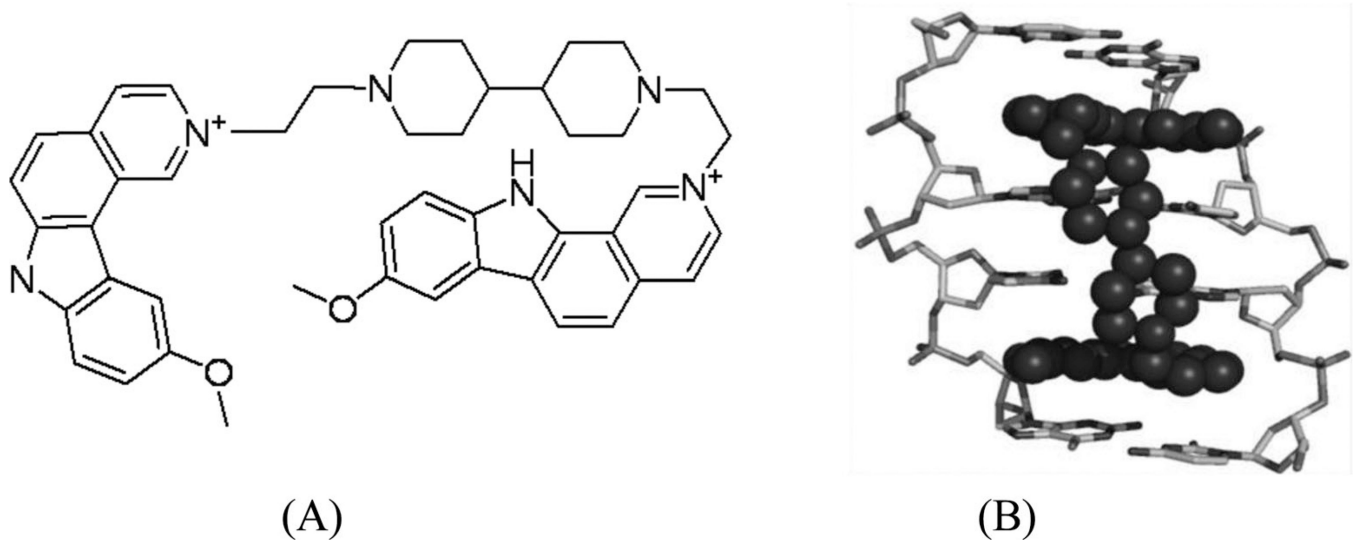

Figure 29.
(A) Chemical structure of ditercalinium. (B) Overall structure (PDB ID: 1D32) of the ditercalinium–DNA complex (1:1 ratio). The DNA duplex is 5′-d(CGCG)$_2$-3′, and the darker structure is ditercalinium.

