Abstract. Beijing is a megacity situated in the rapidly developing Beijing-Tianjin-Hebei region of northern China. In this study, we analyze data on ozone and nitrogen oxide levels obtained at six urban sites in Beijing between the months of July and September. Our goal is to investigate average trends and interpretations over the 2001–2006 period. Average concentrations of NO_x (NO_x=NO+NO_2), O_3, and O_x (O_x=O_3+NO_2) were 49.2±5.9 ppbv, 26.6±2.8 ppbv, and 60.3±1.9 ppbv, respectively. NO_x concentrations decreased linearly at a rate of 3.9±0.5 ppbv/yr after 2002, while ozone concentrations increased at a rate of 1.1±0.5 ppbv/yr during 2001–2006, and O_x concentrations remained nearly constant. The reduction of NO_x emissions and elevated non-methane hydrocarbon (NMHCs) emissions may have contributed to the increased O_3 concentrations in Beijing. When the contributions from Beijing's urban and surrounding areas were disaggregated via trajectory cluster analysis, daily maximum and average O_x concentrations attributable to Beijing's local emissions increased linearly at rates of 1.3±0.6 ppbv/yr and 0.8±0.6 ppbv/yr, while the O_x concentrations attributable to regional areas decreased linearly at rates of 0.6±0.3 ppbv/yr and 0.5±0.3 ppbv/yr, respectively. The decrease in O_x concentrations of the surrounding areas was found to counteract increasing Beijing urban O_x production, leading to nearly constant O_x concentrations in the Beijing region over the study period. Our results may be helpful for redefining government strategies to control the photochemical formation of air pollutants in the Beijing region. Our conclusions have relevance for developing megacities worldwide.

1 Introduction

Ozone is produced naturally both in the Earth's upper atmosphere and at ground level. Tropospheric ozone is both a greenhouse gas (Houghton et al., 2001) and an important source of global O_3 (Akimoto, 2003). Aside from these global effects, emissions of anthropogenic ozone precursors from urban and industrialized areas can elevate ozone concentrations in downwind suburban and rural areas (NRC, 1991). In addition, photochemical ozone is a key determinant of the atmospheric oxidation state and a major constituent of photochemical smog, which impacts local air quality (Finlayson-Pitts and Pitts, 2000). The production of elevated levels of O_3 at ground level is of particular concern because ozone is known to have adverse effects on human health, vegetation, and a variety of materials (NRC, 1991; POPG, 1997). Along with accelerated urbanization, increases in surface ozone concentrations have been observed in areas throughout China (Xiaoyan et al., 1989; Xiaoyan et al., 1995; Zhang et al., 1998; Ma et al., 2000; Xu et al., 2008). Understanding the determinants of tropospheric O_3 formation in Beijing may help us better understand and forecast air quality in Chinese cities and around the globe.

Beijing has a population of 16 million within an area of 16 800 km^2, making it one of the largest and most densely populated cities in Northern China. Coal emissions and photochemical smog pollution have become increasingly serious with the rapid growth of Beijing's industrial sector since the 1980s. Zhang et al. (1998) began measuring O_3 concentrations at a single site in Beijing in 1982. The resulting time series reveals a marked increase in photooxidant concentrations over the 1982–1998 period. Since 1998, pollution from the burning of coal has been reduced substantially
Fig. 1. NO_x and NMHCs emissions and the ratio of NMHCs to NO_x in Beijing, 2001–2006. (National Science and Technology Department of Rural and Social Development Division, 2002; Beijing Municipal Environmental Protection Bureau, 2007; Beijing Municipal Environmental Protection Bureau, 2006; Tsinghua University, 2007).

(Zhang et al., 2006). However, skyrocketing land prices in the downtown area, accompanied by accelerated construction of commercial developments, have led to substantial urban sprawl and the migration of residential neighborhoods to peripheral districts. Changes in urban structure and in residents' lifestyles have increased the number of automobiles in the Beijing region (Beijing Municipal Bureau of Statistics, 2008). Photochemical air pollution from domestic sources has become increasingly problematic. Since Beijing's successful bid in 2001 to host the Olympic Games, the local government has gradually tightened the regulations that govern emissions from automobiles and from non-vehicular sources in the city. These changing regulations have produced rapid shifts in the spatial and temporal distributions of NO_x and NMHCs emissions (total amount of emissions) in the city (Fig. 1). This situation offers us a meaningful context to investigate the relationships between O_3 and its precursors in an urban environment.

In this study, we illustrate the annual trends in atmospheric concentrations of O_3 and related components in Beijing's urban areas during the period from July 2001 until September 2006. A combined approach incorporating emissions inventories, meteorological data, and trajectory cluster analysis is used to evaluate factors influencing O_3 and O_x concentrations in Beijing and to identify strategies for controlling photochemical pollution in that city.

