Supporting Information

ABSTRACT: There has been an ongoing effort to overcome the limitations associated with the stability of hybrid organic-inorganic perovskite solar cells by using different organic agents as additives to the perovskite formulations. The functionality of organic additives has been predominantly limited to exploiting hydrogen bonding interactions, with the relevant atomic-level binding modes remaining elusive. Herein, we introduce a new bifunctional supramolecular modulator, 1,2,4,5-tetrafluoro-3,6-diiodobenzene, which interacts with the surface of the triple-cation double-halide perovskite material via halogen bonding. We elucidate its binding mode using two-dimensional solid-state ¹⁹F NMR spectroscopy in conjunction with DFT calculations. As a result, we demonstrate a stability enhancement of the perovskite solar cells upon supramolecular modulation, without compromising the high photovoltaic performances.

Introduction

Over the past decade, hybrid perovskite solar cells have achieved extraordinary success, demonstrating solar-toelectric power conversion efficiencies exceeding 25% and surpassing the performance of polycrystalline silicon.¹⁻³ The structure of the corresponding light absorber, hybrid organic-inorganic perovskites, can be defined by the AMX₃ formula, which represents a 3D perovskite structure (Figure 1a). In a typical perovskite composition, A cations can be organic (e.g., methylammonium (MA⁺), formamidinium (FA⁺)) or inorganic (e.g., Cs⁺), M are divalent metal cations (mainly Pb^{2+} or Sn^{2+}) and X are halide anions (I⁻, Br⁻, Cl⁻).¹⁻³ Despite its remarkable performance, the progress of this thin-film photovoltaic technology is limited by the material stability, particularly with respect to the reactivity to light, oxygen and water, as well as the internal ion migration under the device operation conditions.⁴

Figure 1. (a) The structure of hybrid perovskites (AMX₃). Schematic representation of different binding modes of the prospective molecular modulator to the perovskite, i.e., (b) *asymmetric* interaction (*A*) and (c) *symmetric* crosslinking of the phases (*S*), both of which feature two distinct binding sites, either the A-cation vacancy (Aa/Sa) or halogen anions (Ax/Sx).

Various strategies have been used to overcome this challenge, such as employing different organic molecules as additives to the perovskite composition, as well as use of hydrophobic agents to treat (i.e. passivate; Figure 1b) the surface of the perovskite material.^{1,5} However, there are several shortcomings associated with this widely employed approach. Firstly, many organic agents provide stabilization at the expense of performance by stabilizing the devices at lower power conversion efficiencies,^{6,7} and overcoming this requires advanced function-driven molecular design. Furthermore, most of the research effort is based on the trialand-error approach and predominantly exploits ammonium-functionalized organic molecules¹ that are assumed to form hydrogen bonds with the perovskite surface, thereby mimicking the native A-site cation. In this context, bifunctional organic systems are gaining increasing interest due to their potential to *crosslink* perovskite grains (Figure 1c), which is beneficial for the performance,^{8,9} although the crosslinking role of the organic components is seldom identified at the atomic level. Bifunctional systems also favor the formation of layered two-dimensional structures with superior environmental stability.¹⁰⁻¹² There are very few examples of using alternative noncovalent interactions, such as halogen bonding,^{13,14} despite its immense potential.¹⁵⁻¹⁸ Until now, the corresponding device performance has been the overarching focus of these studies, while structureproperty relationships and the underlying modes of interaction have remained poorly understood, thus limiting the prospects of advanced molecular-level design.¹⁹

We recently demonstrated that solid-state NMR spectroscopy is a powerful tool for unraveling the atomic-level interactions of molecularly engineered organic molecules with hybrid perovskites.¹⁹ While these molecular modulators encompassed multiple functional groups with complementary roles and their interactions with the perovskite surface (e.g., through hydrogen bonding), as well as PbI₂ (e.g., via metal coordination), were evidenced, the different binding modes within the perovskite framework could not be distinguished by conventional 1D NMR spectroscopy (Figure 1b-c). Moreover, these modulators have been based on conventional hydrogen bonding and metal-coordination, whereas the role of halogen bonding interactions remain poorly understood. In this regard, a more versatile tool is required, and we recently showed that the 2D spin diffusion (SD) NMR spectroscopy can be effectively employed to scrutinize the structure of layered hybrid perovskites.¹¹ This unique diagnostic tool could provide the atomic-level understanding necessary to extend the impact of modulation on the perovskite solar cell performance and stability, such as by exploiting alternative noncovalent interactions.