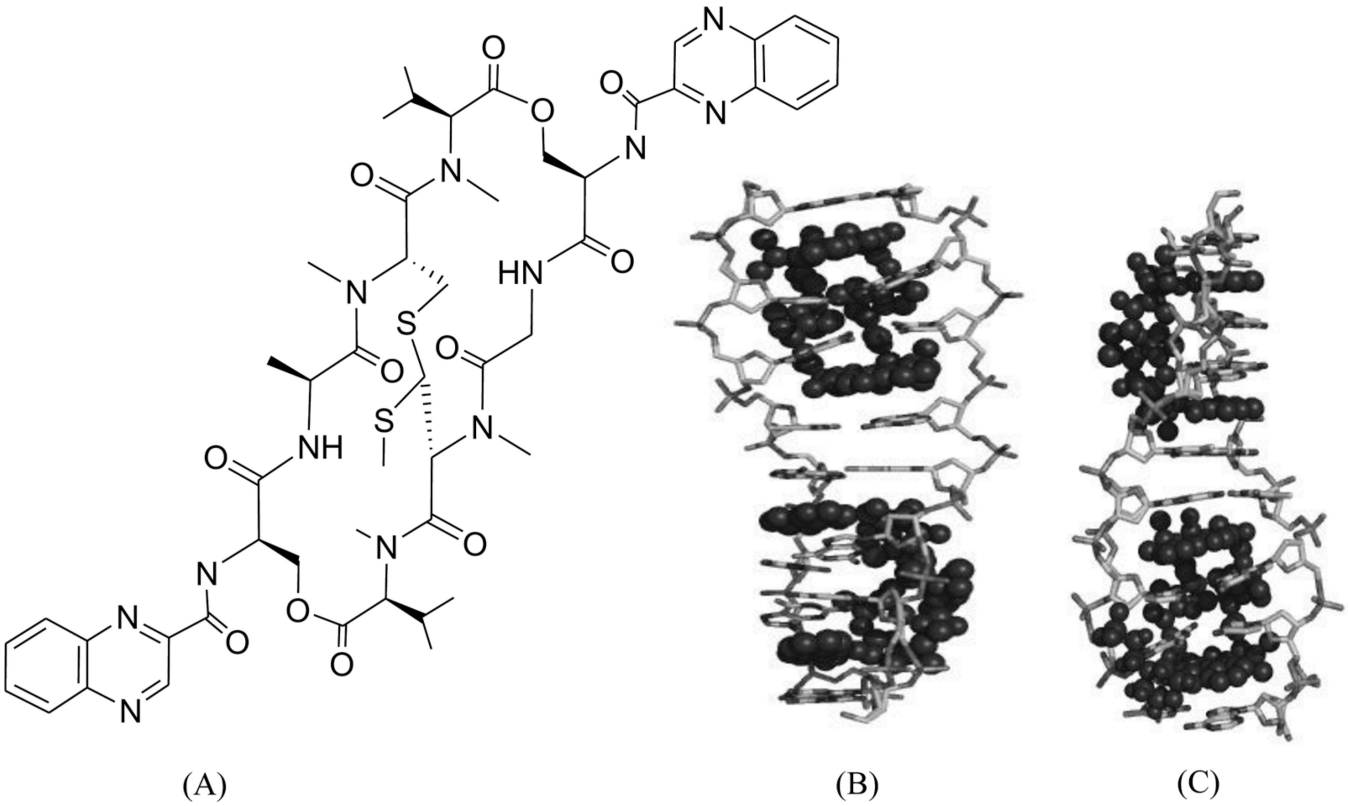

Figure 30.
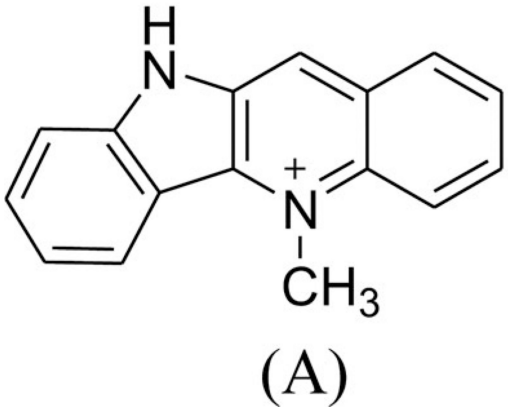
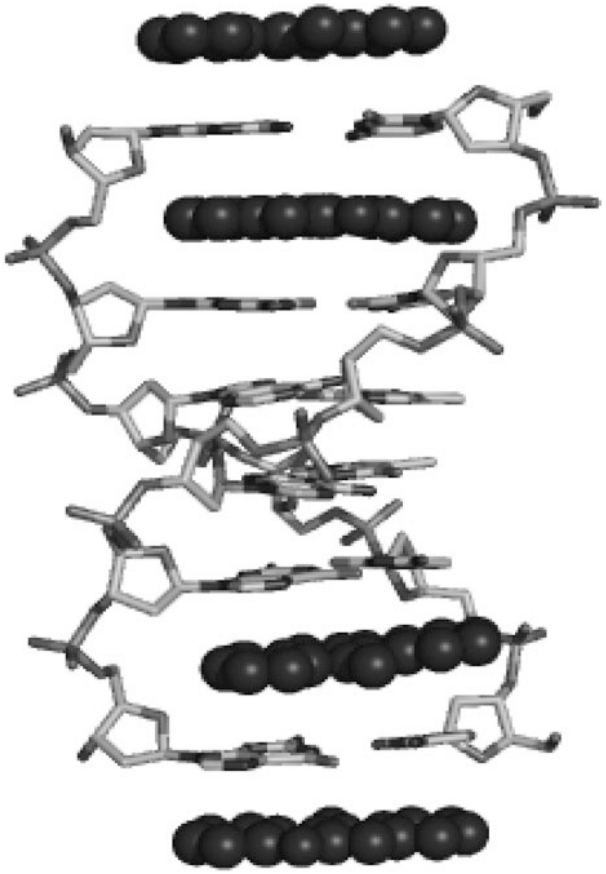
(A) Chemical structure of echinomycin. (B) Overall structure (PDB ID: 1PFE) of the echinomycin–DNA complex (2:1 ratio). The DNA duplex is 5′-d(GCGTACGC)$_2$-3′, and the darker structure is echinomycin. (C) Overall structure (PDB ID: 2ADW) of the echinomycin–DNA complex (2:1 ratio). DNA duplex is 5′-d(ACGTACGT)$_2$-3′, and the darker structure is echinomycin.



(A)



(B)

Figure 31.
(A) Chemical structure of cryptolepine. (B) Overall structure (PDB ID: 1K9G) of the cryptolepine–DNA complex (4:1 ratio). The DNA duplex is 5′-d(CGTACG)$_2$-3′, and the darker structure is cryptolepine.

