111 Abstract

112

113 Background

- 114 WHO documents characterize stunting as, "...impaired growth and development that children
- 115 experience from poor nutrition, repeated infection, and inadequate psychosocial stimulation." The
- equation of stunting with malnutrition is common. This contrasts with historic and modern observations
- 117 indicating that growth in height is largely independent of the extent and nature of the diet.

118

119 Subjects

We measured 1716 Indonesian children, aged 6.0-13.2 years, from urban Kupang/West-Timor and
 rural Soe/West-Timor, urban Ubud/Bali, and rural Marbau/North Sumatra. We clinically assessed

122 signs of malnutrition and skin infections.

123

124 Results

125 There was no relevant correlation between nutritional status (indicated by skinfold thickness) and 126 height SDS (hSDS). 53% of boys, and 46% girls in rural Soe were short and thin, with no meaningful 127 association between mean of triceps and subscapular skinfolds (xSF) and height. Skinfold thickness 128 was close to German values. Shortest and tallest children did not differ relevantly in skinfold thickness. 129 The same applied for the association between hSDS and mid upper arm circumference (MUAC) using 130 linear mixed effects models with both fixed and random effects. 35.6% boys and 29.2% girls in urban 131 Ubud were overweight; 21.4% boys and 12.4% girls obese, but with hSDS = -0.3, still short. Relevant 132 associations between hSDS and $\overline{x}SF$ and MUAC were only found among the overweight urban 133 children confirming that growth is accelerated in overweight and obese children. There were no visible 134 clinical signs of malnutrition in the stunted children. 135 136 Conclusion

The present data seriously question the concept of stunting as *prima facie* evidence of malnutritionand chronic infection.

139

143 Introduction

144

145 The clinical audience is wedded to the idea that stunting is nutritional. "There is convergence [also] 146 among the nutrition community on the use of length-for-age as the indicator of choice in monitoring the 147 long-term impact of chronic nutritional deficiency" [1]. The conventional definition of height stunting is, 148 "...impaired growth and development that children experience from poor nutrition, repeated infection, 149 and inadequate psychosocial stimulation" (WHO 2018). We accept that malnutrition can result in 150 stunting but question the reverse equation, stunting = malnutrition. Stunting is frequent among children 151 of low and middle-income countries (LMIC) [2]. But it is not specific for poverty, poor health and 152 nutrition. Short stature when compared to modern references has been a frequent feature also among 153 the healthy and wealthy European societies of the past. The pediatric journals of the late 19th and 154 early 20th century reported that breastfed European infants and children, independent of social strata, 155 grew far below WHO standards. Some 15–30% of adequately-fed historic European children would 156 today be classified as stunted by the WHO standards [3]. Historic literature explicitly states that 157 "...growth in height is largely independent of the extent and nature of the diet" [4]. Such statements 158 are even more surprising when considering that the authors of these words were the pediatricians and 159 school doctors of the starving German children raised during and after World War I. These 160 pediatricians were not only aware of the physical effects of starvation on growth, they were also aware 161 of the effects of nutrition interventions in starving children. Bloch and Abderhalden [5] described 162 exceptional catch-up growth in height of 3-5 cm within 6-8 weeks during re-feeding. These outcomes 163 significantly differ from the results of modern nutrition intervention studies in the LMIC [6]. Repeated 164 infections and poor sanitation have also been claimed to be responsible for the shortness of stature in 165 the LMIC. Yet, recent systematic reviews of water-sanitation-hygiene (WaSH), and educational 166 interventions to prevent or treat stunting find little evidence for beneficial effects or effects so small as 167 to fall within the measurement error of body length/height [7]. We feel that the failure of many of the 168 modern interventions is not due to some general insensitivity to improvements in nutrition and living 169 conditions, but it is due to a misconception of the interpretation of short stature. 170

In this context, we note especially the articles by Seoane and Latham [8] and by Waterlow [9,10].
These articles provided a medical classification of malnutrition based on height-for-age that served as
the basis for the modern understanding of the causes of short stature. The reasoning of these papers

174 originated from observations and classification of Gomez et al. [11] who, when drawing up their

175 classification, were assessing the prognosis of malnutrition according to the weight on admission to a

176 hospital in Mexico City in the early 1950s. The significance of these observations was questioned later

177 [12], and even Seoane and Latham criticized a classification based on single parameters.