2 Methods

2.1 Data sources

Air quality data were collected at six sites (A1–A6) in downtown Beijing (Fig. 2). These sites are part of the Air Quality Monitoring Network established by the Institute of Atmospheric Physics (IAP). In order to focus on those months of relevance to the Olympic Games, ambient concentrations were recorded hourly throughout July, August, and September. In some cases, data were discarded due to equipment malfunctions, system failures, and power interruptions.

Surface ozone concentrations were measured using a Model 49 or 49C ozone analyzer from Thermo Environmental Instruments (TEI), Inc. NO_x levels were measured using TEI Model 42C and 42CTL NO and NO_2 analyzers. The TEI Model 49 detector was found to exhibit a detection limit of 2 ppbv and a precision of 2 ppbv, while Model 49C had a detection limit of 1 ppbv and a precision of 1 ppbv. Both NO_x analyzers had a precision of 0.4 ppbv, with detection limits for Model 42C and 42CTL of 0.4 ppbv and 0.05 ppbv, respectively.

Data quality was evaluated and certified by the China National Accreditation Board of Laboratories (CNAL) and is consistent with international requirements. IAP personnel strictly adhered to national environmental monitoring standards. Quality control checks, including automatic zero-calibration and span checks of gas analyzers, were performed daily, and manual calibrations with standard gases were conducted weekly. The NO_x analyzers have been
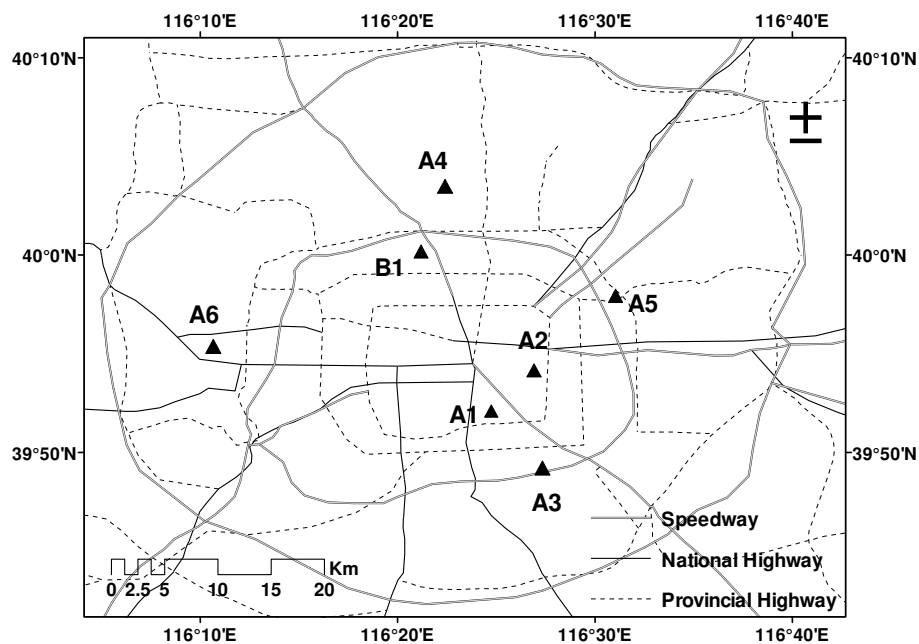

Fig. 2. Monitoring sites in Beijing, 2001–2006.

zero-checked and span-checked using a zero gas generator (TEI Model 111) and an internal ozone source of a multi-gas calibrator (TEI Model 146C) with NO standard (National Centre for Standard Materials, Beijing, China). Multi-point calibrations of the ozone analyzer used an ozone calibrator (TEI Model 49CPS). Sampling methods and instrument protocols, as well as quality assurance/quality control (QA/QC) procedures for air quality monitoring, are described in detail in the Chinese National Environmental Protection Standard, Automated Methods for Ambient Air Quality Monitoring (HJ/T193-2005; State Environmental Protection Administration of China, 2006).

Meteorological variables, including temperature and precipitation, were collected at the B1 site at an altitude of 8 m above ground level (AGL) in downtown Beijing during 2001–2006.

2.2   Total oxidant concentrations

We present a simplified scheme that describes photochemical reactions for O_3 and its precursors in Fig. 3. Atmospheric ozone at ground level is formed in the presence of UV light ($\lambda < 424$ nm) through the direct photolysis of nitrogen dioxide. Nitrogen dioxide, in turn, is formed by the oxidation of nitric oxide, a species typically emitted from fossil fuel combustion (Seinfeld and Pandis, 1998). Two major pathways are known for NO_2 formation in urban atmospheres: NO oxidation either by O_3 or by peroxyl radicals produced by the photooxidation of non-methane hydrocarbons (Atkinson, 2000). In terms of the ozone pathway, it is clear that the O_3 production cycle (Fig. 3b) generates O_3,

whereas the photo-stationary reactions (Fig. 3a) comprise a "do nothing cycle". In urban areas where O_3 precursors are present at sufficiently high concentrations, the radical pathway has been assumed to dominate, especially during summer months. However, the O_3 pathway remains important in areas that are associated with high NO_x emissions, even when the radical pathway dominates. Because NO_x emissions vary across time and space, the contribution of the O_3 pathway has prevented the accurate evaluation of O_3 levels and variability at certain sites. This phenomenon has also presented a barrier to comparisons of O_3 levels between sites with different NO_x concentrations (Kley et al., 1999).

