# 1 ABSTRACT

2 Dolomites occur extensively in the lower Cretaceous along syn-sedimentary fault zones of the Baiyinchagan Sag, westernmost Erlian Basin, within a predominantly fluvial-lacustrine 3 4 sedimentary sequence. Four types of dolomite are identified, associated with hydrothermal 5 minerals such as natrolite, analcime and Fe-bearing magnesite. The finely-crystalline dolomites 6 consist of anhedral to subhedral crystals (2 to 10 µm), evenly commixed with terrigenous sediments that occur either as matrix supporting grains (Fd1) or as massive argillaceous 7 8 dolostone (Fd2). Medium-crystalline (Md) dolomites are composed of subhedral to euhedral 9 crystals aggregates (50 to 250 µm) and occur in syn-sedimentary deformation laminae/bands. 10 Coarse-crystalline (Cd) dolomites consist of non-planar crystals (mean size >1 mm), and occur as fracture infills crosscutting the other dolomite types. Fd1, Md and Cd dolomites have similar 11 values of  $\delta^{18}$ O (-20.5 to -11.0 ‰ Vienna PeeDee Belemnite) and  $\delta^{13}$ C (+1.4 to +4.5 ‰ Vienna 12 PeeDee Belemnite), but Fd2 dolomites are isotopically distinct ( $\delta^{18}O - 8.5$  to -2.3% Vienna 13 PeeDee Belemnite;  $\delta^{13}C$  +1.4‰ to +8.6‰ Vienna PeeDee Belemnite). Samples define three 14 which differ in light rare-earth elements vs. high rare-earth elements 15 groups 16 enrichment/depletion and significance of Tb, Yb and Dy anomalies. Md dolomites have signatures that indicate formation from brines at very high temperature, with salinities of 11.8 17 to 23.2 eq. wt. % NaCl and T<sub>h</sub> values of 167 to 283°C. The calculated temperatures of Fd1 and 18 19 Cd dolomites extend to slightly lower values (141 to 282°C), while Fd2 dolomites are distinctly 20 cooler (81 to 124°C). These results suggest that the dolomites formed from hydrothermal fluid 21 during and/or penecontemporaneous with sediment deposition. Faults and fractures bounding 22 the basin were important conduits through which high-temperature Mg-rich fluids discharged, driven by an abnormally high heat flux associated with local volcanism. It is thought that 23 24 differing amounts of cooling and degassing of these hydrothermal fluids, and of mixing with 25 lake waters, facilitated the precipitation of dolomite and associated minerals, and resulted in the 26 petrographic and geochemical differences between the dolomites.

# 4 INTRODUCTION

5 For more than two centuries, the "dolomite problem" has remained one of the most disputed topics 6 in sedimentary research. Studies suggest that dolomites form in two main realms: either sedimentary 7 or hydrothermal environments. Various mechanisms for early dolomitization have been proposed, 8 both primary microbial and early replacement by sea water-derived fluids, including tidal pumping, 9 sub-mixing zone circulation and brine reflux (e.g. Kaufman et al., 1991; Whitaker & Smart 1993; 10 Jones et al., 2004; Machel, 2004; Nader et al., 2004; Deng et al., 2010). However, in recent years 11 many studies have focused on the formation of hydrothermal dolomites in marine and continental 12 environments (e.g. Machel and Lonnee, 2002; Lavoie et al., 2010; Lapponi, et al., 2014). This is 13 motivated by their implications for understanding ancient hydrothermal activity, their potential as 14 hydrocarbon reservoirs (e.g. Dong et al., 2016; Mansurbeg et al., 2016; Feng et al., 2017) and as 15 hosts to Mississippi Valley-Type lead-zinc mineralization (e.g. Leach and Sangster, 1993; Hendry 16 et al., 2015; Wei et al., 2015). In most cases, hydrothermal dolomites form near faults developed in 17 extensional tectonic settings, where faults provide pathways for hydrothermal fluids (e.g. 18 Vandeginste et al., 2012; Martín-Martín et al., 2013; Martín-Martín et al., 2015; Hollis et al., 2017). 19 Hydrothermal dolomite is generally considered as a post-depositional product, forming from 20 hydrothermal fluids (hotter than ambient rock) by replacement of precursors including limestones 21 or preexisting dolomites, or by infilling of vugs and fractures (Machel and Lonnee, 2002; Lonnee 22 and Machel, 2006). However, a few studies of modern hydrothermal systems suggest that primary 23 dolomites can precipitate from a mixture of hydrothermal fluids and sea water or lake water (e.g. 24 Barnes and O'Neil, 1971; Eickmann et al., 2009). Considerable controversy remains as to whether 25 massive primary dolomites can be produced directly from hydrothermal fluids.