Herein, we demonstrate the effect of a bifunctional molecular modulator, 1,2,4,5-tetrafluoro-3,6-diiodobenzene (**TFDIB**), which uniquely interacts with hybrid perovskites via halogen bonding (XB). We unravel its mode of action by using two-dimensional ¹⁹F solid-state NMR spectroscopy as an unambiguous diagnostic tool in conjunction with density functional theory (DFT) calculations. Modulation of the perovskite solar cells results in improved stability under continuous illumination while the competitive photovoltaic performance is maintained. This showcases the potential of supramolecular modulation via XB in solar cell research. Our work unravels the role of bifunctional halogen bonding in improving perovskite solar cell stability and structure-property relationships for advanced molecular design in hybrid perovskite optoelectronics.

Experimental Details

Material synthesis. Material synthesis involved the perovskite precursor solution (1.4 M) that was prepared by dissolving the corresponding proportion of lead iodide (PbI₂, 99.99%, TCI), lead bromide (PbBr₂, 99.99%, TCI), cesium iodide (CsI, 99.998%, ABCR), methylammonium bromide (MABr, 98%, Greatcellsolar) and formamidinium iodide (FAI, \geq 98%, Greatcellsolar) in dimethylformamide (DMF, 99.8%, Acros) and dimethyl sulfoxide (DMSO, 99.7%, Acros) (DMF: DMSO = 4:1 v/v) to form a triple-cation perovskite containing 5% Cs and 10% MA (on the cations site), 10% Br (on the halogen site) and 3% excess of PbI₂. The perovskite precursor solution was prepared in an argon-filled glovebox.

Thin film preparation. Thin films were prepared by spin-coating the perovskite precursor solution on the defined substrates. The perovskite precursor solution was drop-casted on the substrates and spun at 2000 rpm (acceleration of 200 rpm s⁻¹) and 6000 rpm (acceleration of 2000 rpm s⁻¹) for 10 s and 30 s, respectively. During the last 10 s of the second spin-coating step, 220 µL of the α,α,α -trifluorotoluene antisolvent (TFT, 99%, anhydrous, Sigma-Aldrich) was drop-casted. The perovskite film was then dried on a hot plate at 100 °C for 60 min to form a ca. 450 nm-thick perovskite layer.

Molecular modulation of thin films. Molecular modulation of thin films was performed by using the corresponding modulator (**TFDIB**) in one of the following three ways, which are specified throughout the manuscript, namely: (1) as part of the perovskite precursor solution, (2) by treating the perovskite surface using the solution of the modulator in isopropanol, or (3) by using the modulator within the antisolvent (TFT) in specified concentrations.

Mechanosynthesis. Samples for the NMR experiments were prepared using mechanosynthesis²⁰⁻²² by grinding the reactants in an electric ball mill (Retsch Ball Mill MM-200) using a grinding jar (10 ml) and a ball (\emptyset 10 mm) for 30 min at 25 Hz. The following stoichiometries were used: m-PbI₂: PbI₂ (461 mg, 1 mmol), **TFDIB** (40 mg, 0.1 mmol); m-MAI: MAI (159 mg, 1 mmol), **TFDIB** (20 mg, 0.05 mmol); m-MAPbI₃: MAI (159 mg, 1 mmol), PbI₂ (461 mg, 1 mmol), **TFDIB** (20 mg, 0.05 mmol), m-FAPbI₃: FAI (172 mg, 1 mmol), PbI₂ (461 mg, 1 mmol), **TFDIB** (20 mg, 0.05 mmol). The powders were packed into 3.2 mm zirconia rotors and annealed at 140 °C for 5 min to remove grinding-induced defects, and transferred into the probe. The measurements were carried out under dry nitrogen.

Solid-State NMR experiments. NMR experiments were carried out on a 9.4 T magnet equipped with a Bruker Advance III console using a 3.2 mm LTMAS probe. Echo-detected ¹⁹F and ¹⁹F-¹⁹F spin-diffusion MAS NMR spectra were recorder using 100 kHz RF strength and no ¹H decoupling. Relaxation delays between 5 and 60 s were used. ¹⁹F chemical shifts were referenced to neat CFCl₃ (0 ppm) using solid NaF as a secondary reference (-224 ppm). Further experimental details (number of scans, recycle delays, etc.) are summarised in the Supporting Information (Table S2). We note that the probe background does not contribute appreciably to the detected signals (Figure S2, SI).