In order to accurately measure the photochemical production of ozone, we followed the approach of Liu (1977) and defined "$O_3 + NO_2 + NO_z + O$" as "total oxidant concentrations" ($NO_z = NO_y - NO_x$). In this study, we use "$O_3 + NO_2$" as an estimate of total oxidant concentrations, because atomic oxygen is an ultra-trace species in the troposphere, while NO_z species interfere with NO_2 measurements. The major advantage of analyzing $O_3 + NO_2$ in addition to O_3 is that $O_3 + NO_2$ closely approximates total oxidant concentrations, and is therefore not affected by reactions between NO and ozone via the O_3 pathway. In other words, "$O_3 + NO_2$" is a better measure of the true photochemical production rate of ozone.

2.3   Trajectory cluster analysis

To evaluate and compare circulation patterns, two-day back-trajectories following the 3-D wind components were calculated by means of the HYSPLIT4 (HYbrid Single-Particle
Fig. 3. Schematics of the reactions involved in NO-to-NO$_2$ conversion and O$_3$ formation in **(a)** NO-NO$_2$-O$_3$ systems in the absence of NMHCs, and **(b)** NO-NO$_2$-O$_3$ systems in the presence of NMHCs.

Lagrangian Integrated Trajectory, version 4.7, http://ready.arl.noaa.gov/HYSPLIT.php) model in isentropic coordinates, with 1-h time resolution. HYSPLIT is a well-known trajectory model, updated several times over the last two decades (Draxler and Taylor; 1982; Draxler, 1992; Draxler and Hess, 1997, 1998; Draxler and Rolph, 2003), and now is a complete system for computing simple trajectories for complex dispersion and deposition simulations using either puff or particle approaches. Gridded NCEP FNL (Final) Operational Global Analysis data (http://dss.ucar.edu/datasets/ds083.2/) were used in HYSPLIT calculations for the years 2001–2006. Its salient characteristics are a modest spatial resolution (1°×1°), a temporal resolution of 6 h, global coverage, and the inclusion of observations in the final analysis. The location of the backward trajectory end point was the Meteorological station (B1) with an altitude of 100 m above ground level (AGL), which was roughly at the center of these six sites.

The back trajectories technique is a useful tool in tracing source regions of air pollution and determining transport patterns at receptor sites in general. Although they do not represent exactly the path of an air parcel, they are suitable for identifying particular synoptic situations (Stohl et al., 1995; Stunder, 1996; Stohl, 1998). Considering the large uncertainty and limited significance of a single back trajectory (Stohl, 1998), a more reliable representation of the synoptic airflow in a given region can be achieved through the reconstruction and analysis of a large number of atmospheric trajectories. By doing so, errors in the individual trajectories tend to be averaged out. Cluster analysis is a simple statistical method that identifies homogeneous groups of members,

such as atmospheric trajectories, within large datasets. It has been demonstrated that clusters of back trajectories arriving at a specific location can serve as a surrogate of different synoptic circulation patterns (Dorling et al., 1992; Dorling and Davies, 1995).

In this study, a total of 13 248 two-day trajectories (number of days times number of hours times number of years) were generated. A data reduction technique (P-mode PCA in SPSS v.13) was used to investigate fluctuations over consecutive 6-h intervals of a suite of latitude and longitude. The number of principal components (PC) to be retained was decided using two methods: graphically with a scree test and by examining a scree plot of eigennumber versus eigenvalue for a major break in the plot (Cattell, 1966), retaining PCs with an eigenvector value greater than 1.0 (Preisendorfer an Mobley, 1988). Both methods suggested retaining five PCs, which explained 95.6% of the variance in the original matrix.

To generate clustered trajectories, a non-hierarchical clustering algorithm (k-means algorithm in SPSS v.13) was applied to the principal component scores for each hour. The component scores matrix (13 248 h times 5 PCs) obtained from PCA served as the input matrix for cluster analysis. The reduced size and the absence of co-linearity in the component scores matrix make it ideal data for clustering. This method was originally developed as an iterative classification process from a selected number of representative trajectories called "seeds" (Dorling et al., 1992). A sufficiently large number of synthetic seeds (30 trajectories) were created for Beijing, covering the spread of the individual trajectories. Each of the real PCs were then assigned to the seed that was closest in terms of the distance between their corresponding PCs. The "seed" or "average" PC of each cluster was then recalculated from its members, each time recalculating the cluster averages until all PCs were correctly assigned. The number of clusters was reduced by merging the two clusters whose average PCs are closest. Sudden changes in the total root-mean-square deviation as the number of clusters was reduced were interpreted as the merging of clusters of PCs that were significantly different in terms of the wind directions and speeds that they represented. This statistical test showed that the optimal number of clusters is 7.

