We systematically investigate the structural, electronic, and magnetic properties of Mn_n clusters (n = 2-20) within the *ab initio* pseudopotential plane wave method using generalized gradient approximation for the exchange-correlation energy. A new kind of icosahedral structural growth has been predicted in the intermediate size range. Calculated magnetic moments show an excellent agreement with the Stern-Gerlach experiment. A transition from ferromagnetic to ferrimagnetic Mn-Mn coupling takes place at n=5 and the ferrimagnetic states continue to be the ground states for the entire size range. Possible presence of multiple isomers in the experimental beam has been argued. No signature of nonmetal to metal transition is observed in this size range and the coordination dependence of *d*-electron localization is discussed.

I. INTRODUCTION

The search for magnetic behavior in the transition metal clusters is motivated largely by the desire to understand how magnetic properties change in the reduced dimension. This is a question of considerable technological importance. Several unexpected magnetic orderings have already been reported in the reduced dimension. This ranges from the prediction of net magnetic moment in clusters of nonmagnetic (Rh, Ref. 1) or antiferromagnetic (Cr, Ref. 2 and Mn, Refs. 3 and 4) bulk materials to the enhancement in magnetic moment in clusters of ferromagnetic metals (Fe, Ref. 5 and Co, Ref. 6).

Manganese clusters are particularly interesting among all 3*d* transition metal elements due to the $4s^2$, $3d^5$ electronic configuration in Mn atoms. Because of the filled 4s and half-filled 3d shells and the large energy gap $\sim 8 \text{ eV}$ between these levels and as well as due to the high $4s^23d^5 \rightarrow 4s^{1}3d^6$ promotion energy of 2.14 eV,⁷ Mn atoms do not bind strongly. As a result, Mn₂ is a weakly bound van der Waals dimer with reported bond dissociation energy ranging from 0.1 ± 0.1 to 0.56 ± 0.26 eV depending upon the different method of analysis.⁸⁻¹¹ This weak Mn-Mn bonding has been demonstrated through the photodissociation experiments for Mn⁺_n ($n \leq 7$) cluster cations.^{11,12} Consequently, the bulk α -Mn, which has a very complex lattice structure with 58 atoms in the unit cell, has the lowest binding energy among all the 3*d* transition metal elements.

Magnetic properties of manganese clusters are rather unusual. According to Hund's rule, the half-filled localized 3*d* electrons give rise to large atomic magnetic moment of 5 μ_B . An early electron spin resonance (ESR) study suggested a magnetic moment of 5 μ_B /atom for very small Mn clusters.¹³ However, Stern-Gerlach (SG) molecular beam experiments on Mn_{5–99} clusters by Knickelbein recently revealed the net magnetic moments ranging from 0.4 to 1.7 μ_B /atom.^{3,4} This differs both from the ferromagnetic (FM) small clusters and from the antiferromagnetic (AFM) bulk α -Mn. This experimental results can be explained either way that the individual atomic moments are small and ordered ferromagnetically or the individual atomic moments remain large but their orientation flips from site to site, i.e., they are coupled ferrimagnetically. In the SG experiment, it is important to note the relative decrease in the magnetic moment for Mn_{13} and Mn_{19} , as well as the relatively very large experimental uncertainty in the measured magnetic moment for Mn_7 .^{3,4} In the present work, we will show that the local minima for Mn_{13} and Mn_{19} arise due to their "closed" icosahedral structures, whereas the large experimental uncertainty (±58% of the measured value) in the magnetic moment of Mn_7 is plausibly due to the production of different magnetic isomers (in addition with statistical fluctuation) in the subsequent measurements.

Earlier all electron (AE) studies¹⁴⁻¹⁶ found Mn-Mn FM ordering for Mn_n (n > 4) clusters, which, in turn, is not consistent with the SG experiment. However, Nayak et al. first predicted ferrimagnetic ground state for Mn₁₃ with a total magnetic moment of 33 μ_B .¹⁷ Consistent with the SG experiments, very recent AE studies by Parvanova et al.18,19 (n =2-9, 12, and 13) and Jones et al.²⁰ (n=5 and 6) reported ferrimagnetic ordering in Mn_n clusters. Briere *et al.*²¹ used ultrasoft pseudopotentials (US-PP) to study the intermediate size Mn_n clusters (n=13, 15, 19, and 23) and found icosahedral structural growth with an exception for Mn₁₅. However, their predicted magnetic moments differ widely from the experimental values. This might be attributed to the reason that the US-PP may not be appropriate in describing the transition metals with large magnetic moments. This will be discussed briefly later in Sec. II. Our main motivation of this work is particularly driven by the SG experiments.^{3,4} Here we shall investigate (i) the structural and magnetic evolution of Mn_n clusters, n=2-20; (ii) the sudden drop in the magnetic moment at n=13 and 19 and the very large experimental uncertainty in the measured magnetic moment for Mn_7 , and (iii) the possible presence of isomers with different magnetic structures in the SG experimental molecular beam.

It has also been found by Parks *et al.* that the Mn_n clusters show a downward discontinuity in their reaction rate with

molecular hydrogen at n=16, and this was attributed to nonmetal to metal transition in Mn_{16} .²² But if this is indeed true then there should be a downward decrease in the ionization potential too. However, no such abrupt decrease has been seen in the measured ionization potential.²³ In the present paper, we calculate both the spin gaps to investigate this issue.