Device fabrication. Photovoltaic devices were fabricated using the n-ip architecture with the constituent layers as follows: FTO/(40 nm) c-TiO₂/(250 nm) mp-TiO₂/(450 nm) perovskite/(180 nm) Spiro-OMeTAD/(80 nm) Au. An active area of $0.25 \text{ cm}^2 (5 \text{ mm} \times 5 \text{ mm})$ was defined by the gold electrodes and a 0.16 cm² black metal mask was used during PV measurements to define the aperture area. For this purpose, glass sheets covered by fluorine-doped tin oxide (Nippon sheet glass $8 \Omega \cdot sq^{-1}$) was thoroughly brushed with a 10% Hellmanex (Hellma GmbH) water solution and then placed under sonication in a 2% Hellmanex water solution for 30 min. After that, the Hellmanex solution was replaced by acetone and later ethanol and sonicated during 15 min and 10 min, respectively. Then, a ca. 40 nm-thick TiO2 compact layer (c-TiO₂) was deposited by spray pyrolysis with a precursor solution of titanium diisopropoxide bis(acetylacetonate) (75 wt% in isopropanol, Sigma-Aldrich) in anhydrous ethanol (99.5%, Fischer Scientific) at 450 °C. After the spraying, the substrates were kept at 450 °C for 30 min. Then, a suspension of TiO2 paste (Dyesol 30 NR-D) in ethanol was used to cast a ca. 250 nm-thick mesoporous TiO₂ (mp-TiO₂) layer by spin coating at 4000 rpm for 20 s with an acceleration of 2000 rpm s⁻¹. After the spin coating, the solvent was allowed to evaporate on a hot plate at 80 °C for 10 min and then sintered at 450 °C for 30 min under dry air flow. UV-ozone treatment for 15 min was used before the deposition of the c-TiO2 and mp-TiO2 layers. A ca. 450 nm-thick perovskite layer was deposited on the substrates by spin coating following the antisolvent method. The precursor perovskite solution was drop-casted on the substrates and spun at 2000 rpm (acceleration of 200 rpm s⁻¹) and 6000 rpm (acceleration of 2000 rpm s⁻¹) for 10 s and 30 s, respectively. During the last 10 s of the second spin-coating step, 220 μ L of the α,α,α -Trifluorotoluene antisolvent (TFT, 99%, anhydrous, Sigma-Aldrich) was drop-casted. The perovskite film was then dried on a hot plate at 100 °C for 60 min. The substrates were allowed to cool down for 10 min. A 70 mM solution of Spiro-OMeTAD (99%, Merck) in chlorobenzene (CB, 99.8%, ACROS) was prepared. Lithium bis(trifluoro-methylsulphonyl)imide (Li-TFSI, 99.95%, Sigma) and 4-tert-butylpyridine (4tBP, 96%, Sigma-Aldrich) were used as additives in a 0.5 and 3.3 mol% (relative to Spiro-OMeTAD), respectively. This solution was spincoated on the perovskite layer at 2000 rpm (acceleration of 1200 rpm s⁻ 1) for 20 s to form a ca. 180 nm HTL. The perovskite and Spiro-OMeTAD layers were deposited in a dry air glovebox. Finally, 80 nmthick gold electrodes were deposited by thermal evaporation.

Transient capacitance measurements. Ionic motion was analyzed by carrying out the temperature-dependent transient capacitance measurements in accordance with the previously reported procedures,²³ which are further detailed in the Supporting Information.

Other experimental details are provided in corresponding sections of the Supporting Information.

Supramolecular Design

It has been shown that organic molecules featuring strong hydrogen bond donors, typically ammonium (NH_3^+)

groups, have the capacity to interact with the A-cation vacancies on the surface of hybrid perovskites through hydrogen bonding (HB).^{1,19,25,26} This can lead to morphology alteration, passivation of anionic defects (e.g., halide ions), or increase in stability by inducing resilience towards moisture and oxygen.¹ These effects can be amplified by employing systems featuring multiple functional groups that may, for instance, crosslink perovskite grains (Figure 1c),⁹ or simultaneously interact with the perovskite surface while passivating perovskite defects.¹⁹ These effects can be achieved by effectively employing alternative noncovalent interactions, such as halogen bonding (XB).¹⁷ Unlike hydrogen bonding, XB requires a halogen bond donor, which is a highly polarized halogen atom (X), and a nucleophilic halogen bond acceptor, such as N, O, or another halogen. The XB interaction takes place through an area of positive potential along the C-X bond axis known as the σ hole, which renders halogen bonding highly directional (Figure 2a).²⁷⁻²⁹ Since the strength of XB is determined by the orientation of the participating groups and the size of the σ hole, it can be enhanced by employing strongly electronwithdrawing groups as carriers of the XB donor atom, which should be highly polarizable.¹⁵⁻¹⁷ In addition to these requirements associated with XB, a suitable supramolecular agent for stabilizing the perovskite should also feature increased hydrophobicity, ensuring resilience against environmental factors. TFDIB is a bifunctional halogen bond donating molecule that meets these design criteria, while incorporating them into a perfluorinated π system with pronounced hydrophobicity (Figure 2). We assessed the capacity of TFDIB to act as a supramolecular XB modulator with scanning electron microscopy (SEM), UV-Vis absorption and photoluminescence (PL) spectroscopy, and X-ray diffraction, complemented by NMR spectroscopy.