Figure 4 displays the trajectory clusters for these six years. Our chosen sites in Beijing are predominantly influenced by air masses from the south, consistent with the powerful effects of the Asian summer monsoon. Nearly 45% of the air masses reaching Beijing originate from the south, approximately 30% from northern China, and 25% from the local area. These seven catalogs with different marks in Fig. 4 were then merged into two catalogs. The first catalog, named Class I, is marked with crosses (+) in Fig. 4b, and its back-trajectories in the cluster are much shorter than the back-trajectories in other oriented clusters and stay relatively close to their origin. The second catalog, named Class II, included the rest six catalogs except Class I in Fig. 4. Through the second stage cluster analysis, longer and

3 Results and discussion

This section is divided into four subsections. First, there is a brief comparison of pollutant concentrations at sites with different pollution characteristics. In the second and third subsections, annual July–September trends of average concentrations and diurnal variability in O_3 and its related precursors are discussed, respectively. At last, NO_x and NMHCs emissions, cluster trajectories analysis and meteorological data are applied to show the interpretations of ozone, total oxidants concentration changes and observed interannual variability, respectively.

3.1 Comparison of pollutant concentrations at sites with different pollution characteristics

Table 2 summarizes pollutant data recorded from sites A1–A6 in July–September 2001–2006. The A1 site, located in the center of Beijing, is generally exposed to greater concentrations of vehicular NO_x emissions. The reaction of more ozone with vehicular NO results in lower ozone levels at A1 than at the other sites, while lower combined NO_x emissions cause higher ozone levels at the A6 site. This inverse spatial relationship between ozone and NO_x levels is consistent with the findings of other groups (Bower et al., 1994; Mckendry, 1993; Wu and Chan, 2000; Chou et al., 2006). Site-to-site variability is clearly closely related to site characteristics. Differences in annual average ozone concentrations among the various sites were determined by taking into account differences in the rates of surface ozone elimination mechanisms at the respective locations. However, the potential for surface ozone production in ground level was found

shorter back-trajectories were disaggregated, as they approximately represent total pollutant concentrations due to regional contributions and local emission sources, respectively. Using this method, local circulation and regional transportation are disaggregated and average concentrations of Class I and Class II are calculated (Table 1), standing for the influence of local and regional pollutants, respectively.

to be roughly equivalent across all of the 6 sites in downtown Beijing. Figure 5 shows scatter plots of O_x concentrations at A1 and A6. A first-order linear regression of O_x concentrations at these two points identified a strong correlation with a slope of 0.83. Possible explanations for variations in pollutant concentrations between different sites have been discussed by Clapp and Jenkin (2001). Explanations include variability in the fractional contributions of NO_2 to emitted NO_x, differences that might be linked to different vehicle fleet compositions, and different driving conditions around each site. Although both concentrations exhibit small site-to-site variations, O_x concentrations are thought to represent regional total oxidant levels better than O_3 concentrations.

3.2 Annual July–September trends with interannual variability

Table 3 lists the trends in average annual July–September concentrations of NO, NO_2, NO_x, O_3, O_3_max (daily maximum 1 h ozone), and O_x in these six sites during the period 2001–2006. All the sites showed downward trends (ranged from −2.1 to −8.0 ppbv/yr for NO_x mean) in the period of 2002–2006. Five sites showed upward trends (ranged from 1.0 to 2.2 ppbv/yr for ozone mean and from 1.5 to 3.2 ppbv/yr for ozone daily maximum) during 2001–2006. On the other hand, the A6 station showed downward trends (−2.0 ppbv/yr for ozone mean and −3.9 ppbv/yr for ozone daily maximum) due to the relocation of industrial areas. Moreover, two each of the six sites showed upward, downward and no significant trends for O_x. When average concentrations of these six sites were considered, linear regressions showed that concentrations of NO, NO_2, and NO_x decreased at rates of 2.0±0.4 ppbv/yr (slope ± standard deviation of the mean for the first order linear regression), 1.9±0.1 ppbv/yr, and 3.9±0.5 ppbv/yr since 2002,

respectively (Fig. 6a). Meanwhile, concentrations of O_3 and O_3_max increased by 1.1±0.5 ppbv/yr and 1.6±0.7 ppbv/yr, respectively. However, concentrations of O_x showed no significant trends. Additionally, concentrations of O_3, O_3_max and O_x showed an interannual variability in which odd-year concentrations exceeded those for even years, with values of 2.0 ppbv, 5.9 ppbv and 4.0 ppbv, respectively (Fig. 6b).