178 Nevertheless, the basic strategy of associating nutrition and height remained and became entrenched

in the literature by the publications of Waterlow who described a deficit in height-for-age due to

180 undernutrition over a long period as, "...nutritional growth failure, but for the sake of brevity I shall call

181 this condition *stunting*" [10]. This purely anthropometric definition of nutritional status was discussed in

detail in a World Health Organization 1971 report [13] and was broadly accepted after publication of a

183 Nestlé Nutrition Workshop in 1988 [14].

These papers have become the corner stones for the 21st century diagnosis of undernutrition. The terms "stunting", "malnutrition", and "undernutrition" are used as synonyms in the epidemiological, medical and scientific literature. Prendergast & Humphrey [15] summarized: "Linear growth failure is the most common form of undernutrition globally." We guestion this statement.

188

189

190

Considering that the history of the word "stunting" originates from observations in hospitalized Mexican children almost 70 years ago, and was used with weight cut-off points at 90%, 80%, and 70% of "expected weight for height", and 95%, 87.5%, and 80% of "expected height for age" based on "Boston 50th percentiles" and that this approach was presented again by Waterlow in 1973 [10] by the example of "two hypothetical children", rather than empirical data, we feel justified to question if the terminology and limited geographical criteria are still valid for global use and classification of undernutrition.

198

Starvation inhibits growth. This statement cannot be questioned, and there is ample evidence also in historic studies that this is the case. Keys and colleagues explicitly state that "there can be no doubt from the evidence in the literature that the growth of children can be and is influenced by a restriction in the food intake." [16, p. 1000-1001]. But reversing the line of argument by connecting short stature with shortage of food, lacks substantiation [17]. Scheffler et al. [18] re-analyzed cross-sectional growth studies of middle-class school children performed in Kolkata, India, and failed to detect an association 205 between nutritional status (as indicated by skinfold thickness) and body height [19]. Even in 206 socioeconomically disadvantaged children with below average skinfold thickness, when nutritionally 207 supplemented the net effect of nutrition on body height is generally small [20]. Out of 22 nutrition 208 intervention studies in urban areas of LMICs only 6 interventions had a small positive effect on length-209 or height-for-age, often within the 0.3 cm measurement error, weight and fat increased in 9, and all 210 other studies showed no beneficial effect on body height or body mass [21]. Even when nutrition 211 interventions on nutritional status were integrated with a child development component, Grantham-212 McGregor et al. summarized [22]: "There was generally little benefit of at-scale programs to nutritional 213 status", and reported an effect size on height-for-age z-score of 0.23 SD. Though significant 214 statistically this is a small biological effect compared with the historic observations on re-feeding 215 reported by Bloch and Abderhalden [5] with effect sizes of more than 1.0 SD. Based on the reviews 216 cited here and others with similar findings we propose that though widely used for assessing the 217 effectiveness of health and nutrition intervention programs, stature has falsely been adopted as the 218 tool of choice for detecting undernutrition.

219

We measured Indonesian children, with particular focus on West Timor, one of the poorest provinces of Indonesia, with a prevalence of stunting of up to 50% [23]. Skinfold thickness is a valid indicator of body fat stores and reflects the nutritional status as recognized historically by Keys et al. [16]. We used the association of skinfold thickness as an indicator of the nutritional status and mid-upper arm circumference and elbow breadth as a proxy for skeletal frame size and physical activity [24], and based on the conventional definition of height stunting, and the well-known association of parental education with childhood undernutrition in low- and middle-income countries [25,26] we hypothesize:

2281. Stunted children are characterized by depleted fat stores, measurable by decreased triceps and

subscapular skinfold thickness [16,27].

2302. Better nutrition leads to less stunting.

231 1. Fat stores of less stunted children are less depleted, measurable by positive correlations between

height standard deviation scores (hSDS) and skinfold thickness.

233 2. Positive correlations between hSDS and the educational level of the parents assuming a priori that

better parental education might minimize the risk of child malnutrition [25,26].

2353. 3. Stunted children exhibit one or more visible clinical signs of malnutrition [27].

We question that "Linear growth failure is the most common form of undernutrition globally" [15],
especially when stunting is prevalent in wealthy populations of LMICs. We present such data for
[ndonesia.]