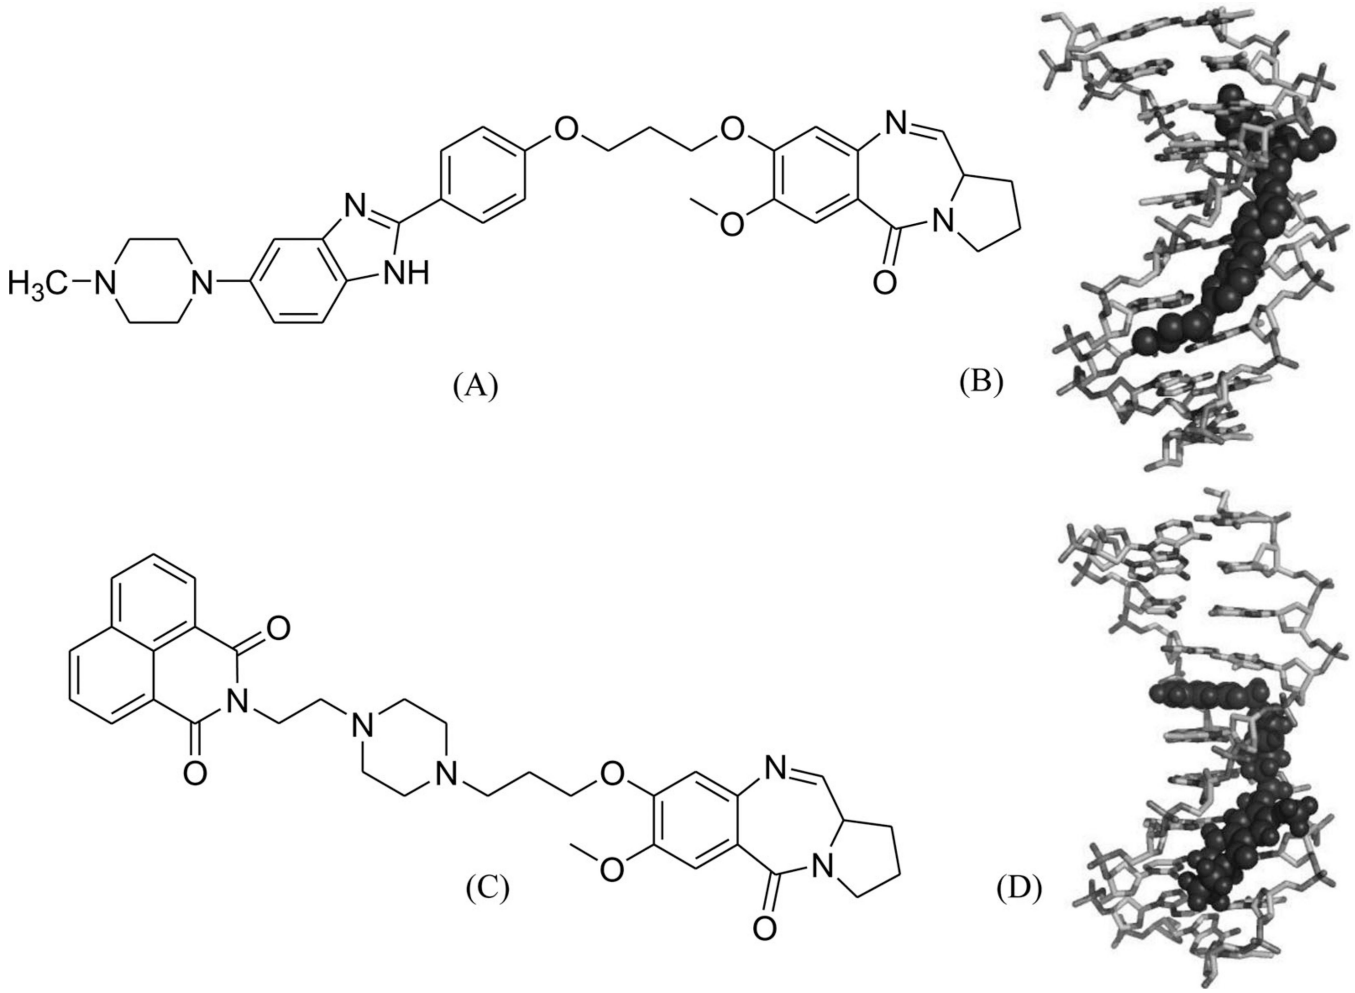


Figure 32.

(A) Chemical structure of the PBD-BIMZ conjugate. (B) Overall structure (PDB ID: 2KTT) of the DNA decamer complexed with PBD-BIMZ. The DNA duplex is 5′-d(AACAATTGTT)$_2$-3′, and the darker structure is PBD-BIMZ. (C) Chemical structure of the PBD-naphthalimide conjugate. (D) Overall structure (PDB ID: 2KY7) of the DNA decamer with PBD-naphthalimide. The DNA duplex is 5′-d(AACAATTGTT)$_2$-3′, and the darker structure is PBD-naphthalimide.

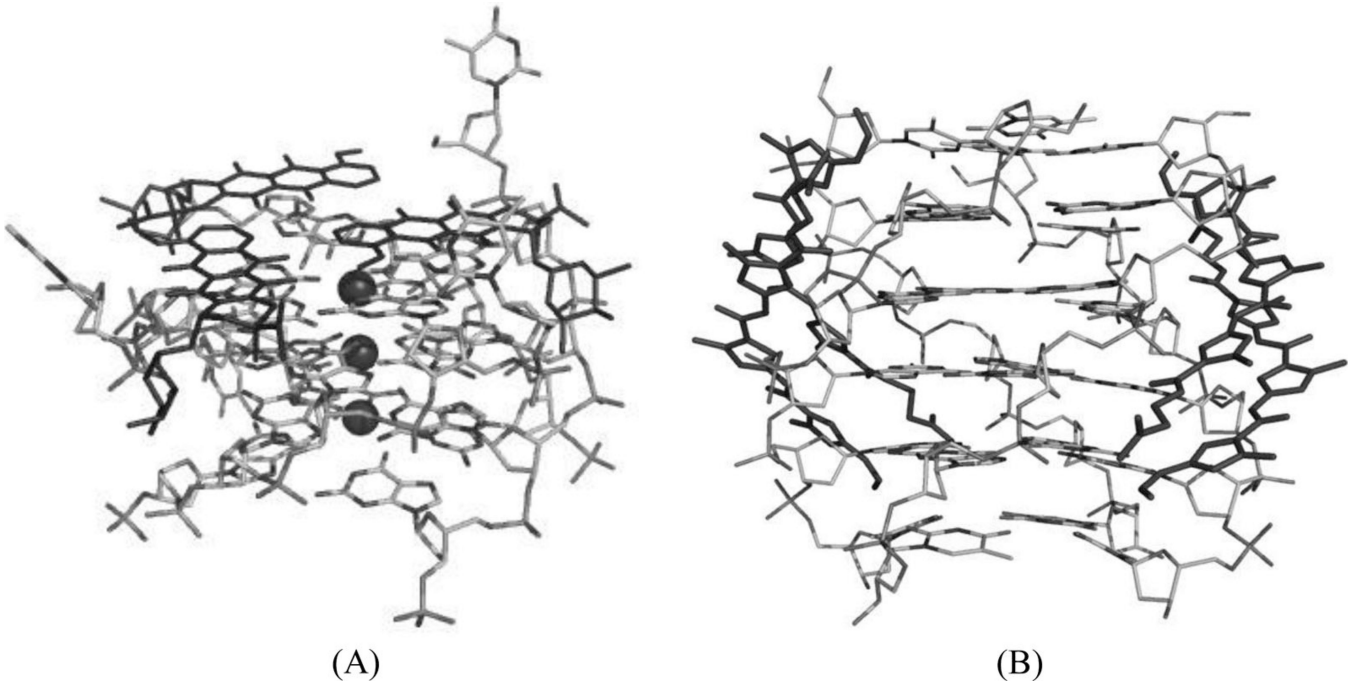

Figure 33.