II. COMPUTATIONAL DETAILS

The calculations are performed using density functional theory (DFT), within the pseudopotential plane wave method. We have used projector augmented wave (PAW) method^{24,25} and Perdew-Bruke-Ernzerhof exchange-correlation functional²⁶ for spin-polarized generalized gradient correction (GGA) as implemented in the Vienna ab initio Simulation Package (VASP).²⁷ The 3d and 4s electrons are treated as valence electrons and the wave functions are expanded in the plane wave basis set with the kinetic energy cut-off 337.3 eV. Reciprocal space integrations are carried out at the Γ point. Symmetry unrestricted geometry and spin optimizations are performed using conjugate gradient and quasi-Newtonian methods until all the force components are less than a threshold value 0.005 eV/Å. Simple cubic supercells are used with the periodic boundary conditions, where two neighboring clusters are kept separated by at least 12 Å vacuum space. For each size, several initial geometrical structures have been considered. To get the ground state magnetic moment we have explicitly considered all possible spin configurations for each geometrical structure. For transition metals with large magnetic moments, the PAW method seems to be more appropriate (as good as the AE calculations) than the US-PP approach.²⁵ The US-PP overestimates the magnetization energies and this overestimation is even larger for GGA calculations than local spin density approximation (LSDA). This is due to the fact that the GGA functionals are more sensitive to the shape of the wave functions than the LSDA functionals. However, the difference between these two methods, US-PP and PAW, is solely related to the pseudization of the augmentation charges in the US-PP approach, which can be removed by choosing very accurate pseudized augmentation function, which is then computationally expensive. For a better description see Ref. 25 by Kresse and Joubert.

The binding energy per atom is calculated as

$$E_b(\mathrm{Mn}_n) = \frac{1}{n} [E(\mathrm{Mn}_n) - nE(\mathrm{Mn})], \qquad (1)$$

n being the size of the cluster. The local magnetic moment \mathcal{M} at each site can be calculated as

$$\mathcal{M} = \int_0^R \left[\rho^{\uparrow}(\mathbf{r}) - \rho^{\downarrow}(\mathbf{r}) \right] d\mathbf{r}, \qquad (2)$$

where $\rho^{\uparrow}(\mathbf{r})$ and $\rho^{\downarrow}(\mathbf{r})$ are spin-up and spin-down charge densities, respectively, and *R* is the radius of the sphere centering the atom. For a particular cluster, *R* is taken such that no two spheres overlap i.e., *R* is equal to the half of the shortest bond length in that cluster.

III. RESULTS AND DISCUSSIONS

A. Small ferromagnetic clusters (Mn₂-Mn₄)

The Mn₂ dimer is the most controversial among all the sizes we have studied. Experiments based on resonance Raman spectroscopy²⁸ and ESR²⁹ observed an AFM ground state with a bond length 3.17 Å. Experimentally the binding energy was estimated to be 0.44±0.30 eV/atom.⁸⁻¹⁰ However, previous AE-DFT calculations,^{14,16,18,19} predicted a FM state to be the ground state with much smaller bond length $(\sim 2.60 \text{ A})$ than that of the experimental value. In agreement with these calculations, our present PAW pseudopotential calculations with PBE exchange-correlation functionals predict a FM ground state with total spin 10 μ_B and with bond length 2.58 Å. Very small binding energy, 0.52 eV/atom, is essentially the characteristic of a van der Waals system. However, the bond dissociation energy increases by a considerable amount due to the reduction of one electron from the Mn_2 dimer, i.e., by creating a hole in the 4s level. As measured by the photodissociation experiment the bond dissociation ($Mn^+ \cdots Mn$) energy increases to 1.39 eV for Mn_2^+ cation.³⁰ We find that the bond length of Mn₂ decreases monotonically as the net moment decreases. This is consistent with the physical picture that the reduction of the interatomic spacing leads to comparatively stronger overlap of the atomic orbitals which, in turn, reduces the magnetic moment. However, we find Mn₂ with total moment 4 and 6 μ_B are not bound. An AF Mn₂ is 0.52 eV higher in energy with bond length 2.61 Å. The present results, along with the previous AE-DFT calculations,^{14,16,18,19} do not agree with the experimental results. This might be attributed to the fact that the density functional theory is not adequate in treating van der Waals interaction properly. However, there are no experimental results available in the gas phase Mn₂ dimer and the ESR experiment was done in a rare gas matrix. Therefore, it is possible that the Mn atoms do interact with the matrix, which could stretch the bond length and could lead to the observed AFM state.

The case of Mn₃ is extremely interesting as it could have either FM or a frustrated AFM structure. We have studied triangular and linear structures. An equilateral triangular FM state with total moment 15 μ_B is found to be the ground state with bond lengths 2.74 Å and binding energy 0.82 eV/atom. The frustrated AFM state with total moment 5 μ_B is found to be nearly degenerate with the FM ground state (lies only 0.05 eV higher in energy). This has an isosceles triangular structure with one long and two short bond lengths of 2.50 and 2.45 Å, respectively (Fig. 1). The resonance Raman spectra studies by Bier *et al.*²⁸ suggest the ground state to be the Jahn-Teller distorted D_{3h} structure with an odd integer magnetic moment.

For the Mn₄ cluster, we examined three different conformations: square, rhombus, and tetrahedron. A perfect tetrahedral structure with bond lengths 2.7 Å and binding energy 1.18 eV/atom is the ground state, where Mn-Mn coupling is FM with total moment 20 μ_B (Fig. 1). Three isomers are found and all of them are tetrahedral. A ferrimagnetic state with total moment 10 μ_B is only 0.08 eV higher in energy. Another ferrimagnetic state with total moment 8 μ_B is found STRUCTURE, ELECTRONIC PROPERTIES, AND ...