Figure 2. (a) Upper: Schematic representation of halogen bonding (XB) between an XB acceptor (A) and donor (X). Lower: The structure and optimized geometry (DFT calculations at the B3LYP/def2tzvp level of theory²⁴) of 1,2,4,5-tetrafluoro-3,6-diiodobenzene (**TFDIB**), with the corresponding top and side views of the electrostatic potential surface (ESP) highlighting the σ -hole.¹⁷ (b) Envisaged modes of interaction of **TFDIB** with the hybrid perovskite: *asymmetric* surface passivation (top) and *symmetric* crosslinking (bottom) of the perovskite grains.

Effect of XB on Hybrid Perovskite Material Properties

To assess the effect of XB on the perovskite, thin films of $(FA_{0.9}MA_{0.1})_{0.95}Cs_{0.05}Pb_{1.03}(I_{0.93}Br_{0.1})_3$ were deposited onto microscope glass slides using two-step spin-coating (for details see the experimental section and Supporting Information, SI). The XB modulating layer was cast over the perovskite layer by spin-coating a solution containing **TFDIB** in a highly hydrophobic solvent, namely α, α, α -trifluorotoluene (TFT), used to induce perovskite film crystallization (i.e. antisolvent).³⁰ The solution was spun at a velocity of 4000 rpm for 20 s with an acceleration of 2000 rpm s⁻¹ followed by annealing at 100 °C for 10 min.

Figure 3. Morphology and structural properties of the perovskite thin films. (a) Top-view SEM image of the pristine (control) and XB-modulated perovskite film. (b) X-ray diffraction (XRD) patterns of pristine (control) and XB-modulated films on FTO/c-TiO₂/mp-TiO₂. No signals were observed at $2\theta < 10^\circ$. FTO = fluorine doped tin oxide; c = compact; mp = mesoporous.

The surface morphology of pristine and XB-modulated perovskite films was analyzed by scanning electron microscopy. Top-view SEM images reveal a comparable grain size of the pristine and modulated samples (Figure 3a). Furthermore, the XRD patterns of thin films suggest that the XBmodulating layer does not lead to substantial structural changes, as the characteristic angle reflections remain unaltered (Figure 3b). Similarly, the optical properties were not significantly altered, as demonstrated by the UV-Vis absorption spectroscopy and photoluminescence spectra of the films (Figure 4). Tauc analysis of the absorption spectra reveals a band gap of ~1.59 eV for both pristine and XBmodulated films (Figure 4a, inset). This value correlates very well with the PL emission peak (\sim 1.59 eV; Figure 4b). The close match between the band gap extracted from optical absorption and the PL emission peak indicates that the latter originates from band-to-band recombination. We can thus conclude that the optoelectronic properties of the material are not substantially affected by halogen bonding. This observation, however, does not exclude possible effects on the conductivities of the materials. For more insight into the electronic quality of the perovskite films, time-resolved PL measurements were performed to assess the photogenerated charge carrier dynamics.³¹⁻³⁴

Figure 4. Optoelectronic properties of pristine (control, black) and XB-modulated (mod.; red) perovskite films. (a) UV-Vis absorption spectra and (b) steady-state photoluminescence (PL) spectra. Tauc plots are shown in the inset. (c) Time-resolved PL trace upon excitation at 420 nm and detection at 790 nm. The corresponding fitted PL curves (Figure S1) and parameters (Table S1) are shown in the SI.

An exponential function was fitted to the decay traces measured on a control perovskite film and a XB-modulated film deposited on a glass microscope slide (Figure 4c; see SI for details) to estimate the PL decay time. The decay time was found to be similar for both the control (1.57 μ s) and modulated (1.53 μ s) samples (Table S1, SI). The analysis of the decay profiles estimates lifetimes on the order of μ s, which indicates high electronic quality of the perovskite films that is preserved in the presence of the modulator.

In summary, the analysis of the effects of XB modulation on the properties of the perovskite suggests the modulation does not affect the electronic quality of the perovskite films. Since the XRD patterns did not reveal substantial changes in the long-range crystalline order, the short-range local structure of the modulated hybrid perovskite materials was further investigated by solid-state NMR spectroscopy.³⁵⁻³⁹

Local Structure of XB-Modulated Perovskites

To assess the atomic-level structure of the XB-modulated perovskites, we recorded powder XRD (PXRD; Figure S1, SI), ¹⁹F echo-detected (Figure 5a–e) and ¹⁹F-¹⁹F spin-diffusion (SD; Figure 5f–i) magic angle spinning (MAS) NMR spectra of modulated materials prepared by solid-state mechanosynthesis. XRD patterns of the corresponding perovskite powders do not reveal any substantial changes upon modulation for various perovskite compositions (Figure S1, SI). However, we observe presence of non-perovskite δ -FAPbI₃ phase in the pristine FAPbI₃ material, which was not observed in the modulated (m–) FAPbI₃, suggesting that the modulator stabilizes the *a*-FAPbI₃ perovskite phase under these conditions.^{11,36-37}