(A) Overall structure (PDB ID: 1O0K) of the G-quadruplex [d(TGGGGT)$_4$] complexed with daunomycin (the darker structures). (B)Overall structure (PDB ID: 2JT7) of the G-quadruplex [d(TGGGGT)$_4$] complexed with distamycin A (the darker structures). The ligand molecules are in black. The dark spheres represent the sodium atoms.

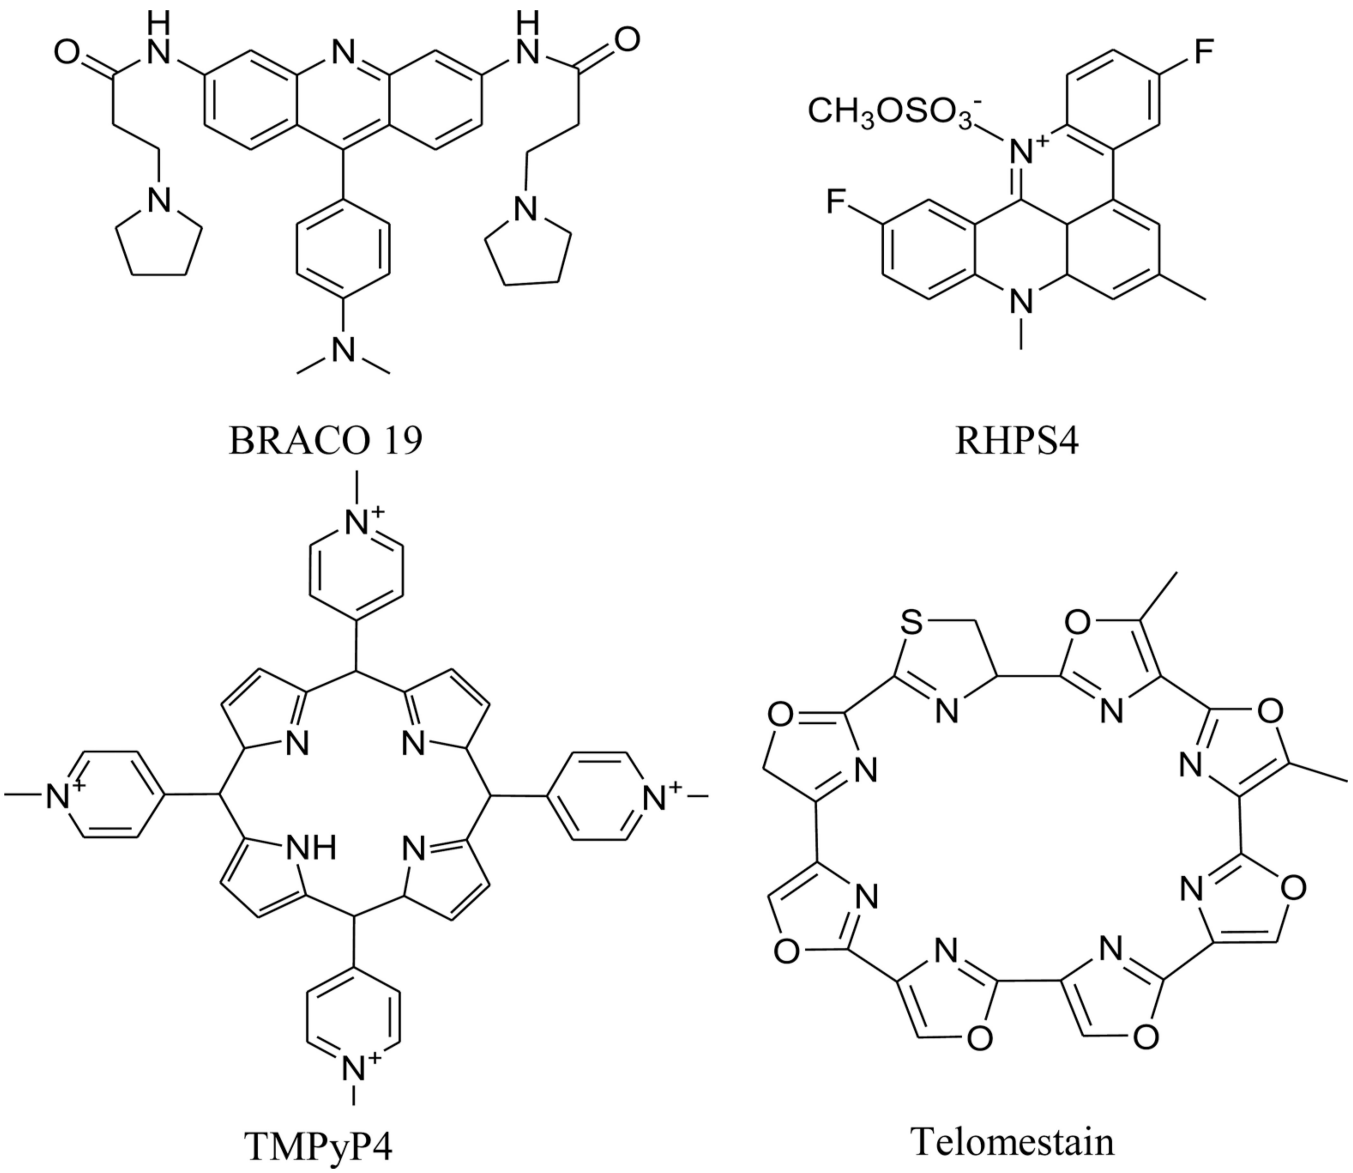

Figure 34.
Chemical structures of several DNA quadruplex-binding ligands.