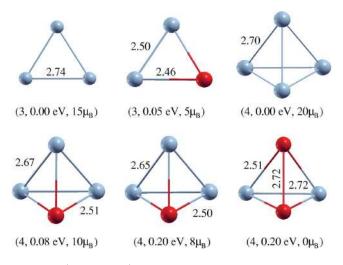

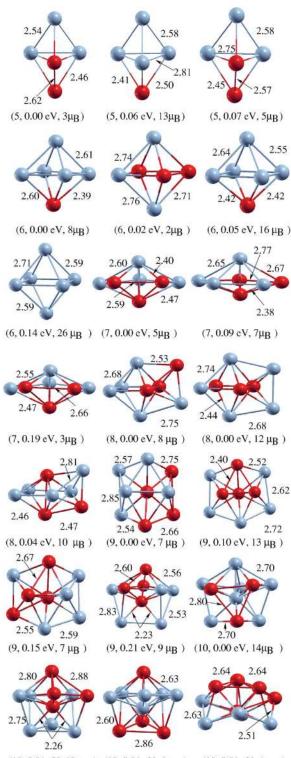

FIG. 1. (Color online) Atomic spin ordering of the ground state and low-lying isomers for Mn_3 and Mn_4 clusters. Numbers in parentheses represent the number of atoms in the cluster, relative energy to the ground state, and total magnetic moment, respectively. Bond lengths are given in Å. Blue (gray) color represents up or positive and red (dark gray) represents down or negative magnetic moment. We will follow the same convention throughout.

to be degenerate with the AF state with no net moment and they are 0.20 eV higher in energy. In all these optimal structures the distances between two similar spins $(d_{\uparrow\uparrow} \text{ or } d_{\downarrow\downarrow})$ are larger than those of between two opposite spins $(d_{\uparrow\downarrow})$. Our results are consistent with the previous AE calculations.^{14,16,18,19} Ludwig *et al.*³¹ have studied Mn₄ in solid silicon and observed a 21-line hyperfine pattern that not only establishes the four atoms to be equivalent, but also the total moment to be 20 μ_B . However, the present results cannot directly be compared with this experiment because of possible Si-Mn interaction and there is no available report of magnetic ordering for Mn₄ in its gas phase.

B. Mn₅-Mn₁₀

As the number of atoms in the cluster (n) increases the determination of the structural and magnetic ground state becomes a very delicate task as the number of local minima in the corresponding potential energy surface increases exponentially with *n*. Therefore, more than one geometric and/or magnetic structures of comparable stability are possible. In Fig. 2 we depict the atomic and magnetic structures for the ground state as well as for the closely lying isomers for the size range n=5-10. As mentioned earlier, to hit the ground state more reliably, we have studied *all possible* spin multiplicities for several geometric structures for a particular cluster size *n*. Calculated binding energies, relative energies, magnetic moments, and two spin gaps are given in Table I for the entire size range n=2-20.

For the Mn₅ cluster, a square pyramid and a triangular bi-pyramid (TBP) were studied. Transition in the magnetic order, from FM to ferrimagnetic, is found. A ferrimagnetic TBP is found to be the ground state with total spin 3 μ_B . The next two isomers are also ferrimagnetic in nature with total spins 13 μ_B and 5 μ_B . Both of these structures also have

 $(10, 0.01 \text{ eV}, 10\mu\text{B})$ $(10, 0.01 \text{ eV}, 4\mu\text{B})$ $(10, 0.01 \text{ eV}, 4\mu\text{B})$

FIG. 2. (Color online) Atomic spin ordering of the ground and isomeric geometries for n=5-10. The same ordering has been followed as in Table I.

TBP structure and lie 0.06 and 0.07 eV, respectively, higher in energy. The next lowest energy arrangement is FM and also has a TBP structure with total spin 23 μ_B and lies 0.19 eV higher in energy. Our results are in agreement with the very recent AE calculations.^{18–20} However, previously the

FM ground state was predicted by both Nayak *et al.*^{14,15} and Pederson *et al.*¹⁶ In the recent SG experiment,⁴ magnetic moment was found to be $0.79\pm0.25 \ \mu_B$ /atom, which is very close to our predicted value 0.60 μ_B /atom for the ground state.

We have investigated both the octahedral and the capped trigonal bi-pyramid for Mn_6 cluster. A ferrimagnetic octahedral structure with total spin 8 μ_B is found to be the ground state with binding energy 1.57 eV/atom. Another octahedral ferrimagnetic isomer with total moment 2 μ_B is nearly degenerate (0.02 eV higher in energy). The next isomer is also a ferrimagnetic octahedra, which possesses a total moment of

16 μ_B and lies 0.05 eV higher. The next favorable isomer is FM and has a total moment 26 μ_B and is 0.14 eV higher than the ground state. In an earlier calculation, Pederson *et al.*¹⁶ predicted a FM octahedral structure with moment 4.33 μ_B /atom to be the ground state. However, in agreement with the recent AE-DFT calculations,^{18–20} present calculation predicts the same ground state and isomers. Experimentally measured magnetic moment 0.55±0.10 μ_B /atom⁴ lies between that of our predicted ground state, 1.33 μ_B /atom and the first isomer, 0.33 μ_B /atom, which are almost degenerate. It is possible that in the SG experimental beam, multiple isomers were produced such that the measured value is al-