3.3 Annual July–September trends of diurnal variability in O_3 concentration and in related precursors

Figure 7a–d illustrate the average diurnal variation in the hourly averages of NO_2, NO, O_x and O_3, respectively, in Beijing during 2001–2006. Maximum mean NO concentrations are observed between 07:00 h–08:00 h and at midnight (Fig. 7b). From 07:00 h on, NO is converted to NO_2 via reaction with O_3, while NO_2 is converted back to NO during daylight hours as a result of photolysis, which also leads to the regeneration of O_3 (Jenkin and Clemitshaw, 2000). During the early daylight hours, NO concentrations rise, mainly due to the increase in traffic. Figure 7a shows that the NO_2 production rates are greatest near 08:00 h (after dawn), a result that can be explained by reactions that involve NO and hydrocarbons (Finlayson-Pitts and Pitts, 1986; Seinfeld and Pandis, 1998). After 08:00 h, [NO] diminishes until it reaches its lowest levels between 14:00 h–15:00 h (Fig. 7b). This NO decrease matches the increase in O_3 levels. The highest O_3 and O_x values are evident between 14:00 h and
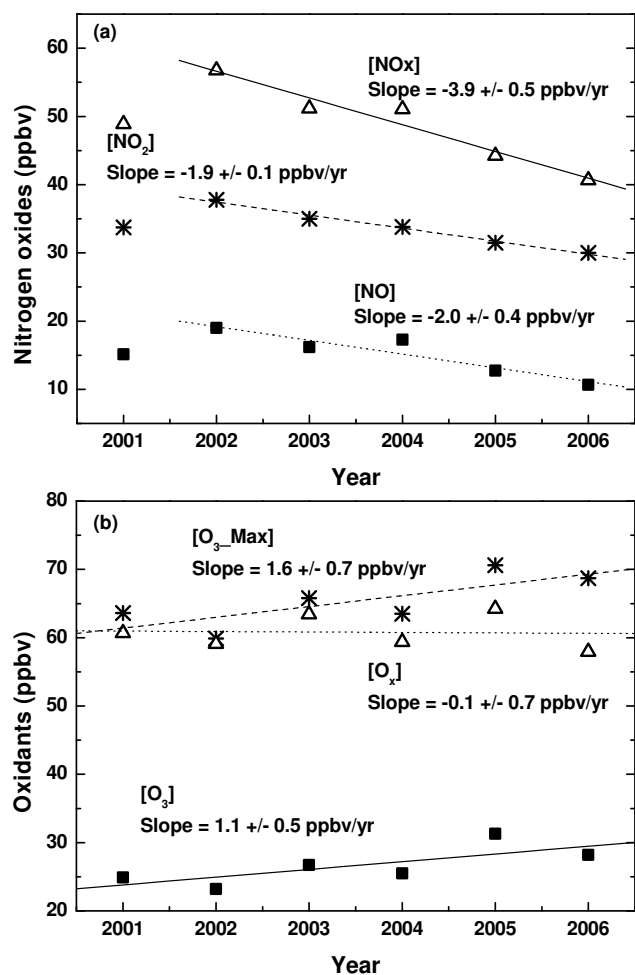

Fig. 6. Concentration trends for **(a)** NO, NO_2, NO_x, **(b)** O_3, O_x, 2001–2006. The concentration of each species represents an average of measurements from all six representative stations in Beijing from July to September.

Fig. 7. Diurnal trends of NO_2 **(a)**, NO **(b)**, O_x **(c)**, O_3 **(d)**, 2001–2006. The concentration of each species represents an average of measurements taken from the six representative stations in Beijing.

15:00 h, after which O_3 and O_x levels decrease gradually (Fig. 7c–d). NO_2 decreases as O_3 increases, with rising concentrations after 15:00 h. NO increases with the onset of evening traffic, reaching its highest value between 01:00 h and 03:00 h. As NO reacts with O_3, ozone concentrations fall. Another factor that influences pollutant concentrations is the height of the mixing layer over the city. From 08:00 h to 14:00–15:00 h, increasing global radiation and an increase in the height of the mixing layer (Ulke and Mazzeo, 1998) lead to a decrease in hourly NO_x concentrations and a trend toward increasing O_3. At night, low mixing layer heights may allow hourly NO_x concentrations to increase.