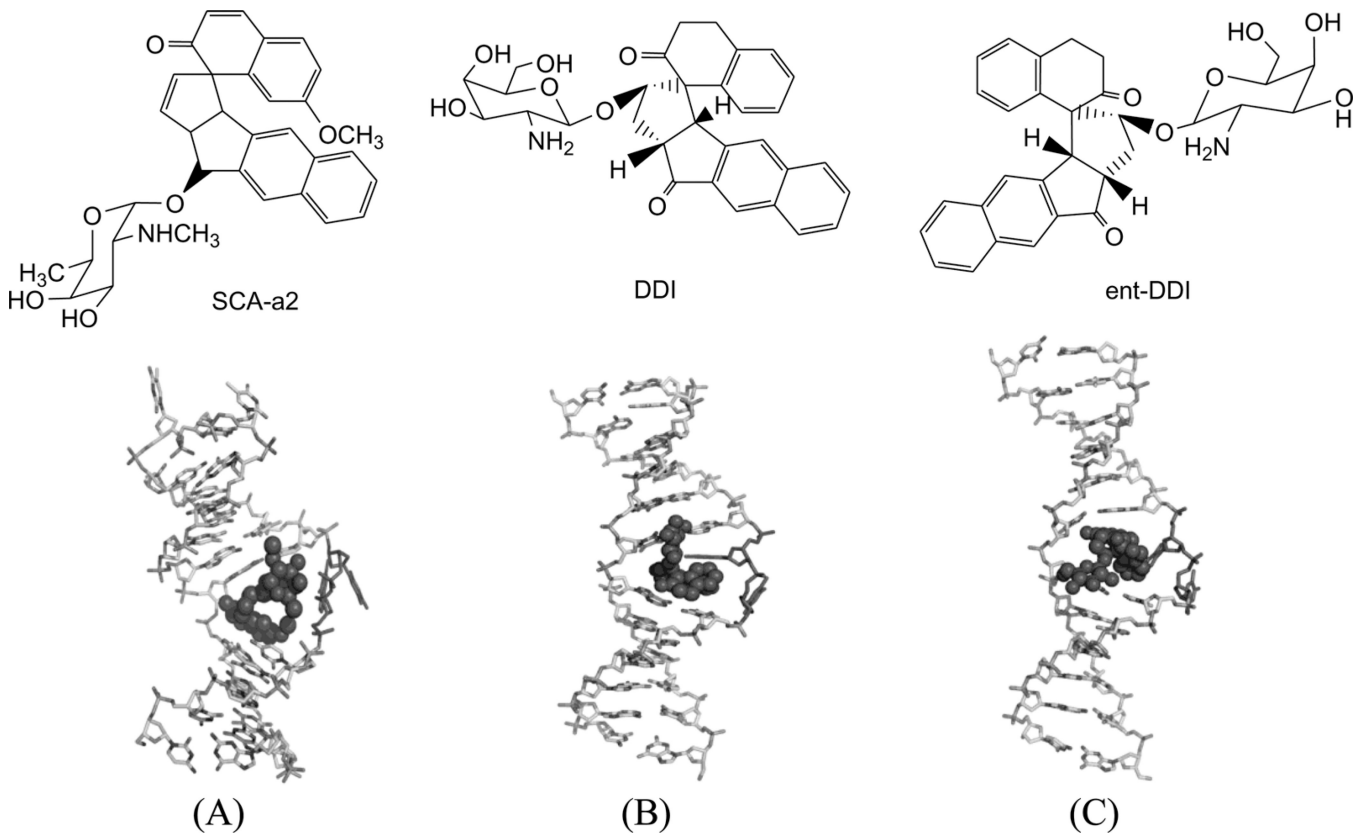

Figure 35.

Structures of SCA-α2, DDI, ent-DDI, and their DNA complexes. (A) Overall structure (PDB ID: 2OEY) of SCA-α2-bound DNA duplex with a two-base bulge [d(5′-CCATCGTCTACCTTTGGTAGGATGG-3′)$_2$]. (B) Overall structure (PDB ID: 1P96) of DDI-bound DNA duplex with a two-base bulge. (C) Overall structure (PDB ID: 1R4E) of ent-DDI-bound DNA duplex with a two-base bulge. The duplex sequences for C and D are 5′-CACGCAGTTCGGAC-3′ and 5′-GTCCGATGCGTG-3′. The ligands are showed as black spheres.