We have considered pentagonal bi-pyramid (PBP), capped octahedron and bi-capped trigonal pyramid as the possible candidates for the ground state of Mn₇. The most stable configuration is a PBP structure with ferrimagnetic spin ordering, which has a total moment 5 μ_B . The next two closest isomers also have ferrimagnetic arrangements with 7 μ_B and 3 μ_B total moments and they lie 0.09 and 0.20 eV higher than the ground state, respectively. Our ground state magnetic moment agrees with the earlier calculations,18,19,32 though we predict isomers with different spin arrangements. However, Pederson et al. predicted a FM ground state.¹⁶ Present ground state magnetic moment per atom exactly matches with the experimental value, $0.72 \pm 0.42 \ \mu_{B}/\text{atom}^{2}$ We would like to note the rather large uncertainty here. We argue that the plausible presence of these isomers, with total moments 7 μ_B and 3 μ_B along with the ground state (5 μ_B), in the SG beam might lead to this high uncertainty in the measured value.

Motivated by our earlier study on Cu₈,^{33,34} we investigated three different geometries for Mn₈, viz., capped pentagonal bi-pyramid (CPBP), bi-capped octahedron (BCO), and tri-capped trigonal bi-pyramid (TCTBP). The BCO structure with total moments 8 μ_B and 12 μ_B are found to be degenerate ground state. Another BCO structure with total moment 10 μ_B lies only 0.03 eV higher in energy. The SG cluster beam experiment has reported a magnetic moment of $1.04 \pm 0.14 \ \mu_{B}/\text{atom}^{4}$, which is nearly an average of our predicted values. Therefore, our present DFT study together with the experiment in turn indicate the possible presence of these three isomers in the experimental beam with almost equal statistical weight. The optimal CPBP and TCTBP structures have total moments 14 μ_B and 12 μ_B , respectively, and they lie 0.31 and 0.4 eV higher than the ground state. Parvanova et al.¹⁹ found CPBP structure to be the most stable, however, their predicted magnetic moment is very small, 4 μ_B , compared to both of our values and the SG experiment. Pederson et al.16 predicted a FM BCO structure with moment 32 μ_B as the ground state. The optimal FM structure for all three geometrical structures have total moment 32 μ_B and lie 1.01, 0.63, and 1.17 eV higher in energy compared to their respective optimal ferrimagnetic structure, respectively, for BCO, CPBP and TCTBP structures.

For the Mn₉ cluster, as initial configuration we took three stable isomers found for Cu_0 (Refs. 33 and 34) and a capped and a centered antiprism structure. The optimal structure is a centered antiprism structure with total moment 7 μ_B , which is in very good agreement with the experimental value $1.01\pm0.10~\mu_{B}/atom.^{4}$ The local magnetic moment \mathcal{M} [as calculated from Eq. (2)] shows strong environment dependency due to the anisotropy in bonding. The \mathcal{M} of the highly coordinated central atom is very small, $-0.22 \mu_B$, whereas those of the surface atoms are quite high and lie between 3.45 and 3.75 μ_B . Parvanova *et al.*¹⁹ have found a similar structure but with different spin configuration with total moment 9 μ_B to be the optimal structure. The next two isomers have the same geometry and have 13 and 7 μ_B total magnetic moment (Fig. 2 and Table I). The next isomer is a bi-capped pentagonal bi-pyramid, which lies 0.21 eV higher with a total moment of 9 μ_B . The optimal capped antiprism structure lies 0.23 eV higher and has a total moment of 7 μ_B . Note that all these structures have 5 spin-up (N_{\uparrow}) atoms and 4 spin-down (N_{\downarrow}) atoms.

Different tricapped pentagonal bi-pyramidal structures along with different tetra capped octahedral structures were tried as initial structures for Mn_{10} . Four isomers exist with almost the same energy. They lie within ~0.01 eV energy (see Table I and Fig. 3). All of these have a pentagonal ring and could be derived by removing 3 atoms from a 13-atom icosahedra. Ground state has a total magnetic moment 14 μ_B , which is very close to the SG experimental value, $1.34\pm0.09 \mu_B/atom.^4$

C. Intermediate size clusters: Mn₁₁-Mn₂₀

All the intermediate sized clusters with n=11-20 are found to adopt an icosahedral growth pattern. The ground state structures and the few isomers along with their corresponding spin arrangements are shown in Fig. 3. An icosahedral structure without one apex atom is found to be the ground state for the Mn₁₂ cluster. This structure has $N_{\uparrow}=8$ and $N_{\downarrow}=4$ spin configuration with a total moment of 16 μ_B . This value is close to the experimentally measured value of $1.72\pm0.04 \ \mu_B/\text{atom}$.^{3,4} Recently Parvanova *et al.* predicted the same geometrical structure but with comparatively smaller, 1 μ_B/atom , magnetic moment.¹⁹ We have found two closely lying isomers, which have the same geometrical structure with total moments 4 μ_B and 18 μ_B (Table I). Another possible icosahedral structure without the central atom lies much higher in energy.