26

27 There have been very few prior studies of the massive dolomites within the Cretaceous Tengger

1 Formation in the Erlian Basin. Based on previous studies (Guo et al., 2012; Zhong et al., 2015), 2 these dolomites are distinguished by a range of features which suggest their formation relates to 3 hydrothermal processes. Firstly, the dolomites are interbedded, or mixed with normal lacustrine 4 sediments (mainly mudstone and siltstone) and, secondly, they are associated with several high-5 temperature minerals (e.g., natrolite, analcime) rarely seen in dolomites. These observations have 6 led to a hypothesis that the dolomites are synsedimentary, formed as primary lacustrine precipitates 7 associated with discharge of hydrothermal fluids into a lake basin. This study builds on this work 8 and offers the first detailed investigation of the petrographic texture and geochemical composition 9 of these lacustrine dolomites in the Erlian Basin. It is also a clear example of research into the 10 genesis of dolomites in a continental rift basin in China that examines the interaction between 11 hydrothermal activities and sedimentary process. This mechanism has been suggested for similar 12 dolomites in other continental basins of China, including the Santanghu, Jiuquan and Bohaiwan 13 basins (Zheng et al., 2006; Liu et al., 2010, 2011; Li et al., 2012a, b; Wen et al., 2014; Song et al., 14 2015; Jiao et al., 2018). Understanding the formation and distribution of these dolomites is 15 important because they are important as hydrocarbon reservoirs.

16

This study aims to document the petrographic and geochemical characteristics of Tengger Formation dolomites, to understand the reasons behind their characteristic variations, and to elucidate their genetic origins. To achieve this, it is performed by: (i) petrographic examination; (ii) stable oxygen and carbon isotope analysis; (iii) rare-earth element analysis; and (iv) fluid-inclusion studies on dolomite samples from the Baiyinchagan Sag in the westernmost part of the Erlian Basin.

# 23 GEOLOGICAL SETTING AND STUDY AREA

The Erlian Basin is a Mesozoic continental rift basin sitting on folded Hercynian basement in northern China (*Dou et al., 1998; Huang et al., 2003; Li et al., 2012*) (Fig. 1A). During the Late Jurassic and Early Cretaceous, the area experienced the subduction of the Pacific Plate under the Eurasian Plate, accompanied by powerful volcanism. This volcanism is represented in the basin by

1 andesite, pyroclastic rocks, tuffs and related rocks (Ren et al., 1998; Xiao and Yang., 2001; Lu et al., 2 2011; Ji et al., 2012; Li et al., 2014). The Baiyinchagan Sag is located in the westernmost part of the basin and covers an area of 3,200 km<sup>2</sup> and can be subdivided into three parts: the eastern sub-3 sag, the low Maohu uplift and the western sub-sag (Fig. 1B). The sag has undergone a complex 4 5 evolution involving repeated subsidence and uplift events associated with the multiple tectonic cycles recorded within the basin. The main phase of syn-rift deposition in the Baiyinchagan Sag 6 7 occurred during the Early Cretaceous and comprised a series of fluvial-lacustrine sediments, which 8 lie unconformably on Jurassic volcanic basement. From bottom to top, the Cretaceous strata include 9 the Arshan Formation (K<sub>1</sub>a,  $\sim$  250 to 1300 m), the Tengger Formation (K<sub>1</sub>t,  $\sim$  90 to 830 m), the 10 Duhongmu Formation (K<sub>1</sub>d,  $\sim$  220 to 1550 m) and the Saihantala Formation (K<sub>1</sub>s,  $\sim$  0 to 300 m), 11 which comprise mainly dark terrigenous detrital sediments (Fig. 1C) (Huang et al., 2003).