240

241 Subjects and methods

242

We measured 1716 elementary school children, age between 6.0 and 13.2 years, from three
Indonesian provinces in February and March 2018. Indonesia is not a poor country, it ranks 7th out of
190 countries in the World Bank list of GDP [28], but Indonesian children are short in stature, and
officially considered malnourished. 35.6% of Indonesian children were stunted in 2010. The
prevalence of stunting increased to 37.2% in 2013 [29]. With a global hunger index of 22, Indonesia is
considered "seriously" affected by starvation [30]. This view, however, is strongly questioned by
Indonesian pediatricians with direct clinical experience.

250

251 1. West-Timor, belonging to East Nusa Tenggara, is the poorest province of Indonesia with a nominal 252 per capita GDP of US\$ 1,288 [31]. The population of this island is among the shortest of Indonesia 253 [23], with an exceptionally high rate of stunted children. We measured in two representative 254 elementary schools in urban Kupang/West-Timor, and one representative school in rural Soe/West-255 Timor. Kupang and Soe are situated 110 km apart from each other, connected by one asphalted road, 256 driving time approximately three hours by private car. Kupang has some 330,000 inhabitants, a 257 university, an airport and a harbor. Rural Soe has some 40,000 inhabitants, there is very little eco-258 tourism and no remarkable industry. The population of West-Timor is comparably homogeneous. 259 Except for refugees from nearby East-Timor, there was little migration in recent history. The people 260 are very short, physical contact with modern tourists is virtually absent, but the pleasures of modern 261 communication, such as television, internet and cellular phones are ubiquitously present in the young 262 generation.

263

264 2. The "tourist island" Bali, is densely populated and economically more prosperous with a nominal per
265 capita GDP of US\$ 3,791. Balinese people are the tallest Indonesians [23]. We studied elementary
266 school children of the city of Ubud.

3. We studied elementary school children of rural North Sumatra, near Marbau that was selected
because its nominal per capita GDP with \$ 3,588 is close to that of Bali, but the region is known for
high stunting rates. Marbau has some 2500 inhabitants surrounded by rural settlements along the
roads and is strongly involved in modern agro-industry. .

272

273 Parental informed consent was given. Ethical approval was provided by the Medical and Health

274 Research Ethics Committee, Faculty of Medicine, Gadjah Mada University, Yogyakarta, Ref. nr.

275 KE/FK/0175/EC/2018. We excluded one child with trisomy 21, one child with hydrocephalus, one child

with club feet, and one child with gait disorder. Six children refused being measured.

277

278 All measurements were performed in the presence of the children's teachers, and supervised and 279 accompanied by 26 local physicians, pediatricians, and medical residents. Birth date and information 280 on parent education was obtained from school records. Parent education was expressed as the total 281 number of school years of both parents including university education. We measured body height 282 (technical error 2.5 mm), weight (technical error 0.15 kg), triceps (technical error 1.5 mm), subscapular 283 skinfolds (technical error 2.0 mm), and clinical signs of malnutrition (hair, skin, and general 284 appearance [13]). The children were lightly dressed and measured without shoes. Weight of the 285 school uniforms was found to be close to 200g in children below age 10 years, and about 300g in 286 children above age 10 years, and was subtracted from the weight measurements. Body height was 287 determined by digital laser rangefinder GLM Professional® Bosch 250 VF [32] to the nearest 288 millimeter, weight by digital scales (Soehnle, Nassau, Germany, Style Sense Compact 100) to the 289 nearest 100g, and skinfold thickness by caliper (Holtain, Ltd. Crosswell, Crymych, UK) to the nearest 290 0.2 millimeter. All measurements were taken under standardized conditions [33]. The study included 291 travelling of some 900 km by car, and extensive walking through residential areas surveying housing 292 conditions, food markets, and sanitary facilities.