¹⁹F-¹⁹F spin-diffusion measurements yield two-dimensional (2D) spectra that are symmetric across the diagonal. The f1 and f2 projections yield the corresponding one-dimensional $(1D)^{19}$ F spectra, while the cross-peaks arise due to exchange of magnetization through dipole-dipole interaction and therefore provide direct evidence of atomiclevel proximity between ¹⁹F environments with different chemical shifts. Neat TFDIB yields two NMR peaks, which can conceivably correspond to either two inequivalent molecules inside a unit cell or two polymorphs (Figure 5a). We thus carried out ¹⁹F-¹⁹F spin-diffusion (SD) measurements (Figure 5f) to establish if the two species are in close contact, which would be the case for two inequivalent molecules in the unit cell but not for the polymorphs. The two signals exchange magnetization driven by the dipolar coupling rapidly, for mixing times below 5 ms, and therefore correspond to two fluorine environments inside an asymmetric unit cell. The spin-lattice relaxation time is, within the margin of error, identical for both signals $(T_1 = 14.5 \text{ s})$, consistent with fast ¹⁹F-¹⁹F spin diffusion.³⁹⁻⁴⁰

We subsequently verified the propensity of TFDIB to react with PbI₂ (further referred to as a modulated, m–, sample) (Figure 5b) where **TFDIB** is present as a modulator at 5-10 mol% concentration, as indicated in the corresponding figure captions. m-PbI₂ yields four new ¹⁹F signals. Downfield shifts (to higher ppm values) of the TFDIB signal were previously observed for halogen bonding formed with aromatic N-donors.³⁹ We therefore deduce that the new chemical environments correspond to halogen-bonded **TFDIB**. Moreover, ¹⁹F-¹⁹F SD measurements (Figure 5g) indicate that the signals at -108 and -119 ppm correspond to a species within a single phase (assigned as species 1, T_1 =11.9 s), and so do the signals at -115 and -116 ppm (species 2, $T_1=0.8$ s). The broad overlapping signal corresponds to unreacted **TFDIB** (indicated by a red dashed line in Figure 5b-c), whose presence signals a lack of propensity

to form a stoichiometric compound with PbI₂; **TFDIB** rather binds to its surface via weak noncovalent interactions. The interaction of **TFDIB** with PbI₂ via halogen bonding could render the para- and meta- fluorine substituents magnetically inequivalent and lead to two chemical shifts (Figure 2b, top). Another possible scenario is that of *symmetric* coordination of both iodine atoms to two different PbI₂ units, in which case the ortho- and meta- fluorine have comparable or identical chemical shifts, depending on the overall geometry (Figure 2b, bottom). Since two sets of peaks are observed experimentally (assigned as species 1, with a chemical shift difference of 11 ppm, and species 2, with a chemical shift difference of 1 ppm) we tentatively assign species 1 to the *asymmetric* and species 2 to the *sym*metric coordination mode (illustrated schematically in Figure 2b).

Analogous results were obtained for m-MAPbI₃ and m-a-FAPbI₃ (Figure 5c). In m-MAPbI₃, **TFDIB** also forms species 1 (-108, -119 ppm, $T_1=11.7$ and 8.9 s, respectively) and $2(-116 \text{ ppm}, \text{T}_1=0.8 \text{ s})$. Moreover, an additional product (species 3) is formed ($-122 \text{ ppm}, T_1=4.2 \text{ s}$). To assess the origin of this species, we analyzed a mixture of TFDIB with MAI, which yields a single peak at -121 ppm, matching the species present in m-MAPbI₃. This environment therefore most likely corresponds to the interaction with the ammonium group of MAI, as further confirmed by DFT calculations (for details see Section S2 in the SI). The ¹⁹F-¹⁹F SD spectrum of m-MAPbI₃ (Figure 5h) indicates that, as previously, the two signals of species 1 exchange magnetization and correspond to a fluorine environment within a single phase or molecule. The two peaks of species 1 require mixing times longer than 10 ms to efficiently exchange polarization, suggesting that they correspond to F atoms that are separated by a distance larger than that in the unit cell of pristine TFDIB. Species 2 and 3 do not exchange magnetization with any other signals even for very long mixing times (100 ms) and therefore correspond to TFDIB molecules that are spatially separated from TFDIB molecules in the other binding modes. The sample also contains unreacted TFDIB whose peaks exchange polarization within less than 5 ms of mixing and are thereby correlated with each other in the 2D SD spectrum. The presence of unreacted TFDIB strongly indicates that it does not form stoichiometric compounds with the perovskite but rather binds to the limited number of exposed surface sites. The MAI-TFDIB adduct (species 3), accounts for only ~4% of the ¹⁹F environments present in this sample, which suggests that the formation of perovskite-bound TFDIB species is strongly preferred.