The obvious candidates for the Mn₁₃ cluster are the icosahedral, hexagonal close packed (hcp) and cuboctahedral structures. The variation of total energy as a function of the total magnetic moment is plotted in Fig. 4 for all three conformations. The icosahedral structure is found to be the ground state with $N_{\uparrow}=7$ spin structure. The two pentagonal rings are AFM coupled for this structure (Fig. 3). Consequently, the magnetic moment is found to be small, 0.23 μ_B /atom. This predicted magnetic moment is much smaller than those of its neighboring Mn₁₂ and Mn₁₄ clusters (Fig. 6), which has been indeed predicted by the SG experiment.^{3,4} The present value is much lower than the experimental value of $0.54 \pm 0.06 \ \mu_{B}/\text{atom.}^{4}$ However, we have found another icosahedral isomer with magnetic moment exactly the same with the experimental value, which lies only 0.08 eV higher in energy (Table I). This structure also has N_{\uparrow} =7. Recently, Parvanova *et al.* predicted similar magnetic ordering.¹⁹ The optimal hcp and cuboctahedral structures (Fig. 3) have relatively higher magnetic moments 9 μ_B (N_{\uparrow} =7) and 11 μ_B (N_{\uparrow} =8), respectively, and they lie much higher in energy, 0.89 and 1.12 eV, respectively. Nayak et al. first predicted a ferrimagnetic state for Mn₁₃. However, their predicted magnetic moment is quite high (33 μ_B): all the surface atoms are antiferromagnetically coupled with the central atom.¹⁷

The ground state of Mn₁₄ is the first complete icosahedra with a single atom capping. This structure has $N_{\uparrow}=9$, with a magnetic moment 1.29 μ_B /atom. In this structure the magnetic coupling between the two pentagonal rings is FM,

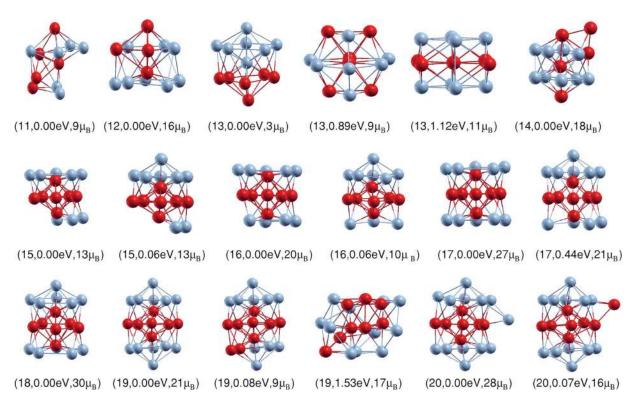

FIG. 3. (Color online) The ground state and a few higher energy structures for the size range n=11-20. Note the grouping of the same kind of spins.

which was coupled antiferromagnetically in the case of Mn_{13} and consequently, it has small magnetic moment. The next two isomers lie very close to the ground state: they lie only 0.02 and 0.05 eV higher and have 1.43 and 1.57 μ_B /atom magnetic moment, respectively. These two isomers (not shown in Fig. 3) have the same $N_{\uparrow}=9$ spin structure, but with their different positional arrangement. The experimentally predicted magnetic moment, 1.48±0.03 μ_B /atom, is an average of the ground state and the two isomers (Table I), which again indicates that these isomers might be produced along with the ground state in the SG experiment.

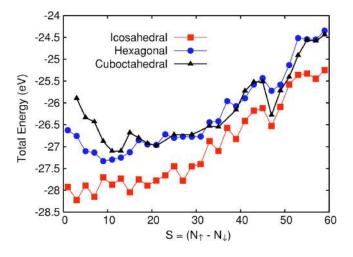

FIG. 4. (Color online) Plot of the total energy as a function of total magnetic moment $S(=N_{\uparrow}-N_{\downarrow})$ for icosahedral, hexagonal closed pack, and cuboctahedral conformations for Mn₁₃ cluster.

The discrepancy between the present theoretical and experimental magnetic moment is rather large for Mn₁₅. The present value is 0.87 μ_B /atom, whereas the corresponding experimental value is $1.66 \pm 0.02 \ \mu_B$ /atom. We have also found several isomers (Table I), but none of them are close to the experimental value. The ground state and all the closely lying isomers within ~ 0.1 eV energy spacing are of derived icosahedral structure. The two competing icosahedral structures with 5,1,5,1,3 and 1,5,1,5,1,2 staking (i.e., without or with the apex atom) are possible (Fig. 3). The first kind of structure is found to be the ground state, whereas the optimal structure for the second kind lies 0.06 eV higher with a magnetic moment 13 μ_B (Fig. 3). Another structure of the second kind is found to be degenerate with this isomer, which has a magnetic moment 7 μ_B (Table I). However, using US-PP Briere *et al.* found a bcc structure to be the ground state with much smaller magnetic moment, 0.20 μ_B /atom.²¹ In the present case this bcc kind of structure lies 0.28 eV higher (Table I).

The same structural trend is observed in the case of Mn_{16} , the two different competing geometries have been found to be the possible candidates for the Mn_{16} cluster. Both of these structures can be derived from the 19-atom double icosahedra, which has a 1,5,1,5,1,5,1-atomic staking. The ground state has a magnetic moment 1.25 μ_B /atom with $N_{\uparrow}=9$ spin structure. This structure has 5,1,5,1,4-atomic staking: both the apex atoms and one atom from the lower pentagonal ring are missing from the double icosahedra. The next isomer has the same atomic arrangement and is almost degenerate, which lies only 0.02 eV higher. This has 1.38 μ_B /atom magnetic moment and the same ($N_{\uparrow}=9$) spin ordering. For both of these structures the central pentagonal ring is antiferromagnetically coupled with the upper and lower (incomplete) pentagonal ring. The experimentally predicted value, $1.58\pm0.02 \mu_B$,^{3,4} is very close to these predicted values and confirms the corresponding ground state to be really of this "strange" staking. The next two isomers have a different icosahedral geometry and have comparatively smaller magnetic moment, 0.63 (Fig. 3) and 0.50 μ_B /atom. They lie 0.06 and 0.1 eV higher, respectively. Both of them have 1,5,1,5,1,3 staking, i.e., the 13-atom icosahedra is complete. The two complete pentagonal rings are antiferromagnetically coupled. All these structures have the same number of N_{\uparrow} and N_{\downarrow} but have two different classes of atomic arrangements, which is consequently the reason for their large difference in the magnetic moment.