293

294 To estimate fatness, energy balance, and nutritional status we used the average of three

295 measurements of triceps and three measurements of subscapular skinfold thickness (xSF). Skinfold

thickness changes with age and the distribution of fat depends on sex [37-39]. By averaging two

298 rather focused on the association between height, body fat and and external skeletal robusticity. 299 Standard deviation scores for height (hSDS) and body mass index (BML_SDS) were calculated 300 according to WHO references [3]. To test whether particular effects only occurred in the very thin, or in 301 the overweight/obese group of children, we focused on children with "normal BMI" (BML_SDS<-1.28; 302 and BML_SDS>1.28). "Thinness" was defined as BMI below the 10 th centile, i.e. BML_SDS<+1.28. The 303 terms "overweight" and "obesity" were defined in the usual way with BML_SDS>+1 or >+2, 304 respectively. 305 To further estimate nutritional status and external skeletal robusticity, we measured mid-upper-arm 306 circumferences (MUAC) and elbow breadth and calculated the frame index (FI, elbow breadth/height 307 [34-36]). The latter has been used as a proxy for everyday physical activity levels [19]. 310 Statistical analysis 311 statistical analysis 312 We performed correlation analyses and linear mixed effects models with both fixed and random 313 effects for hSDS, MUAC and XSF, we then plotted the samples and fitted with LOWESS, LOWESS, 314 also referred to as robust locally weighted regression, is a method for fitting a smooth line through x-y 315	297	skinfolds, we tried to avoid possible confounding due to age, sex, SES, and ethnic influences, and
 according to WHO references [3]. To test whether particular effects only occurred in the very thin, or in the overweight/obese group of children, we focused on children with "normal BMI" (BMI_SDS<-1.28; and BMI_SDS>1.28). were shortest (hSDS -2.08), and thinnest (BMI_SDS -1.41), closely followed by the girls (hSDS -1.90,	322	Indonesian children lack relevant associations between $\overline{x}SF$ and hSDS (table 1). Rural boys of Soe
	323	were shortest (hSDS -2.08), and thinnest (BMI_SDS -1.41), closely followed by the girls (hSDS -1.90,
BMI_SDS -1.25). 53% of the Soe boys, and 46% of the Soe girls were stunted. xSF (boys 5.50 mm,	324	BMI_SDS -1.25). 53% of the Soe boys, and 46% of the Soe girls were stunted. The XSF (boys 5.50 mm,
girls 6.72 mm) was significantly less than in the children of Kupang (boys 7.65 mm, girls 8.75 mm).	325	girls 6.72 mm) was significantly less than in the children of Kupang (boys 7.65 mm, girls 8.75 mm).
Even though the very thin children of Kupang were slightly shorter, they were still significantly taller	326	Even though the very thin children of Kupang were slightly shorter, they were still significantly taller
than the children of Soe. The correlation between $\overline{x}SF$ and hSDS ranged from r=0.12 to r=0.38,	327	than the children of Soe. The correlation between $\overline{x}SF$ and hSDS ranged from r=0.12 to r=0.38,

328 explaining a maximum of 14.4% of the hSDS variance. The average number of parental school years 329 was less in Soe (fathers 11.15 years, mothers 10.73 years) than in Kupang (fathers 13.33 years, 330 mothers 13.05 years, p<0.01). But the correlation between parental education and anthropometry was 331 weak and only explain some 6.5% of the variance in hSDS and some 3.5% of the variance in $\overline{x}SF$. 332 333 To minimize the effects of overweight and thinness on growth, we eliminated the extremes and 334 repeated the calculations with "nutritionally normal" children (BMI between +/- 1.28 BMI SDS [3]). 335 Doing so, the weak correlations between $\overline{x}SF$ and hSDS disappeared completely (table 1). 336 We also studied the thin children from West Timor, with $\overline{x}SF$ below the 10th centile for mean 337 338 subscapular and triceps skinfold thickness of German children [41]. 124 boys and 115 girls from 339 Kupang, and 86 boys and 98 girls from Soe belonged to this sample. In these children, hSDS was 340 slightly lower than the average hSDS of the respective groups of all West Timor children. Yet, the 341 association between hSDS and $\overline{x}SF$ was insignificant. In the children of Kupang, the regression 342 analysis showed insignificant betas of -0.015 (95% CI -0.246, 0.207; boys) and 0.048 (95% CI -0.120, 343 0.204; girls), and in the children of Soe, the regression analysis showed insignificant betas of -0.065 344 (95% CI -0,190, 0,351; boys) and -0.136 (95% CI -0.349, 0.067; girls). 345

On the other side, many children from urban Ubud and rural Marbau were obese (table 1), though still shorter than the WHO reference (hSDS = -0.3). The correlation between hSDS and skinfold thickness was as weak, as in the urban children of Kupang (r = 0.354). In all samples the correlation between hSDS and $\overline{x}SF$ was negligible (Table 1).