In the modulated α -FAPbI₃ sample, **TFDIB** forms only species **1** (-108, -119 ppm, T₁ = 7.3 and 6.5 s, respectively) and **2** (-116 ppm, T₁ = 0.8 s). We have found no evidence for the formation of an analogous FAI-**TFDIB** in this case. As previously, the ¹⁹F-¹⁹F SD spectrum (Figure 5i) shows that the two chemical environments of species **1** are coupled and that species **1** and **2** are spatially separated, which is in accordance with their initial assignment to the *asymmetric* and *symmetric* binding modes, respectively.

Finally, low-temperature (100 K) spectra of neat **TFDIB** and m-MAPbI₃ (Figure 5d) reveal pronounced broadening

associated with the freezing of molecular dynamics of **TFDIB**, leading to static disorder and stronger ¹⁹F-¹⁹F dipole-dipole couplings. Moreover, in the mixture of **TFDIB** with α -FAPbI₃ (Figure 5e), the ¹⁹F spectrum at 298 K visibly evolves over time (t = 0 h corresponds to a measurement directly after thermal annealing at 120 °C). Qualitatively, the same species are present over the whole period but their relative amount changes, suggesting re-equilibration to the most thermodynamically stable state. This process is likely affected by the presence of weak noncovalent interactions.

Figure 5. Structural properties of XB-modulated perovskite materials. ¹⁹F echo-detected and ¹⁹F-¹⁹F spin-diffusion MAS NMR spectra at 9.4 T and 20 kHz MAS. ¹⁹F echo-detected MAS NMR spectra of (a) neat **TFDIB** and mechanochemical bulk modulated (m–) (b) PbI₂ and MAI, as well as (c) MAPbI₃ and α -FAPbI₃ at 298 K. (d) ¹⁹F echo-detected MAS NMR spectra of (d) neat **TFDIB** and mechanochemical bulk m–MAPbI₃ with the (e) evolution of the ¹⁹F echo-detected MAS NMR spectra of m- α -FAPbI₃ at 298 K over time indicating the dynamic nature of the interaction with the modulator. Modulated (m–) materials contain 5 mol% of the **TFDIB** (10 mol% in the case of m-PbI₂). ¹⁹F-¹⁹F spin-diffusion MAS NMR spectra at 9.4 T, 20 kHz MAS, and 298 K of f) neat **TFDIB** and mechanochemical bulk modulated g) PbI₂, h) MAPbI₃, and i) α -FAPbI₃. Further experimental details (recycle delays and number of scans) are reported in the SI (Table S2), along with the confirmation that the probe background does not contribute to the detected signals (Figure S2).

To scrutinize the nature of the two **TFDIB** species observed experimentally for all the modulated samples by ¹⁹F NMR (species **1** at –108 ppm and –119 ppm, and species **2** at –116 ppm), we investigated different binding modes between **TFDIB** and the α -FAPbI₃ surface by means of DFT calculations (for more details see Section S2 in the SI, Figures S3–S11, and Tables S3–S6). We compared the experimental ¹⁹F chemical shifts with calculated chemical shifts for different binding modes. We investigated both *symmetric* (S; Figure 1c and Figure S4–S5 in the SI) and *asymmetric* (A) binding modes (Figure 1b and Figure S3 in the SI).

Moreover, although higher directionality of XB is expected as compared to hydrogen bonding,²⁷⁻²⁹ we also considered the possibility of **TFDIB** occupying the A-site position on the perovskite surface (in modes *Aa* and *Sa* shown in Figure 1b–c). The ¹⁹F chemical shifts were calculated using planewave DFT (described in Section S2 of the SI) and compared to the experimental data (summarized in Figure 6).

The calculated ¹⁹F chemical shifts for each of the asymmetric *Aa* modes are clustered into two distinct groups, separated by around 10 – 20 ppm (see Table S5, SI). These groups correspond, within the expected DFT error, to the experimental ¹⁹F chemical shifts of species **1** (Figure 6). In contrast, the ¹⁹F chemical shifts of the symmetric *Sa* modes are more spread out (at least three groups per mode) and are shifted to much lower chemical shifts (up to -145 ppm), which is not in agreement with any of the observed ¹⁹F species, excluding the bifunctional A-site binding (i.e. *Sa* mode) for XB modulators.