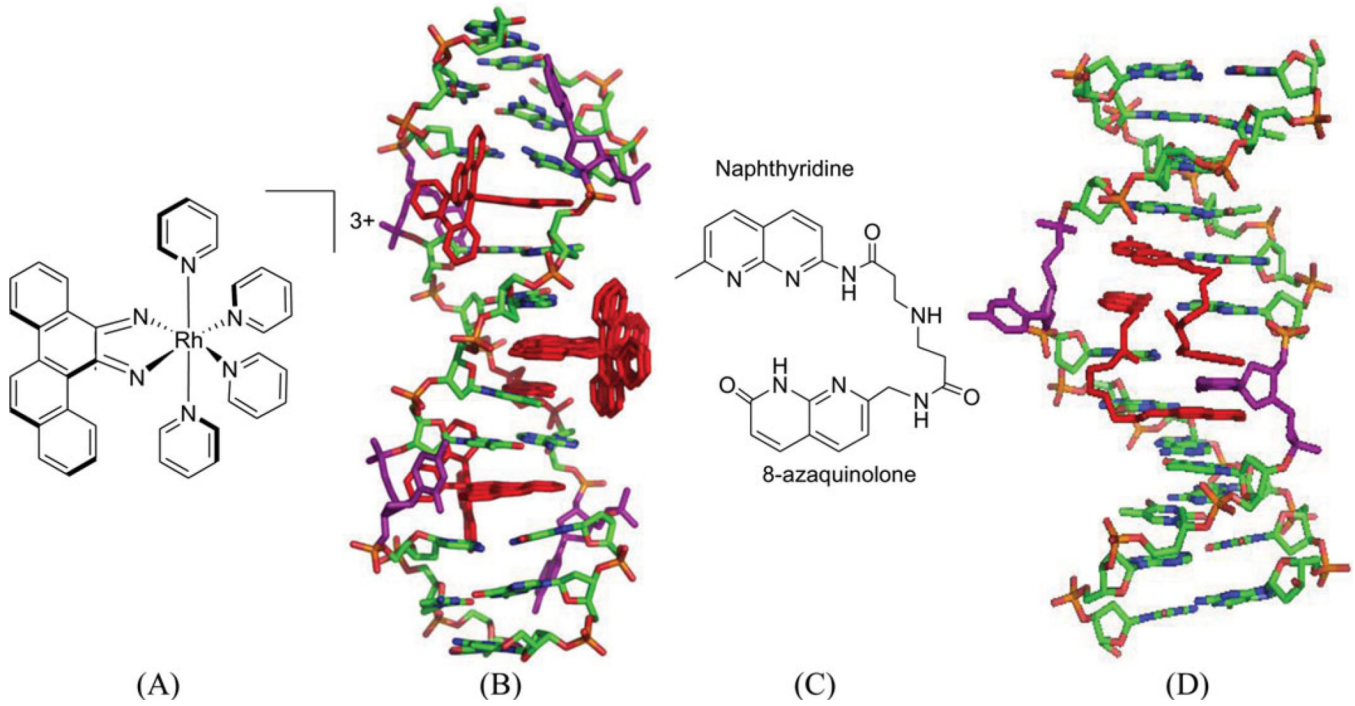

Figure 36.

(A) Chemical structure of rhodium compound ($[Rh(bpy)_2chrysi]^{3+}$. (B) Overall structure (PDB ID: 2O1I) of the rhodium complex (red sticks) bound to the DNA duplex [d(5′-CGGAAATTCCCG-3′)$_2$], with the bulge bases (purple sticks) ejected. (C) Chemical structure of naphtyridine-azaquinoline conjugate (NA). (D) Overall structure of NA (red sticks) bound with a DNA duplex (5′-CTAACAGAATG-3′•5′-CATTCAGTTAG-3′), ejecting the two mismatched cytosine bases (purple sticks), PDB: 1 × 26.

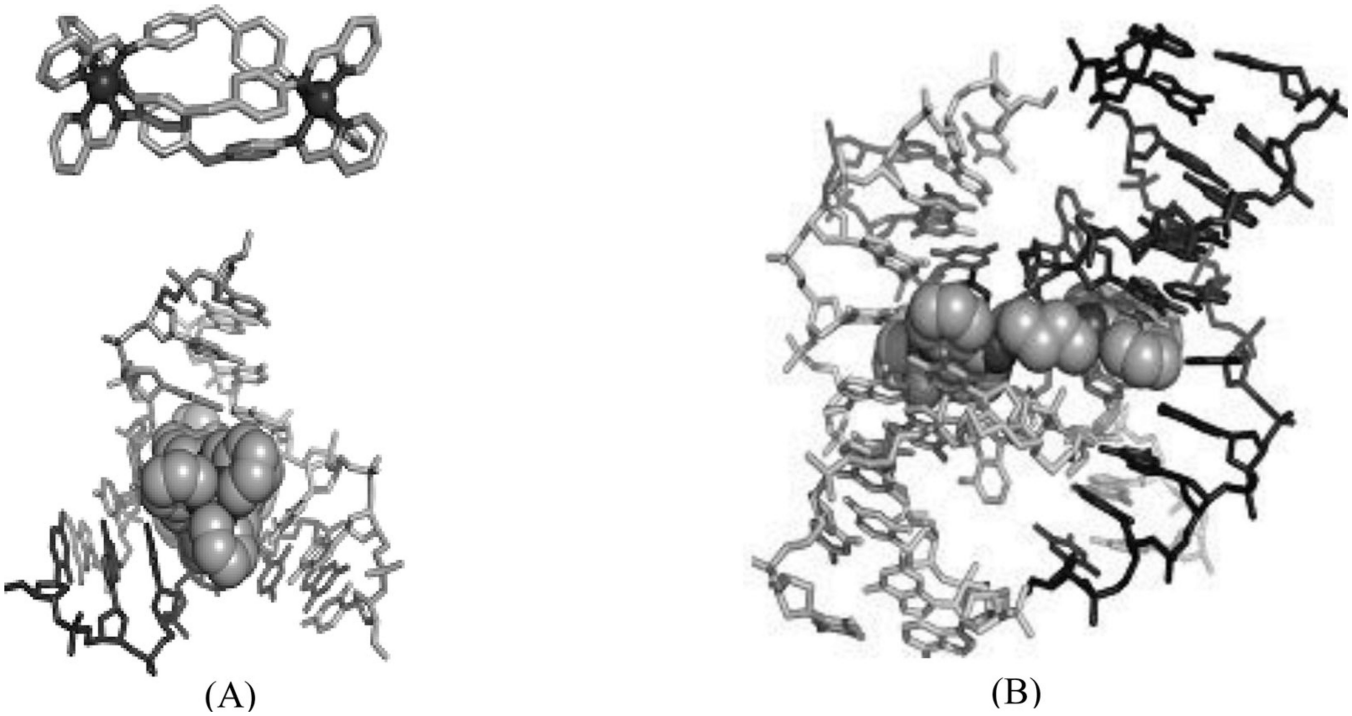

Figure 37.
(A) Structure of the three-way junction-binding ligand and the overall complex structure (PDB 2ET0) with the DNA three-way junction. (B) Structure of the Holiday junction-binding ligand and the overall complex structure (PDB 2GWA) with the Holiday junction.