350 Using linear mixed effects models with both fixed and random effects, we further studied the 351 association between hSDS, MUAC and \overline{x} SF. When considering the whole sample, MUAC and \overline{x} SF. 352 together explained 25.5% of the hSDS variance in boys, and 18.5% of the hSDS variance in girls. But 353 the associations markedly decreased when considering the two parameters, and each population 354 separately (Table 1). It is of particular interest that the shortest population, the children from rural Soe 355 with stunting rates of 53.3% (boys) and 46.0% (girls), showed no meaningful association between 356 hSDS, MUAC and TSF. The hSDS variance explained by both parameters together, was 6.5% 357 (p=0.03) in boys, and 4.8% (p<0.01) in girls. The FI of the frequently stunted rural children of Soe, with 358 40.9 (SD=2.1) mm (boys) and 39.0 (SD=1.8) mm (girls) was highest among the various regions

investigated. The FI of the frequently obese urban children of Ubud, however, was lowest with 38.6
(SD=2.8) mm (boys) and 37.3 (SD=2.6) mm (girls). Previous research reports that FI is positively
correlated with physical activity levels and uncorrelated with body fatness [42. On this basis the high
level of physical activity of the Soe children rather contracts the vision that the short stature of these
children results from malnutrition or infection.

364

365 It is of interest to note that the associations between hSDS and both skinfold thickness and MUAC
366 were least in the stunted rural children of Soe, and greatest in the urban overweight children of Ubud.

367

368 We found no visible clinical signs of PEM such as edema, irritability, apathy, or decreased social 369 responsiveness, and anxiety, nor glossitis and nail changes (iron deficiency), goiter (iodine deficiency), 370 hair changes (vitamin A deficiency), nor signs of diminished immune response such as multiple skin 371 infections and poor wound healing [27]. We rather met happy, vivid, and very interested children in 372 apparently good health. We incidentally found an almost 100% prevalence of untreated dental caries, 373 indicating very poor dental hygiene in the rural children of Soe and Marbau. A systematic review of 374 longitudinal studies reported that, "Evidence of the association between anthropometric 375 measurements and dental caries is conflicting and remains inconclusive" [43]. Less than one percent 376 of the children wore eyeglasses indicating underdiagnosed visual impairments. 377

378

379 Discussion

380

381 The present analysis rejects the three hypotheses proposed here, all of which are based on the 382 conventional definition of height stunting as due primarily to nutritional inadequacy: (1) stunted 383 children are not uniformly characterized by depleted fat stores; (2) fat stores of less stunted children 384 are not less depleted and better parental education does not minimize the risk of child undernutrition; 385 (3) stunted children do not exhibit visible clinical signs of PEM. Quite in contrast to common 386 expectations, the associations between growth and parameters reflecting nutritional status such as 387 skinfold thickness, FI, and MUAC were least in the stunted rural children of Soe, and greatest in the 388 urban overweight children of Ubud. Small subcutaneous fat depots and narrow upper arm 389 circumferences do not appear to inhibit growth. The data rather confirm that growth is accelerated in

overweight and obese children. The investigation in 1716 Indonesian school children with stunting
rates up to 53% in rural Soe, thus, does not support the modern concept of stunting as an indicator of
malnutrition.

393

394 Arguments have been raised that observing signs of adequate or even overnutrtion in stunted school 395 age children does not exclude undernutrition at younger age, as stature is the summary of all previous 396 height increments. Such arguments are compelling at first view. But growth is plastic. Long periods of 397 childhood starvation are usually followed by catch-up growth [44] and complete recovery. This has 398 repeatedly been shown in school children born during and shortly after wars [45,46]. The effect of re-399 feeding was particularly well documented in historic studies of severely undernourished children raised 400 during World War I [47,48] with average catch-up growth rates of 3-5 cm within eight weeks of re-401 feeding. We found no evidence in the historic European pediatric literature that supports the view that 402 intermittent infant undernutrition due to war and post-war food shortages result in permanent height 403 deficits.