Figure 6. DFT calculations of the XB binding modes. Top: Optimized structures of the various binding modes of the **TFDIB** modulator. Bottom: DFT-calculated ¹⁹F chemical shifts for the investigated modes (*Ax, Sx, Sa,* and *Aa*) and experimental ¹⁹F chemical shifts of the species (**1** and **2**), suggesting absence of the *Sa* interaction modes. The solid lines (red and blue) indicate the estimated mean deviation between experimental and calculated ¹⁹F chemical shifts of 7 ppm. The dashed lines (red and blue) indicate the approximated maximum error between experimental and calculated ¹⁹F chemical shifts of around 10 ppm. For details see Section S2 in the SI.

Since XB interaction takes place through the σ hole (Figure 2), rendering halogen bonding highly directional,²⁷⁻²⁹ it is envisaged that the bifunctional halogen bonding would be more likely to take place through binding with the iodide anions of the $[PbI_6]^4$ octahedra, corresponding to the Sx mode. To further assess this hypothesis, we generated an ensemble of 270 XB mode structures (details in Section S2 of the SI) and we considered two main halogen binding modes, namely the Sx, where the TFDIB cations are interlocked between two FAPbI3 surfaces (similar to a 'Dion-Jacobson-type' layered perovskite motifs¹⁰, *Sx-DJ* or *Sx*), and Ax, where the XB occurs asymmetrically on the surface of the perovskite with alternating TFDIB cations shifted with respect to one another (resembling 'Ruddlesden-Poppertype' layered perovskites⁴¹; *Sx-RP* or *Ax*, as detailed in Figure S6 of the SI and represented in Figure 6). After DFT optimization that included fully-relativistic corrections, we selected an ensemble of 16 halogen binding modes (5 from the Ax and 11 from the Sx modes), for which we calculated ¹⁹F chemical shifts (details in Section S2 of the SI).

The calculated ¹⁹F chemical shifts for both the *Sx* and the Ax modes (symmetric crosslinking, Figure 2b and Figure 6) match, within the expected DFT error, the experimental ¹⁹F chemical shifts. While the *Aa* species agree more closely with those of species 1, the *Sx/Ax* align well with the shifts of species 2. The Sx modes are found to be energetically more favorable and their spread is in better agreement with the experimental values, whereas the absolute positions of the Ax modes are in better agreement with the species 2. Furthermore, the relative positions of the ¹⁹F chemical shifts of the Aa (asymmetric surface binding, Figure 2b and Figure 6) and Sx/Ax modes display the same trend as the relative positions of the experimental ¹⁹F chemical shifts of species 1 and 2 (Figure 6), respectively, confirming the assignments. To the best of our knowledge, this finding provides the first atomic-level evidence of a long-hypothesized bifunctional molecular crosslinking in hybrid perovskite materials, in this case via halogen bonding. The existence of these species in the XB-modulated perovskites is expected to affect their photovoltaic performance.

Photovoltaic Performance Upon XB Modulation

Photovoltaic (PV) devices of the *n-i-p* architecture were fabricated by assembling the constituent layers as described in the Experimental Section: FTO/(40 nm) c- $TiO_2/(250 \text{ nm})$ mp- $TiO_2/(450 \text{ nm})$ perovskite/(180 nm) 2,2',7,7'-tetrakis-(*N*,*N*-di-4-methoxyphenylamino)-9,9'-spirobifluorene (Spiro-OMeTAD)/(80 nm) Au. The thicknesses of the layers were estimated by cross-sectional SEM imaging (Figure 7a, inset). The effect of the XB mod-

ulator TFDIB on the photovoltaic devices was tested by either adding it directly into the perovskite precursor solution or by casting it as a modulating layer at the interface between the perovskite and the Spiro-OMeTAD (optimization conditions are detailed in Section S3 of the SI). It was found that higher concentrations (50 mM) of the XB modulator inside the precursor solution provides gains in the open circuit voltage (Voc; Figure S12–S13, SI). However, the fill factor (FF) and the short circuit current density (J_{SC}) are adversely affected, resulting in lower efficiency as compared to control cells without the XB modulator. In contrast, when applying lower concentrations (10 mM), a gain in $V_{\rm OC}$ is achieved without compromising the $J_{\rm SC}$, with a minor effect on the FF, resulting in efficiencies slightly lower than those of control devices (Figure S13, SI). The performances were, however, superior when the XB modulator was applied as an interlayer (Figures S14–S15, SI).

Figure 7. Photovoltaic performance of perovskite solar cells. *J*-*V* curves of representative (a) control and (b) XB-modulated devices in reverse and forward bias with the PV metrics. The cross-sectional SEM image of the device is shown in the inset in a). IPCE spectrum of the champion (c) control and (d) XB-modulated devices with the projected photocurrents (in blue) derived from integrating the IPCE over the spectral emission.