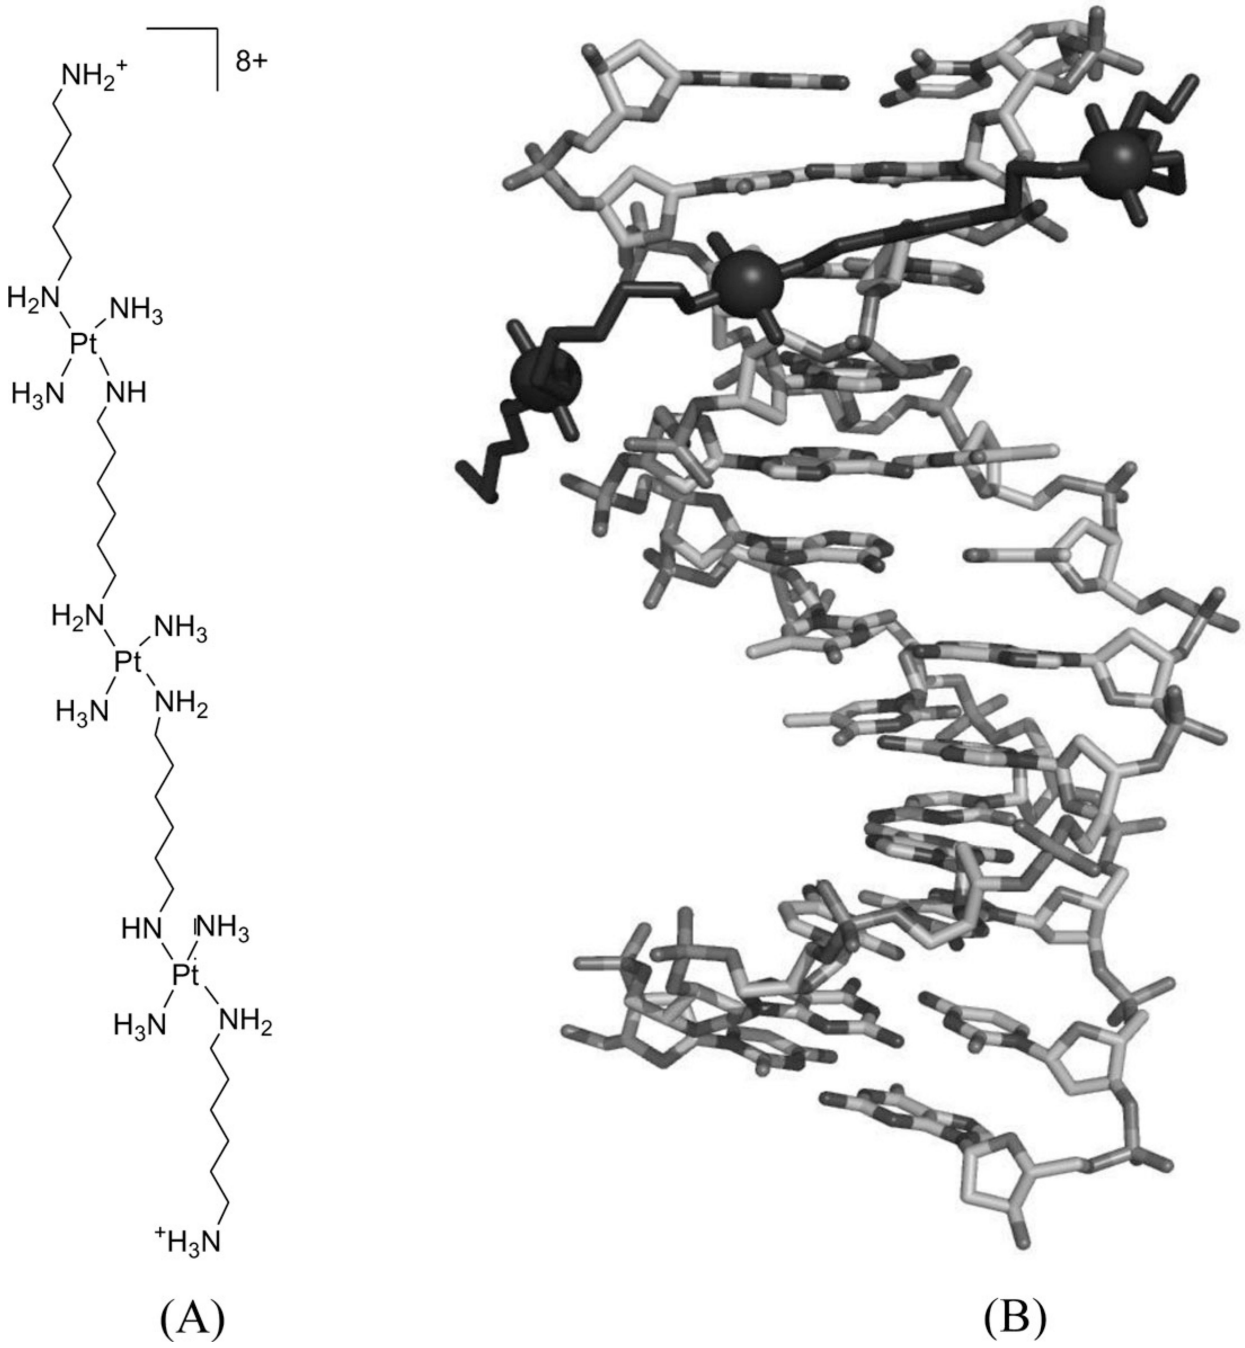

Figure 38.
(A) Chemical structure of triplatinNC. (B) Overall structure (PDB ID: 2DYW) of triplatinNC (darker sticks) bound to DNA duplex [d(5′-CGCGAATTCGCG-3′)$_2$]. The spheres represent the platinum atoms.