Figure 8a shows the annual July–September changes in the daily average morning maximum of the relative diurnal variations of NO and NO_2. Daily average morning maximum values for NO and NO_2 decrease linearly at rates of 3.4 ppbv/yr and 2.5 ppbv/yr, respectively, after 2002, suggesting that mobile emissions of NO_x in Beijing may have
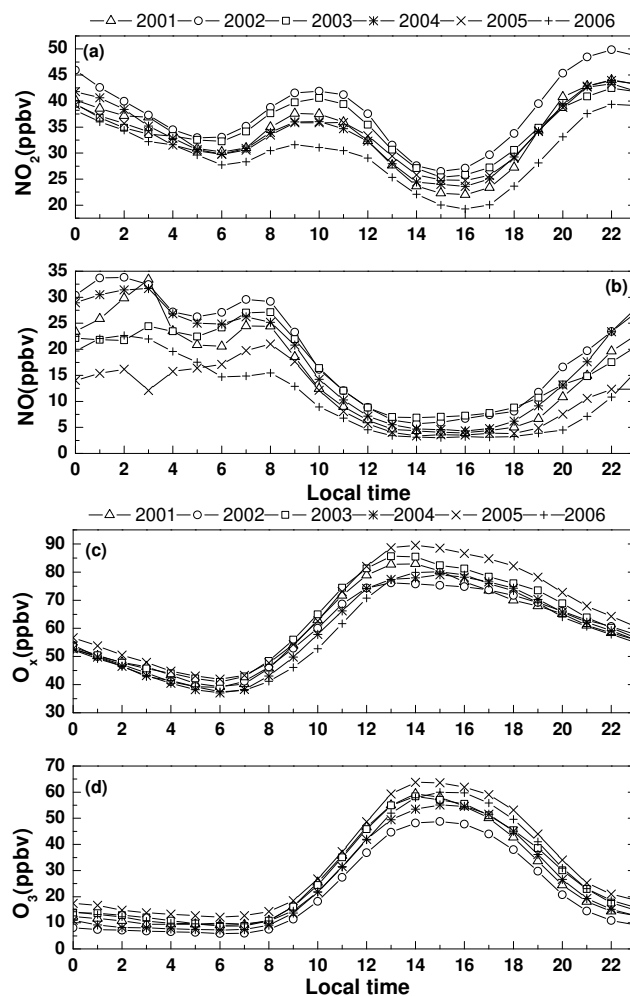

decreased significantly over the period 2002–2006. Figure 8b shows the annual July–September changes in the daily average maximum and minimum of the relative diurnal variations of oxidants in Beijing. Maximum and minimum O_3 concentrations increased linearly at rates of 1.6 ppbv/yr and 0.7 ppbv/yr, respectively. Maximum and minimum O_x concentrations varied linearly at rates of 1.0 ppbv/yr and -0.1 ppbv/yr, respectively. The increase in daily maximum $[O_x]$ relative to constant daily minimum concentrations suggests increasing diurnal variations in ozone concentrations throughout Beijing.

From the above analysis, we arrive at two major conclusions. First, given that the morning maxima of NO and NO_2 concentrations reflect the mobile emission of NO_x, we conclude that the increasing daily minimum $[O_3]$ is likely due to reactions with the decreasing daily morning [NO], accounting for the constant daily minimum $[O_x]$ observed. Second, the increase of the daily maximum $[O_x]$, relative constancy of

Table 3. Annual July–September mean NO_x and oxidants concentration trends in the six sites.

sites	NO (ppbv/yr)	NO_2 (ppbv/yr)	NO_x (ppbv/yr)	O_3 (ppbv/yr)	O_x (ppbv/yr)	O_3_max (ppbv/yr)
A1	−4.8(±1.2)	−3.2(±0.7)	−8.0(±1.9)	1.7(±1.0)	−1.2(±2.1)	2.7(±2.4)

A4	−1.4(±1.3)	−4.2(±0.7)	−5.4(±2.0)	1.9(±1.9)	0.1(±3.0)	3.1(±2.2)
A5	−1.7(±1.0)	−0.5(±0.5)	−2.2(±1.5)	2.2(±1.5)	1.4(±2.0)	3.2(±2.3)
A6	−0.7(±0.3)	−1.4(±0.9)	−2.1(±1.2)	−2.0(±1.6)	−1.8(±2.2)	−3.9(±2.1)
Average	−2.0(±0.4)	−1.9(±0.1)	−3.9(±0.5)	1.1(±0.5)	−0.1(±0.7)	1.6(±0.7)

the daily minimum [O_x], and increase of the daily amplitude of [O_x] reflect enhanced local photochemical production.

3.4 Interpretation of concentration changes

3.4.1 Interpretation of ozone concentration changes

Concentrations of NO_x species, which are known O_3 precursors, decreased significantly after 2002 (Table 3). However, over the same period, we also observed increased O_3 concentrations (Table 3). Seinfeld and Pandis (1998) reported worsening photochemical air pollution under decreasing concentrations of NO_x precursors in metropolitan areas, and pointed to changes in the NMHCs/NO_x ratio as a possible explanation. In the absence of direct measurements of NMHCs concentrations, we use the emission ratio of NMHCs to NO_x in Beijing to explore this hypothesis. Figure 1 illustrates the increasing emission of NMHCs and the decreasing emission of NO_x in Beijing. Given the increasing emission ratio of NMHCs to NO_x, the observed trends of average and maximum [O_3] seem consistent with a system in which Seinfeld's NMHCs/NO_x hypothesis describes the relationship between pollution controls and ozone formation rates.

3.4.2 Interpretation of total oxidant concentration changes

NO, NO_2, O_3, O_x, and O_x_max were calculated for each year by local area and by region based on trajectory cluster analysis. While NO concentrations from all sources were nearly identical, NO_2, O_3, O_x, and O_x_max concentrations in local air masses exceeded those of air masses from regional sources by more than 3 ppbv, 6 ppbv, 9 ppbv and 21 ppbv, respectively (Table 1). Figure 9a shows trends in the daily maximum and average concentrations of total oxidants in local air masses and 75th percentile concentrations of daily maximum aggregate total oxidants over the 2001–2006 period. In contrast to the nearly constant annual July–September average concentrations of total oxidants (Table 1), the maxima and average exhibit a significant upward trend, with slopes of 1.3±0.6 ppbv/yr and 0.8±0.6 ppbv/yr, respectively (Fig. 9a).