Different concentrations in the interlayer precursor solution (5–50 mM) were tested to define the conditions that result in devices with the best characteristics (Figure S14–S20, SI). It was found that, for concentrations below 50 mM, varying the concentration of the XB modulator has little effect on the conversion efficiency of the devices, and that XB modulator concentration of 10 mM results in higher power conversion efficiencies (PCE > 20%) and features better overall reproducibility. Thereby, the study focuses on devices with the XB modulator as an interlayer (Figure S14–S16, SI). The average PV metrics display values of $J_{SC} = 24.4$ mA cm⁻², $V_{OC} = 1.07$ V, FF = 0.78 and PCE = 20.4% for pristine, and $J_{SC} = 24.4$ mA cm⁻², $V_{OC} = 1.08$ V, FF = 0.78 and PCE = 20.6% for XB-modulated devices

(Figure 7a–d; champion cells are shown in Figure S16 of the SI with PV device statistics shown in Figure 8a–d). The current densities of 23.6 mA cm⁻² derived by integrating the incident-photon-conversion-efficiency (IPCE) spectra ($J^{\rm NT}$) were in good agreement with the values obtained from the *J*-*V* curves (Figure 7c–d), which excludes any significant spectral mismatch between the simulator and AM 1.5G solar source. Hysteresis in the XB-modulated cells is only found to be slightly affected.

Figure 8. Performance of XB-modulated perovskite solar cells. (a–d) PCE statistics based on 21 solar cells. *J-V* curves are recorded at a scanning rate of 50 mV s⁻¹ under standard AM 1.5G solar radiation and reverse bias (from V_{OC} to J_{SC}) of pristine (control, black) and XB-modulated (red) devices. (e) Evolution of the PCE based on MPP tracking of unsealed PSCs with aperture area of 0.16 cm² using pristine (black) and XB (red) perovskite films under continuous illumination under nitrogen at ambient temperature. f) Contact angle measurements with the water droplet of the pristine (control) and XB-modulated perovskite films.

The long-term operational stability measurements of the modulated devices highlight their superior performances as compared to those using the pristine perovskite (Figure 8e and Figure S18, SI). The improvement is particularly evident for the devices employing XB-modulated interlayers. Evolution of the maximum power point (MPP) under continuous illumination under nitrogen at room temperature for 500 h shows that the XB-modulated devices retain more than 80% of their initial efficiency, while the control devices retain only about 70% (Figure 8e). The possible role of the modulator in affecting the ion migration could be relevant for long-term operational stability.

Halogen bonding to the halide ions, as well as the capacity of fluoroarene moieties to bind halide ions via π -anion interactions,⁴² was assumed to result in the changes in the ion migration. We have probed ion migration upon insertion of the modulator by conducting temperature-dependent transient capacitance measurements on pristine and modulated perovskite solar cells to establish whether the presence of the modulator results in changes of the halide mobility in the corresponding devices (details are provided in Section S4, SI).²³ The transient ion drift measurements at variable temperatures suggest two mobile anion species with activation energies of 0.12 and 0.10 eV and diffusion coefficients of 3.6×10^{-12} and 2.0×10^{-11} cm²s⁻¹ for the pristine samples (Figures S21-S23 and Tables S7-S8, SI). Upon modulation, both the activation energies and the diffusion coefficients remain comparable, indicating that the effect of the modulation is not primarily related to ion migration under these experimental conditions. We thereby assume that this is more likely to result from the relative stabilization of the a-FAPbI₃ phase, as suggested by the XRD analysis. Furthermore, the hydrophobic nature of the modulator is important for protecting the perovskite from moisture and oxygen exposure, among other degrading factors.43-45 The contact angle measurements of XBmodulated films show a minor increase compared to those of the pristine ones (Figure 8f), presumably as a result of employing small concentrations of the modulator in conjunction with a highly hydrophobic antisolvent. The resulting operational stability enhancement without compromising the performance highlights the potential of supramolecular modulation via weak noncovalent interactions such as halogen bonding for solar cell advancement.

Conclusion

In summary, we have shown the potential of bifunctional halogen bonding to modulate the properties of hybrid lead halide perovskites by employing 1,2,4,5-tetrafluoro-3,6-diiodobenzene (**TFDIB**). We have evaluated the atomiclevel mode of interaction of **TFDIB** with perovskites by solid-state NMR spectroscopy in conjunction with DFT calculations, evidencing crosslinking via halogen bonding. By adding the modulator to perovskite formulations, we obtain highly efficient solar cells with solar-to-electric power conversion efficiencies exceeding 20%. Moreover, supramolecular modulation via halogen bonding leads to enhanced stability under continuous illumination without compromising the resulting photovoltaic performance. This emphasizes the potential of approaches exploiting halogen bonding in hybrid perovskite-based photovoltaics.