12

13 The main study area is located in the southwestern part of the western sub-sag, which is 14 elongated NW–SE, and extends ~20 km in length with a width of ~10 km. The study area is bounded 15 by the ENE-WSW trending Tala fault zone and the NE-SW trending Chagan-Wente fault zone, 16 resulting in the formation of an asymmetric half-graben (Fig. 1D). These two sets of fault zones are 17 composed of a series of normal faults and remained active until the end of the Early Cretaceous 18 (Deng, 2006). They developed upwards from the basement and appear to have fundamentally 19 controlled processes of lacustrine deposition. The present study was conducted mainly in the 20 Tengger Formation, which can be subdivided into the Lower and Upper Members. The Lower 21 Member consists of clastic sedimentary rocks, mainly conglomerates, sandstones and mudstones. 22 The Upper Member is composed of argillaceous dolomite, dolomitic mudstone, siltstones and 23 mudstones.

# 24 SAMPLES AND ANALYTICAL METHODS

More than fifty wells have been drilled into the Tengger Formation in the Baiyinchagan Sag from
which detailed well-logging information is available. Some 312 m of dolomite of the Tengger
Formation were examined and described from eight cored wells (*X2*, *X26*, *X31*, *X32*, *X36*, *X3-69*, *C36 and C39*; Table S1; Fig. 2) preserved in library of the Zhongyuan Oil Field. All the cores are

located in the Upper Member of the Tengger Formation, with a total of 185 core samples being collected and analyzed to calibrate data from wireline logs in the cored intervals (Fig. 3). All core samples were carefully examined and 93 samples were selected for thin sections. Based on the petrographic results, representative samples were further selected for microprobe and geochemical analysis.

6

7 The thin sections were cut to a standard thickness of 0.03 mm, polished and stained with 8 Alizarin Red-S and potassium ferricyanide (*Dickson, 1966*), and analyzed under a Leica PM4500 9 polarizing microscope (Leica, Wetzlar, Germany). Cathodoluminescence (CL) microscopy was 10 performed using a CL8200MK5-2 (CITL company, Hatfield, UK) instrument with a 17-kV beam 11 and a current intensity of 300 to 500 µA. Textural characteristics of dolomite and associated mineral 12 assemblages were investigated in detail with a scanning electron microscope (SEM) Quanta 200 13 FEI with a dispersive X-ray spectrometer (EDS) (FEI Company, Hillsboro, OR, USA). Petrographic 14 microscopy, CL and SEM were conducted at the China University of Petroleum, Beijing. Analysis 15 of major-element composition of minerals was carried out by electron probe micro analysis (EPMA) using an electron microprobe EPMA-1600 (15-kV, beam size 1×10<sup>-8</sup> Å, beam spot size 1µm, 16 17 correction ZAF, standard GB/T 115, 074-2008; Shimadzu Corporation, Beijing, China) in the 18 Laboratory of Geoanalysis and Geochronology of Geological Research Centre, Tianjing, China.

19

20 The different types of dolomites were sampled for oxygen and carbon isotopic and rare-earth 21 element analyses using a two-speed rotary tool to extract the desired quantity of powdered dolomite 22 after carefully targeting apparently homogeneous areas of each thin section. For oxygen and carbon 23 isotopic analysis, approximately 5 mg of micro-drilled dolomite was reacted with pure phosphoric 24 acid for 12 h at 50°C. The resultant CO<sub>2</sub> was analyzed for its oxygen and carbon isotopic ratios 25 using a Finnigan-MAT252 gas-isotope mass spectrometer (Thermo Fisher Scientific, Waltham, MA, 26 USA) at the University of Petroleum, Beijing. The results based on replicate analyses of GBW 04405, are given using conventional  $\delta^{13}$ C and  $\delta^{18}$ O notations with respect to the Vienna PeeDee 27 28 Belemnite (VPDB) standard, with an analytical error of  $\pm 0.1\%$ .

Rare-earth element (REE) contents were measured using a NexION300D ICP-MS (PerkinElmer Inc., Waltham, MA, USA) at the Beijing Research Institute of Uranium Geology (BRIUG). Approximately 2 mg of sample powder was reacted with 2.5% HNO<sub>3</sub>. Precision was in the range 5 to 10%, and the element detection limit was 0.002 ppm. REE concentrations were normalized to NACS (North American Composite Shale; *Gromet et al., 1985*). Anomalies of europium, (Eu/Eu\*)<sub>SN</sub> = Eu<sub>SN</sub>/(0.67Sm<sub>SN</sub> + 0.33Tb<sub>SN</sub>) and cerium, (Ce/Ce\*)<sub>SN</sub> = Ce<sub>SN</sub>/(0.5La<sub>SN</sub> + 0.5Pr<sub>SN</sub>) were calculated according to the formulae of *Bau and Dulski* (1996).