404

405 Thus, we cannot share the opinion expressed in the quotation in our Introduction that length-for-age is 406 the indicator of choice to monitor chronic nutritional deficiency [1]. We appreciate that this is the 407 working agenda of public health specialists, governments, the food industry and funding bodies. In 408 recent communication with the German Federal Ministry for Economic Cooperation and Development 409 (Bundesministerium für wirtschaftliche Zusammenarbeit und Entwicklung) we were told that this 410 Ministry, "...follows the international definition that stunting results from chronic malnutrition - so-called 411 "hidden hunger". Affected people often receive a sufficient (energy-rich) but not a balanced diet" (email 412 communication to MH, 09 May 2018). The belief that height growth depends on an ideal intake of food 413 and essential nutrients is intuitive. But intuition may not necessarily be true [49]. We are aware that the 414 estimates of the global prevalence of stunting for under 5-year-olds is close to 155 million [50]. We do 415 not question that these children are short in stature, but we question that all these children are 416 undernourished [51]. Nearly 100 years ago, after World War I, the German pediatrician and school 417 physician Schlesinger summarized that "the child's longitudinal growth is largely independent of the 418 extent and nature of the diet ...". Very similar data were published by other paediatricians [4,5].

419

420 Our new Indonesian study consisted of extensive ethnographic observations of residential areas and 421 was supervised and accompanied by 26 local physicians, pediatricians, and medical residents, with 422 direct clinical experience of urban and rural communities. All of us failed to detect visible clinical signs 423 of PEM and essential nutrient deficiencies. Instead we detected obesity except for Soe children. A 424 positive energy balance has mild stimulatory effects on developmental tempo and growth [25], but the 425 obese children were not the tall children. Quite in contrast, even the obese populations were shorter in 426 height than WHO references. In Guatemala it has been known since the 1990s that the high 427 prevalence of stunting is caused by factors other than nutrient intake [52]. A survey of eight rural, 428 Maya villages and an urban medical clinic in Quetzaltenango, Guatemala with a high percentage of 429 Maya patients found that for 306 newborns, with a median age of 19 days postpartum, 38% were 430 'stunted' at birth and that maternal height explained only 3% of the variability in hSDS of the newborns 431 [53]. The nutrient intake of the mothers may have been inadequate but as we discussed above, 432 systematic reviews of numerous nutrient supplementation interventions in Guatemala and elsewhere 433 find little or no positive impact on newborn length. 434 The same research team published a more recent report based on their participatory action research 435 conducted within a socioecological framework [54]. The study enrolled a longitudinal cohort of 155 436 women, followed during pregnancy (6-9 months), early (0-6 weeks), and later (4-6 months) 437 postpartum, and 2 cross-sectional cohorts (60 early and 56 later postpartum). The authors report that 438 diet diversity and adult food security (38%) were low. Urinary and gastrointestinal infections were rare 439 (<5%) but reports of distress in meaningful Maya social categories was frequent (20%-50%). 440 "Participants reported low maternal autonomy (81%), high paternal support (70%), small social 441 support networks (2.7 +/- 1.3 individuals), and high trust in family (88%) and community-based 442 institutions (61%-65%) but low trust in government services (6%). Domestic violence was commonly 443 reported (22%). Infant stunting was common (36% early postpartum and 43% later postpartum) 444 despite frequent antenatal care visits (7.5 + 3.8). Participant engagement with the research team did 445 not influence study outcomes based on comparisons between longitudinal and cross-sectional 446 cohorts" (p. 415). These findings confirm the earlier study of high stunting prevalence at birth and 447 associates this with maternal psychosocial distress and insecurity more than diet or infection. 448 449 Education matters [23,24]. Social strata and education are associated with child growth. The

450 differences in height between the Indonesian groups of lower SES and higher SES support this view.

But again, the within-group correlations were weak. Within each group, parental education failed to
suggest major impact of education on height. We found no satisfying educational explanation for the
one standard deviation height difference between rural Soe and urban Kupang.

454

455 Heredity has been an argument for short stature. West-Timor, a far-off region with little migration from 456 outside and almost no physical contact with modern Europeans, might serve as an example of genetic 457 isolation, but it fails to explain the difference of one SD between height of children raised only 110 km 458 apart from each other. Similar considerations apply for Maya children from Guatemala born in the 459 United States. They are, on average, 11 cm taller than their siblings born and raised in Guatemala 460 [55]. The genetic argument is further weakened when considering recent Genome-Wide Association 461 Studies stating that genetic loci associated with height only explain some 12.3% of the total variance 462 in adult human height [56].