The Mn₁₇ cluster follows the same structural trend seen in both Mn₁₅ and Mn₁₆. The ground state is a double icosahedra without both the apex atoms, i.e., it has 5,1,5,1,5 staking. The spin structure is N_{\uparrow} =10 and the central pentagonal ring is AFM coupled with the other rings. This structure has a magnetic moment of 1.59 μ_B /atom, which is in excellent agreement with the experiment, 1.44±0.02 μ_B /atom.⁴ The next two isomers also have the same conformation as well as the same spin structure. For this size the structure of the second kind, i.e., the icosahedral structure with one apex atom (Fig. 3) lies rather higher in energy. To our knowledge, there is no available report for any other elements where this kind of staking has been observed to be the ground state for Mn₁₅-Mn₁₇ clusters.

The Mn₁₈ is the 19-atom double icosahedra without one apex atom. The predicted magnetic moment is 1.67 μ_B /atom, whereas the experimental value is slightly smaller, 1.20±0.02 μ_B /atom.⁴ Next two isomers are nearly degenerate and have 1.56 and 1.44 μ_B /atom magnetic moment (Table I). For all these structures the integrated magnetization densities \mathcal{M} for the central pentagonal bi-pyramid are negative (Fig. 3).

The double icosahedral conformation is found to be the ground state for Mn₁₉. The predicted magnetic moment is 1.10 μ_B /atom (Fig. 3), which is smaller than those of its neighboring clusters, which has been predicted by the experiment.^{3,4} Another magnetic structure has been found to be degenerate with 1 μ_B /atom magnetic moment (not shown in Fig. 3). Both of the structures have $N_{\downarrow}=7$ and the central pentagonal ring is AFM coupled with the other two rings. However, the predicted magnetic moment is larger than the experimentally measured value, $0.41\pm0.04 \mu_B$ /atom.⁴ In our case a magnetic structure with a magnetic moment $0.47 \mu_B$ /atom ($N_{\downarrow}=9$), which is very close to the experimentally measured value, lies only 0.08 eV higher in energy (Fig. 3). The optimal fcc structure lies much higher, 1.53 eV, in energy, which is shown in Fig. 3.

Two degenerate ground states have been found with 1.40 and 1.50 μ_B /atom magnetic moment for Mn₂₀ cluster. Both the structures have $N_{\downarrow}=7$ (Fig. 3) spin configuration and the conformation can be seen as a singly capped 19-atom double icosahedra. The central pentagonal ring is antiferromagnetically coupled with the other two rings. The predicted ground state magnetic moment is larger than the experimental value, $0.93\pm0.03 \mu_B$ /atom.⁴ However, a different spin structure

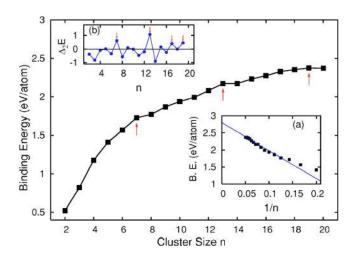

FIG. 5. (Color online) Plot of binding energy per atom as a function of cluster size *n* for the entire size range $2 \le n \le 20$. (a) Plot of the same as a function of 1/n for the ferrimagnetic clusters, $5 \le n \le 20$ and a linear fit [B.E.=-8.20(1/n)+2.80] to the data. (b) Plot of second difference, $\Delta_2 E$ in energy, which represents the relative stability.

 $(N \downarrow = 8)$ with magnetic moment 0.80 μ_B /atom, which is close to the experimentally predicted value, lies only 0.07 eV higher (Fig. 3).

In the intermediate size range, the grouping of like spin atoms, i.e., spin segregation occurs (Fig. 3). For a particular sized cluster, we find that the ferromagnetically aligned atoms have longer average bond lengths³⁵ than those of the antiferromagnetically aligned ones. This is because of the Pauli repulsion.

D. Binding energies

The size dependence of the ground state binding energy for Mn_n clusters (n=2-20) is shown in Fig. 5. Due to the lack of hybridization between the half-filled 3d and filled 4s states and due to high $4s^23d^5 \rightarrow 4s^13d^6$ promotion energy, the Mn₂ dimer is a weakly bound dimer, which is a characteristic of van der Waals bonding.⁸⁻¹⁰ As the number of atoms in the cluster increases, the binding energy increases monotonically due to the increase in the *s*-*d* hybridization. However, it remains weak as compared to the other transition metal clusters in the same size range. This weak bonding has been demonstrated through the photodissociation experiments for Mn_n^+ ($n \le 7$) cluster cations.^{11,12} Recently, we have shown³⁶ that if an As atom is doped to the Mn_n clusters, the binding energies of the resultant Mn_nAs clusters increase substantially due to their hybridized s-d electrons bond with the pelectrons of As. Similar enhancement in bonding has also been seen due to the single nitrogen doping.³⁷

Upon extrapolation of the linear fit to the binding energy per atom data to $1/n \rightarrow 0$ [Fig. 5(a)], we obtained the binding energy for an infinitely large cluster as 2.80 eV, which is very close to the experimental AF bulk α -Mn (2.92 eV). It is important here to note the kinks observed at n=7 and 13 in the binding energy curve (Fig. 5). These kinks represent enhanced stability rendered by their "closed" geometric struc-