9

Fluid-inclusion microthermometry was performed on doubly polished thin sections using a Linkam mK 1000 heating-freezing stage calibrated using synthetic fluid-inclusion standards at the Petroleum Geology Research and Central Laboratory, Beijing. Homogenization temperatures  $(T_h)$ and ice melting temperatures  $(T_m)$  were measured according to the procedures of *Shepherd et al.* (1985). The accuracy of  $T_h$  and Tm is within 3°C and 0.5°C, respectively. Salinity estimates were calculated by applying the measured Tm values to the equation of *Bodnar* (1993), and reported as equivalent weight percent NaCl (eq. wt. % NaCl).

17

# 18 LITHOSTRATIGRAPHIC FEATURES AND OCCURRENCE OF 19 DOLOMITE

20 Logging data and core observation indicated that the Upper Member of Tengger Formation is a 21 mixed sedimentary sequence of argillaceous dolomite, dolomitic mudstone, mudstone, siltstone and 22 rare sandstone (Fig. 3). In well logs, rocks containing dolomite are electrically characterized by 23 natural gamma (GR,  $\sim$  300 to 1500 API) which is significantly higher than that of the normal terrigenous sediments (GR, <250 API) in the study area (Fig. 3). In addition, rocks containing 24 dolomite are locally identified by ultra-high and ultra-low deep resistivity (ILD,  $\sim 0.2$  to 2000  $\Omega \cdot m$ ) 25 26 (Fig. 3). Combining log data with observation of cores, four lithological units from bottom to top 27 can be defined in the Upper Member of the Tengger Formation on the basic of their lithological 28 association (Fig. 2): Unit I is 40 to 170 m thick and is a mixture with highly variable amounts of

1 argillaceous dolomite, dolomitic mudstone and mudstone/siltstone; Unit II is 100 to 190 m thick and 2 is dominated by argillaceous dolomite and dolomitic mudstone locally intercalated mudstone; Unit 3 III is 70 to 150 m thick and is characterized by frequent alternation of dolomite and mudstone/siltstone; Unit IV is 40 to 150 m thick and is dominated by mudstone, with thin beds of 4 5 dolomite at the top of the unit in many wells. In each unit, rocks containing dolomite mainly show unique structures, like white grains, laminae and band, and breccia, which markedly distinguish 6 7 from dark colour lacustrine clastic rocks (Fig. 3). Dolomites and lacustrine clastic rocks appear 8 alternately, indicating that the sedimentary environment changed dramatically at that time.

9

10 The occurrence of dolomites in the Upper Member of the Tengger Formation is proximal to 11 the fault zones and developed on the footwall blocks of normal faults (Figs 2 and 3). The thickness 12 of dolomite in the NW-SE cross-section is shown to decrease from the faults towards the centre of 13 the basin, although the total stratigraphic thickness increases (Fig. 3). It is also apparent that the 14 dolomite bodies have mounded geometries and gradually thin then pinch out into the surrounding 15 mudstone. The dolomite bodies appear to be elongated NE-SW, parallel to the fault zones (Fig. 2). 16 Their precise dimensions are difficult to assess because the single layer of dolomite-bearing rock is 17 too thin and there is a lack of obvious contacts between dolomite-bearing rock and terrigenous 18 sediments, but the total thickness of dolomite-bearing rocks reaches a maximum of 320 m and 19 dolomite-bearing rock extends for several thousands of square kilometers over the study area (Fig. 20 2).

# 21 **PETROGRAPHIC FEATURES OF DOLOMITE**

Based on observations of structure, texture and mineral composition in argillaceous dolomite and dolomitic mudstone, four types of dolomite can be identified. However, information on the abundance and occurrence of each type of dolomite at a larger scale is not available because of observations are limited to cores. In the following section the petrographic characteristics of these dolomites are described in order of decreasing abundance.