Because the highest 25% of concentrations were measured primarily at times when air masses originated from the Beijing urban area (Table 1), the 75th percentile concentration measurements also show an increasing trend at a rate of 1.2±0.5 ppbv/yr. Given the increasing emission of NMHCs and the decreasing emission of NO_x, an increasing photochemical production rate of O_x is to be expected. Therefore, the fact that total oxidant concentrations remained largely constant during the 2001–2006 period is of great interest.

The concentration of O_x at a given location is made up of two contributions: a regional contribution, equivalent to the background O_x concentration, and a local contribution, which depends on the level of primary pollution in the area (Nicolas et al., 2005). Considering the consistency between the trends of peak concentrations for oxidants and their precursors, we can infer that oxidant production from photochemical reactions in Beijing's local air masses likely increased during the 2001–2006 period. Hence, the contradictory observations of constant average oxidant levels over this period must be due to unknown factors that exactly offset this increased O_x production. The decrease in regional oxidant levels was identified as the most likely source of this phenomenon. The data in Fig. 9b suggest a decreasing trend in the daily maximum and average total oxidant concentrations from regional area sources. In terms of annual July–September averages, the concentrations of daily maximum and average O_x decreased by 0.6±0.3 ppbv/yr and 0.5±0.3 ppbv/yr, respectively, during the 2001–2006 period. We speculate that decreasing regional background oxidant concentrations may have offset the increased local average oxidant production over this period, accounting for the constant average oxidant levels observed.

3.4.3 Interpretation of the observed interannual variability

In addition to precursor emissions, O_3 concentrations in urban areas are directly tied to meteorological conditions, such as maximum temperatures, solar intensity, precipitation, and stagnation. NRC (1991), Davidson (1993), and Wakamatsu et al. (1996) identified a positive relationship between
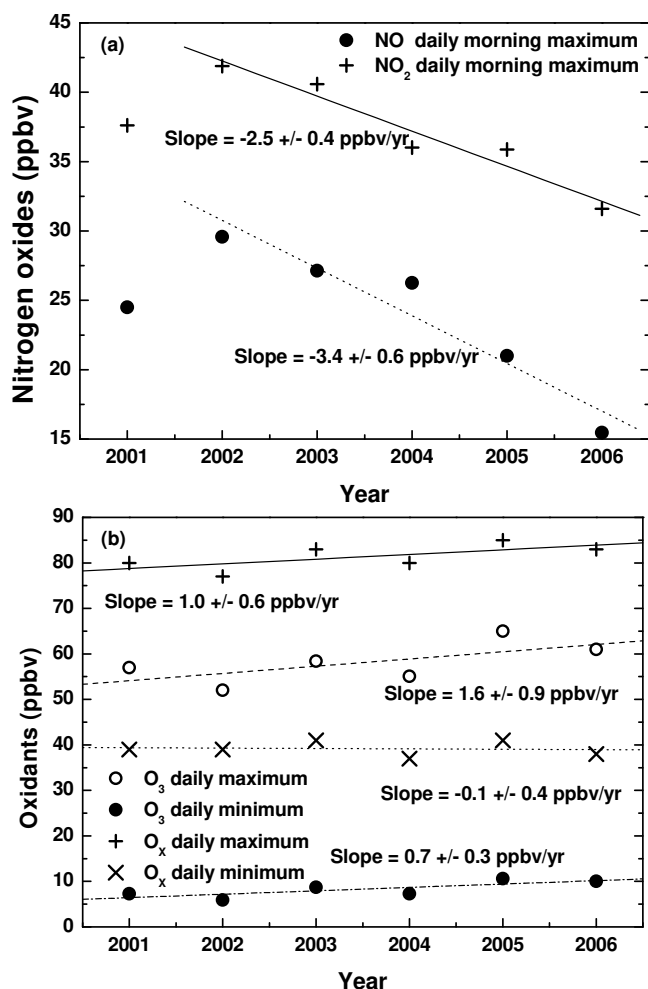

Fig. 8. Annual July–September trends **(a)** in the daily morning maximum concentrations of NO, NO$_2$ and **(b)** in the daily average maximum and minimum concentrations of O$_3$, O$_x$, in 2001-2006. The concentration of each species represents an average of measurements taken from the six representative stations in Beijing.