463 464

465 Why are these children so short?

466 This question is difficult, as it might imply a negative connotation of being short. We rather suggest

467 asking why are these children not as tall as modern European children? Modern Indonesians are

468 slightly taller than wealthy Europeans some 150 years ago. Kotelmann studied upper class adolescent

469 boys from an elite humanistic school in Hamburg [57]. These boys were delayed in pubertal

470 development by almost two years and reached an average near final height around 165 cm. Similar

471 patterns of growth delay and short height were reported from aristocratic and working-class boys

472 educated at Carlsschule, Stuttgart, an 18th century boarding school [58].

473 Recent evidence suggests community effects on height [59]. Among social mammals, strategic growth

adjustments have been described [60], mechanisms that may also apply for the regulation of human

475 growth [61].

476 We propose that living in poverty with food and housing insecurity, emotional trauma, and other stress

477 insults are some, but not all of the factors that explain the comparably short stature of those many

478 modern nations listed by the NCD Risk Factor Collaboration [62].

479

480

482 In addition, we propose that children can be short because they lack those social, economic, political 483 and psychological infrastructures that in the modern Western world have stimulated growth beyond all 484 previously recorded limits for height [62]. Good nutrition, health, general living conditions and care-485 giving are essential prerequisites for growth, but they do not in themselves, maximize stature. We 486 emphasize the bilateral link between height and social position [63]. Taller stature is associated with 487 higher socioeconomic status [64], but also social position and political environment modulate growth 488 [59, 65], a vision that opens new fields of biosocial research. Here, the classical verdict of Liberté, 489 Egalité, Fraternité, becomes more than just a revolutionary statement. Groups who feel liberty, who 490 practice social equality and peaceful coexistence – the Northern European countries may serve as 491 political examples - are known to be tall.

492

There are limits to this study. The underlying mechanisms of social-emotional growth adjustments are
still unclear. The present investigation lacks detailed information on daily food intake and the
composition of the diet, and confirmative laboratory data on serum iron, zinc, thyroid hormones,
vitamin D levels, etc.

497

This work does not question the obvious causal association of energy insufficiency, essential nutrient and chronic infection with reduced linear growth. We are not advocating the discredited idea that the short stature of children and adults living in poverty may be a genetic adaptation or beneficial homeostatic response acquired from generations of malnutrition and is without any pathological consequence.

503

504 But we do question the inappropriate use of global growth standards to conclude that stunting is prima 505 facie evidence of malnutrition and chronic infection. We question that government ministries and non-506 governmental organizations base their raison d'être on the term "stunting" as a synonym for "chronic 507 malnutrition". We intend to stimulate the debate about the inappropriate misapplication of a global 508 growth reference derived from high SES and mostly westernized populations when applied to 509 apparently healthy and well-nourished low SES children raised in remote areas of former European 510 colonies. We propose a more precise identification of growth inhibition caused by malnutrition based 511 on a combination of measurements, including height, triceps and subscapular skinfolds, and other 512 indicators of energy balance and nutrient adequacy.

513	We protest against the	misinterpretation	of short stature as a	a proxy indicator	for malnutrition.
-----	------------------------	-------------------	-----------------------	-------------------	-------------------

514 Malnutrition leads to stunting, but stunting by itself does not indicate malnutrition.

744

747 Legend to figure 1:

748

- hSDS and mean skinfold thickness [(subscapular + triceps)/2] of 206 children from urban
- 750 Kupang/West-Timor, Indonesia, 107 children from rural Soe/West-Timor, Indonesia, and 591 children
- from urban Ubud/Bali, Indonesia. Age and sex averaged centiles (p3, p50, and p97) of mean
- subscapular and triceps skinfold thickness of German children [41] (bars) are added for comparison.
- hSDS and xSF were plotted and fitted with LOWESS to better highlight the overall shape of the
- relationship between the x and y variables. Please note that the scale of the Ubud children differs due
- to the exuberant prevalence of obesity.
- 756

Table 1 Anthropometric data and parental education of 908 boys and 808 girls from elementary
schools in Ubud (Bali), Kupang (two schools, West-Timor), Soe (West-Timor), and Marbau (two
schools, North Sumatra). SD scores were obtained using WHO references [3].