### 1 Fine-crystalline (Fd1 and Fd2) dolomite

2 Fd1 dolomite (26 to 37%) occurs mixed with very fine terrigenous feldspar (7 to 37%), analcime and natrolite (8 to 19%) and/or minor amounts of illite ( $\leq$ 10%), as a dark-grey matrix supporting a 3 4 mass of white grains (Fig. 4A to D). Fd1 dolomite deposits have a thickness ranging from 5 centimetres to several metres. Grains are scattered throughout the matrix, but with the long axis of 6 the white grains often oriented normal to the bedding planes (Fig. 4A to D). The grains vary in shape 7 and may be irregular and elongate (Fig. 4A and B), small and spherical (Fig. 4C), or droplet-shape 8 with a small tail (Fig. 4D). They range in size from coarse-grained (>1 mm) to fine-grained (<5 9 μm). In some cases, grains are wrapped around by depositional laminae (Fig. 4F), indicating a syn-10 sedimentary relationship between grains and laminae. The major components of these grains are 11 natrolite, with euhedral crystals up to 200 µm long and 50 µm wide (Fig. 4F and G), and/or analcime 12 with octahedral crystals of 10 to 200 µm diameter (Fig. 4H and I). Secondary components include 13 radiaxial-fibrous Fe-bearing magnesite, cubic pyrite and/or subhedral-euhedral dolomite (Fig. 4F, 14 H, I and J), which replaces natrolite and analcime, and rare occurrences of barite within the 15 intracrystalline pores of natrolite grains (Fig. 4K).

16

Fd2 dolomite (25 to 36%) also occurs mixed with fine terrigenous feldspar (25 to 44%), natrolite and analcime (6 to 37%) and illite (<10%) to form finely laminated or massive dolomitic mudstone (Fig. 4E). These dolomitic mudstones form layers up to several metres in thickness which can be difficult to differentiate from overlying or underlying mudstones.

21

Although Fd1 and Fd2 dolomites show different rock structures, they are microcrystalline, with a crystalline size range of 2 to 10  $\mu$ m (Fig. 4F, H and L). SEM observations indicate that crystals are anhedral to subhedral (Fig. 4M), and sometimes spherical. CL reveals the presence of slightly luminescent Fd2 dolomite with a non-dull-red colour (Fig. 4N), while Fd1 dolomite shows no luminescence. The fine terrigenous feldspar, which commonly appears synchronic and concordant with the fine-crystalline dolomites, is general anhedral and ranges in size from 2 to 10  $\mu$ m (Fig. 4M), and the majority are albite with a small amount of K-feldspar. There is no petrographic evidence of 1 primary replacement fabrics, or of dissolution/replacement of fine-crystalline dolomite.

### 2 Medium-crystalline (Md) dolomite

3 Md dolomite occurs as white or light-yellow laminae (from several um to mm thick) which alternate 4 with dark-grey laminae composed of terrigenous sediments and are interlayered with dark-grey 5 mudstone (Fig. 5A and B). The dark-grey laminae are dominated by fine albite and minor amount 6 of K-feldspar. In most cases, the white laminae show small (cm) scale folding and faulting as a result of plastic and soft sediment deformation in an unconsolidated to semi-consolidated deposit (Fig. 5A 7 8 and B). Md dolomite is present in white bands several cm in thickness, which also show evidence 9 of soft deformation and movement induced by syn-sedimentary fracturing (Fig. 5C and D). Locally, 10 the white consolidated laminae and bands are broken to form irregular breccia of varied size (Figs 11 4B, 5C and D), comparable to syn-depositional brecciation textures described by *Selleck* (1978).

12

13 Md dolomite is made up of interlocking subhedral to euhedral crystal aggregates with a size 14 range of 50 to 250 µm, with poorly defined individual crystal boundaries (Fig. 5E, F, G and H). Md 15 dolomites are slightly stained by Alizarin Red-S and K-ferricyanide indicative of a high iron content 16 (not in Fd dolomites due to their small size). These dolomite crystals show a unique internal structure 17 with no alternating rims and display no luminescence (Fig. 5I). Calcite is observed between the 18 dolomite crystals as an intercrystalline pore infill, and consists of dull luminescent sparry crystals 19 (Fig. 5I). Natrolite and analcime are generally replaced by Md dolomites in the white laminae and 20 bands (Fig. 5E, F and J). Compared with the laminae, the bands contain more Md dolomite, but less 21 natrolite, analcime and calcite.