Table I

Summary of the DNA-Targeting Small Molecules as Drugs or Therapeutic Candidates

Entry	Name	Chemical structure	DNA sequences	PDB	Ref.
(A) Covalent binders					
1	Cisplatin		5′-CCTCTGGTCTCC-3′ 3′-GGAGACCAGAGG-5′	1AIO 3LPV	15, 16
2	Cisplatin		5′-CCUCTCTGGACCTTCC-3′ 3′-GGAGAGACCTGGAAGG-5′	1CKT	18
3	Cisplatin		5′-TCTTCTGTGCTCACCAC-3′ 5′-GTGGTGAGC-3′	2WTF	20
4	Nitrogen mustard		5′-(CGCGAATTCGCG)$_2$-3′	2QEF	25
5	Mitomycin C		5′-ICACGTCIT-3′ 3′-CGTGCAGCA-5′	199D	27
6	2,7-diaminomitosene		5′-(GTGGTATACCAC)$_2$-3′	1JOI	28
7	4′-(hydroxymethyl)-4,5′, 8-trimethylpsoralen		5′-(CCGGTACCGG)$_2$-3′	204D	29

Entry	Name	Chemical structure	DNA sequences	PDB	Ref.
8	AFB-FAPY		5′-CTATGATTCA-3′ 3′-GATACTAAGT-5′	2KH3	33
(B) Minor and major groove binders					
9	DAPI		5′-(CGCGAATTCGCG)$_2$-3′	1D30	52
10	Berenil		5′-(CGCGAATTCGCG)$_2$-3′	2DBE	54
11	Pentamidine		5′-(CGCGAATTCGCG)$_2$-3′	1D64	55
12	Hoechst 33258		5′-(CGCGAATTCGCG)$_2$-3′	8BNA	53
13	Netropsin		5′-(C$^{5\text{-Br}}$CCCIIII)$_2$-3′	358D	51
14	Distamycin		5′-d(GTATATAC)$_2$-3′	378D	55

Entry	Name	Chemical structure	DNA sequences	PDB	Ref.
15	8-ring cyclic Py-Im polyamide-α		5′-(CCAGGCCTGG)$_2$-3′	315L	66
16	8-ring cyclic Py-Im polyamide-β		5′-(CCAGTACTGG)$_2$-3′	3OMJ	70
17	KWKK		5′-GCTAGCGAGTCC-3′ 3′-CGATCGCTCAGG-5′	2KV6	76
18	Pentamidine		5′-(ATATATATAT)$_2$-3′	3EY0	78
19	Hoechst 33258		5′-(CGCGGATfUCGCG)$_2$-3′	3AJK	80
20	DB921		5′-(CGAATTCGCG)$_2$-3′	2B0K	84

Entry	Name	Chemical structure	DNA sequences	PDB	Ref.
21	DB1055		5′-(CGCGAATTCGCG)$_2$-3′	2I5A	85
22	Netropsin		5′-(CTTAATTCGAATTAAG)$_2$	1ZTT	86
23	CD27		5′-(CTTAATTCGAATTAAG)$_2$	3FSI	87
24	NCSi-gb		5′-CCCGATGC-3′ 3′-GGGCTTAACG-5′	1KVH	98
25	NCSi-glu		5′-(GCCAGAGAGC)$_2$-3′	1MP7	99

Entry	Name	Chemical structure	DNA sequences	PDB	Ref.
26	Neomycin-Hoechst-NH1		5′-(CGCAAATTTGCG)$_2$-3′	Model	103
27	Neomycin-Hoechst-NH2		5′-(CGCAAATTTGCG)$_2$-3′	Model	103
28	Neomycin-Hoechst-pyrene (NHP)		5′-(CGCAAATTTGCG)$_2$-3′	Model	104
(C) Intercalators					
29	Daunomycin		5′-(dC)(rG)d(ATCG)$_2$-3′	1D10	124
30	Adriamycin		5′-d(CGATCG)$_2$-3′	1D12	118

Entry	Name	Chemical structure	DNA sequences	PDB	Ref.
31	Ditercalinium		5′-d(CGCG)$_2$-3′	1D32	131
32	Echinomycin		5′-d(GCGTACGC)$_2$-3′	1PFE	140
33	Echinomycin		5′-(ACGTACGT)$_2$-3′	2ADW	141
34	Cryptolepine		5′-(CGTACG)$_2$-3′	1K9G	143

(D) Multimode binders

Entry	Name	Chemical structure	DNA sequences	PDB	Ref.
35	PBD-BIMZ		5′-(AACAATTGTT)$_2$-3′	2KTT	147
36	PDB-naphthalimide		5′-d(AACAATTGTT)$_2$-3′	2KY7	148
(E) Quadruplex binders					
37	Daunomycin		5′-d(TGGGGT)$_4$-3′	1O0K	163
38	Distamycin A		5′-d(TGGGGT)$_4$-3′	2JT7	166
(F) Bulge, junctions and phosphate backbone binders					
39	SCA-α2		5′-(CCATCGTCTACCTTTGGT AGGATGG)$_2$-3′	2OEY	99

Entry	Name	Chemical structure	DNA sequences	PDB	Ref.
40	DDI		5′-CACGCAGTTCGGAC-3′ 5′-GTCCGATGCGTG-3′	1P96	[171]
41	ent-DDI		5′-CACGCAGTTCGGAC-3′ 5′-GTCCGATGCGTG-3′	1R4E	[172]
42	$[Rh(bpy)_2chrysi]^{3+}$		5′-$(CGGAAATTCCCG)_2$-3′	2O1I	[173]
43	Naphtyridine-azaquinoline (NA)		5′-CTAACAGAATG-3′ 5′-CATTCAGTTAG-3′	1 × 26	[174]
44	NPM		5′-$(CGTACG)_2$-3′	2ET0	[174]

Entry	Name	Chemical structure	DNA sequences	PDB	Ref.