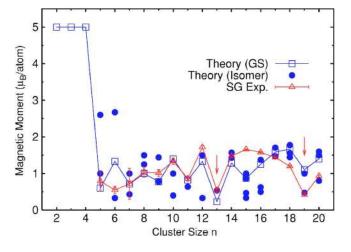

FIG. 6. (Color online) Size dependent variation of magnetic moment. For the size range $5 \le x \le 20$, it shows excellent agreement with the SG experiment. Isomers which lie very close to the corresponding GS energy are also shown.

tures: Mn₇ is PBP and Mn₁₃ is the first complete icosahedra. If this argument is valid then there should also be a kink at n=19, due to the fact it has double icosahedral structure. But we do not see any prominent kink in the binding energy curve. So, it will be interesting to investigate the second difference in the binding energy, $\Delta_2 E(n) = E(n+1) + E(n-1) - 2E(n)$, where E(n) represents the total energy of an *n*-atom cluster. As $\Delta_2 E(n)$ represents stability of the corresponding cluster compared to its neighbors, the effect will be prominent. $\Delta_2 E$ is plotted in Fig. 5(b), where we see a peak for Mn₁₉ too along with n=7 and 13. However, in addition, without any *a priori* reason, we observe another peak at n = 17, which does not have closed structure (a double icosahedra without two apex atoms).

E. Transition in magnetic ordering

For very small clusters, $n \leq 4$, the magnetic coupling is found to be FM with magnetic moments 5 μ_B /atom, which is the Hund's rule value for an isolated Mn atom. We see that for Mn₂ cluster the FM solution is nearly degenerate with the frustrated AFM solution. The size dependence of the magnetic moment per atom is plotted in Fig. 6. We see the transition in the magnetic coupling (from FM to ferrimagnetic) takes place at n=5 and the ferrimagnetic states continue to be the ground state for the entire size range n=5-20. Figure 6 shows a very good agreement between experimentally measured and our predicted magnetic moments. It was seen in the SG experiment that the experimental uncertainty in measuring the magnetic moment decreases with the cluster size. However, this is not the case for Mn₇, for which the measured uncertainty is quite large (0.72±0.42 μ_{B} , ±58% of the measured value) as compared to the neighboring sizes. This large uncertainty might arise from the presence of isomers with different magnetic moments in the SG beam for subsequent measurements. However, in addition to the statistical fluctuation, the above explanation only stands for a plausible reason as for all other sizes we did find many iso-

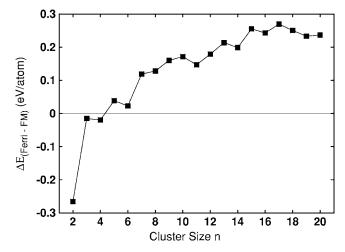

FIG. 7. Plot of $\Delta E_{(\text{Ferri-FM})}$ as a function of cluster size *n*.

mers with different magnetic moments (see Table I and Fig. 6), but the corresponding experimental uncertainty is not that large. Another striking feature observed in the experiment is the sudden decrease in the magnetic moment at n=13 and 19, compared to their neighbors. Our calculation reproduces this feature. This is attributed to their closed icosahedral structures: first complete icosahedra for Mn₁₃ and a double icosahedra for Mn₁₉. The other geometries studied viz., hexagonal closed packed and cuboctahedral structures for Mn₁₃ and a fcc structure for Mn₁₉ lie much higher in energy, 0.89 eV (9 μ_B), 1.12 eV (11 μ_B) and 1.53 eV (17 μ_B), respectively, than their corresponding ground state.

In Fig. 6 we have depicted the magnetic moments of the very closely lying isomers with their ground state (see Table I) and while comparing those with the experimentally observed values, we come to the conclusion that for a particular size of cluster, the isomers with different magnetic moments are likely to be present in the SG cluster beam with a statistical weight and essentially, the measured moment is the weighted average of those isomers. We calculate the energy difference between the optimal FM and optimal ferrimagnetic solutions, $\Delta E_{(\text{Ferri-FM})} = E(\text{Ferri}) - E(\text{FM})$, and plot them as a function of cluster size n in Fig. 7. For both Mn₃ and Mn₄ the FM solutions are slightly lower in energy than those of their respective optimal ferrimagnetic solutions, whereas the optimal FM solutions are slightly higher than the corresponding ferrimagnetic ground states for Mn₅ and Mn₆. Thereafter, as the cluster size increases, this energy difference, $\Delta E_{(\text{Ferri-FM})}$, increases almost monotonically indicating that the optimal FM solutions become more and more unlikely. All these optimal FM states have $\sim 4 \mu_B$ /atom magnetic moments.