Fig. 9. Annual July–September trends of **(a)** daily maximum and average total oxidant concentrations from local area sources (Class I) and 75th percentile daily maximum total oxidant concentrations from all sources, and **(b)** daily maximum and average total oxidant concentrations from regional area sources (Class II) during the 2001–2006 period. The concentration of each species represents the average of measurements across all six representative stations in Beijing.

ambient maximum temperature and daily maximum O$_3$ concentrations. Liu, et al. (1994) also indicated that the absence of precipitation is a crucial parameter accompanying elevated noontime ozone levels. The relationship between the daily average maximum temperatures, total precipitation, and O$_3$ concentrations during 2001–2006 is shown in Fig. 10. A positive correlation is evident between the daily average maximum temperature and O$_3$ concentration, while increased precipitation is found to negatively impact O$_3$ production. These two factors appear to account for the observed interannual variability of O$_3$ and O$_x$ concentrations in Beijing.

Additionally, the tropical sea surface temperature (SST) and the East Asian summer monsoon are related in a system resembling the tropical biennial oscillation (TBO) described by Meehl (1987, 1997) and others. There is also a correlation between the monsoon and the tropical western Pacific
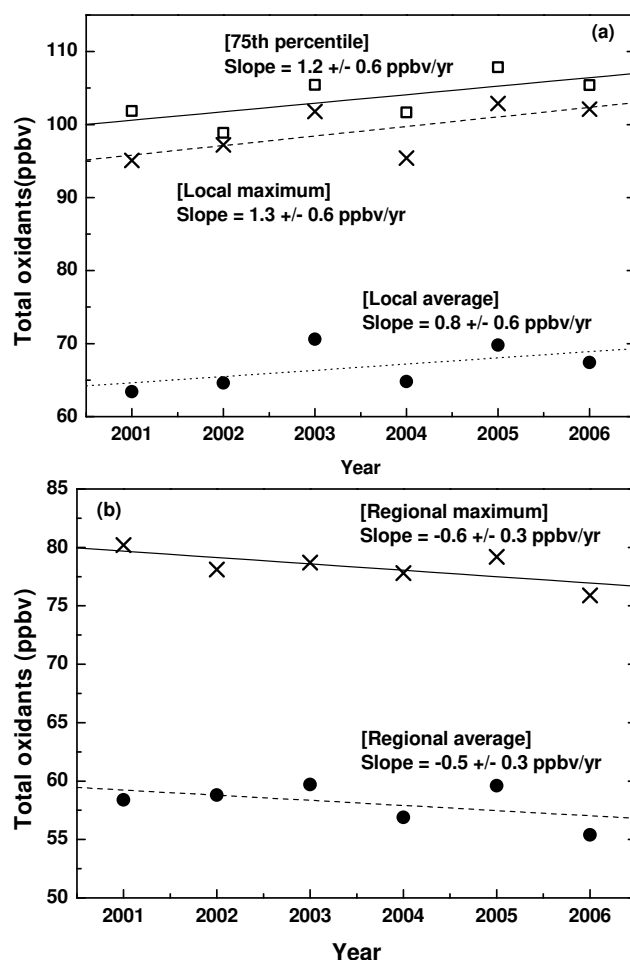

SST that is opposite to that of the eastern Pacific SST (Wang et al., 2001). In this TBO relationship, the summer monsoon in China will be strong after an El Niño-like condition in the preceding winter. The SST anomalies change sign in northern spring just before this strong monsoon starts, and in the following year, a weak summer monsoon will follow a La Niña-like condition in the winter. This TBO relationship of the summer monsoon in China resulted in the interannual variability of temperature and precipitation. Considering the relationship between meteorology and ozone mixing ratio, this interannual variability will likely continue to occur on alternate years. However, ozone and precursors should be observed in Beijing continuously in order to confirm this assertion.
Fig. 10. Annual July–September trends of daily average maximum temperatures, total precipitation and O_3 concentrations in July–September during 2001–2006.

4 Conclusions

This work aimed to identify the reasons for increased O_3 concentrations by analyzing the relationship between O_3 and its precursors. We tracked O_3+NO_2 in addition to O_3 because the former is approximately equal to the total oxidant concentration and can reveal regional atmospheric oxidation capacity better than O_3 alone.

We present annual July–September trends in the concentrations of surface ozone and related components in Beijing. Our results suggest a decrease in average $[NO_x]$ and an increase in average $[O_3]$, with significant site-to-site variability. Our data also show a relatively constant average $[O_x]$, with minimal site-to-site variability. Furthermore, we identified an increase in the daily amplitude of diurnal concentration variations, in the context of a interannual variability for O_3 and O_x. All of these trends lead us to three major conclusions:

1. Beijing's surface ozone variability is accentuated primarily by a decrease in NO_x emissions and an increase in NMHCs emissions.

2. A decrease in regional O_x concentrations seems to counteract increasing local O_x production levels, and it leads to near-constant O_x levels in Beijing.

3. The influence of meteorological factors is the main explanation for the observed interannual variability.

Increasing daily maximum ozone concentrations may exert negative impacts on human health and vegetation. Therefore, control measures should be taken to avoid further exacerbation of ozone pollution. Measures should include efforts to reduce NMHCs emissions.