F. Coordination and the *d*-electron localization

The angular momentum projected local density of states (LDOS) show interesting site dependency. The *s*-, *p*-, and *d*-projected LDOS for the central and surface atoms are plotted in Fig. 8 for the Mn_{13} and Mn_{19} clusters. We see only *d*-projected LDOS are significant and are of great interest here. The *d*-projected LDOS of both Mn_{13} and Mn_{19} for the

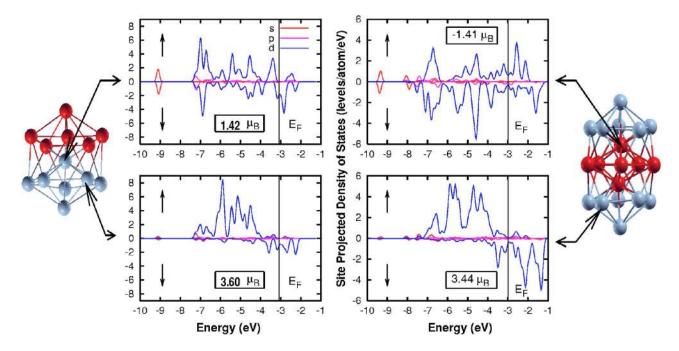

FIG. 8. (Color online) The *s*-, *p*-, and *d*-projected density of states for the central and surface atoms for Mn_{13} and Mn_{19} in their ground state. Gaussian broadening of half-width 0.1 eV has been used. Integrated magnetization density \mathcal{M} for each atom is given in the box.

central atoms are broad for both majority and minority spin states, which are also reflected through their small values of the integrated spin densities \mathcal{M} (1.42 and -1.41 μ_B for Mn₁₃ and Mn₁₉, respectively). The broadening occurs due to the high coordination of the central atom. On the other hand, the *d*-projected LDOS of the surface atoms are rather localized and the majority spins are nearly fully occupied, which is in agreement with the relatively large local magnetic moments of the surface atoms (3.60 and 3.44 μ_B for Mn₁₃ and Mn₁₉, respectively).

G. Spin gaps: Nonmetal-metal transition?

A spin arrangement in any magnetic clusters is magnetically stable only if both the spin gaps,

$$\delta_{1} = -\left[\epsilon_{\text{HOMO}}^{\text{majority}} - \epsilon_{\text{LUMO}}^{\text{minority}}\right], \quad \delta_{2} = -\left[\epsilon_{\text{HOMO}}^{\text{minority}} - \epsilon_{\text{LUMO}}^{\text{majority}}\right], \tag{3}$$

are positive, i.e., the lowest unoccupied molecular orbital (LUMO) of the majority spin lies above the highest occupied molecular orbital (HOMO) of the minority spin and vice versa. We find these two spin gaps to be positive for all the clusters (Table I) discussed here and are plotted in Fig. 9. δ_1 and δ_2 have local structures, but generally decreases slowly as the coordination increases with cluster size. Parks *et al.* found that the Mn_n clusters with $n \le 15$ are not reactive toward molecular hydrogen, whereas they form stable hydrides at and above n=16, and the reaction rate varies considerably with the cluster size.²² They argued it to be attributed from

the nonmetal to metal transition at n=16. If this is indeed the reason, it is likely that the ionization potential would show a significant decrease at Mn₁₆, similar to what has been observed for free mercury clusters.³⁸ Therefore, we expect closing up of the spin gaps at n=16. However, Koretsky *et al.* observed no sudden decrease in the measured ionization potential²³ and we do not find any spin gap closing at Mn₁₆ either. The spin gaps have reasonable value, $\delta_1=0.33$ eV and $\delta_2=0.22$ eV for Mn₁₆ cluster (Fig. 9 and Table I). This abrupt change in the reaction rate with H₂ at Mn₁₆ is not due to any structural change either, as we find that all the medium sized clusters adopt icosahedral growth pattern and the reason for the observed change in the reaction rate remains unknown.

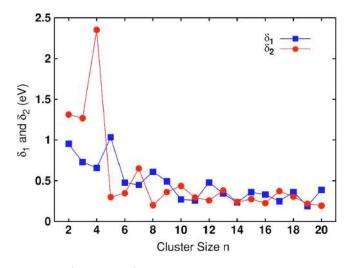

FIG. 9. (Color online) Plot of spin gaps as a function of cluster size n. See Table I for the numerical values.

IV. SUMMARY AND CONCLUSIONS

We have systematically investigated the structural, electronic, and magnetic properties of Mn_n (n=2-20) clusters from the first-principles density functional theory. An extensive search has been made to locate the global minima. Due to the intrinsic $4s^2 3d^5$ electronic structure and high $4s^23d^5$ $\rightarrow 4s^{1}3d^{6}$ promotion energy Mn atoms do not bind strongly when they come closer to form a cluster. However, binding energy increases with the cluster size as the coordination number increases and reaches a value 2.37 eV/atom for Mn_{20} , which is 81% of the bulk value. A magnetic transition from FM to ferrimagnetic ordering takes place at n=5 and thereafter the energy difference between the optimal ferrimagnetic and optimal FM structure increases with the cluster size, which indicates that the optimal FM states become more and more unfavorable with increasing cluster size. However, different ferrimagnetic states are possible within a small $\sim 0.1 \text{ eV}$ energy difference and their plausible presence in the experimental SG beam along with the ground state has been argued. The predicted magnetic moments are in agreement with the SG experiment. The sudden decrease in the magnetic moment at n=13 and 19 is due to their closed icosahedral structure. It should be pointed out here that in the present calculation we assumed only collinear alignment of spins. However, spin canting or noncollinear magnetic ordering is possible in small magnetic clusters as it occurs more easily in a low symmetry magnetic system.³⁶ Icosahedral growth pattern is observed for the intermediate size range. However, to our knowledge, a different kind of icosahedral packing has been observed for Mn_{15} - Mn_{17} clusters. In any particular cluster, the average bond length between antiferromagnetically aligned atoms is 3–8% shorter than that of the ferromagnetically aligned, which can be explained in terms of the Pauli repulsion. Spin segregation has been observed in the intermediate size range. The *d*-electron localization strongly depends on coordination: localization decreases with the coordination number. There is no signature of nonmetal to metal transition at n=16, which has been predicted²² through the downward discontinuity observed in the reaction rate with H₂.