22

### 23 Coarse-crystalline (Cd) dolomite

Cd dolomite fills fractures that crosscut the bedded Fd and Md dolomites indicating they are a later phase of dolomitization. This type of dolomite is easily distinguished by its white colour, contrasting with the dark-grey colour of other dolomites, and forms irregular masses in pores and voids (Fig. 6A). However, the Cd dolomite was identified in only one of the eight wells studied and occurs over 1 a length of < 0.5 m of the core.

2

3 Cd dolomite is composed of multiple individual, cloudy, non-planar dolomite crystals, with a 4 mean size of >1 mm (Fig. 6B and C). The dolomite is lightly stained by Alizarin Red-S and K-5 ferricyanide. Under cross-polarized light, the dolomite crystals are characterized by typical 6 undulatory extinction comparable with that of the saddle dolomite described by Nader et al. (2004) 7 and Haeri-Ardakani et al. (2013). However, these crystals exhibit non-luminescence under CL, and 8 show no cloudy centres and clear rims or more complex zonation. There are scattered sub-9 millimetre-sized intercrystalline pores between the Cd crystals (Fig. 6B), and a small amount of 10 analcime and radiaxial-fibrous Fe-bearing magnesite intergrown with the Cd dolomites (Fig. 6C).

11

# **12 GEOCHEMICAL FEATURES OF DOLOMITE**

### 13 Major-element composition

14 Major-element composition of CaO, MgO and FeO was determined by electron probe micro-15 analysis (EPMA) to characterize different types of dolomite (Fd1, Fd2, Md and Cd dolomite) (Table 1), and are plotted in Fig. 7. All dolomites have >1.6 wt. % FeO and are defined as ferroan dolomite 16 17 (Tucker and Wright, 1990). Fd1 and Fd2 dolomites have a similar composition, forming a group 18 (n=29) with 24.92 ± 1.57 wt. % CaO, 14.37 ± 1.46 wt. % MgO and 7.65 ± 1.71 wt. % FeO contents 19 (Fig. 7A and B). Compared to Fd1 and Fd2 dolomites, Cd dolomites show a slightly higher content 20 of CaO (mean  $26.50 \pm 2.28$  wt. %, n=17) and MgO (mean  $15.44 \pm 1.66$  wt.%, n=17) (Fig. 7A), but 21 have a very similar FeO content (mean  $7.68 \pm 1.23$  wt. %, n=17) (Fig. 7B). Interestingly, Md 22 dolomites are chemically distinct from the other dolomites, with the highest CaO content (mean 23  $26.84 \pm 1.51$  wt. %, n=35) and MgO content (mean  $18.10 \pm 1.24$  wt. %, n=35) and the lowest FeO 24 content (mean  $4.47 \pm 1.08$  wt. %, n=35) (Fig. 7A and B). Md dolomite displays a significantly higher 25 Mg/Ca ratio (mean  $0.94 \pm 0.04$ , n=35) than the Fd1, Fd 2 and Cd dolomites ( $0.81 \pm 0.06$ , n=46), 26 despite also having a lower FeO content. The inverse relationship between FeO and MgO may reflect the ease with which  $Fe^{2+}$  substitutes for  $Mg^{2+}$  rather than  $Ca^{2+}$  (*Gregg et al., 2015*). 27

### 1 Oxygen and carbon isotopes

2 The  $\delta^{13}$ C values of all types of dolomite lie within a narrow range (+2% to +4%), with the exception of Fd2 dolomite, which extend to much heavier  $\delta^{13}$ C values. In contrast, the  $\delta^{18}$ O values for the 3 dolomites are spread over a relatively wide range (Table 2; Table S2). Based on their  $\delta^{18}$ O and  $\delta^{13}$ C 4 5 values, the different types of dolomites can be divided into two groups (Fig. 8). Fd2 dolomites have the highest isotopic values, with  $\delta^{18}$ O values of -8.5 to -4.3‰ (mean -6.8 ± 1.5 ‰, n=5) and  $\delta^{13}$ C 6 values of  $\pm 1.4\%$  to  $\pm 8.6\%$  (mean  $\pm 4.9 \pm 2.5\%$ , n=5) (Fig. 8). In comparison, the isotopic values 7 for Fd1 and Md dolomites are very similar, forming a group (n=19) with lower  $\delta^{18}$ O values (mean 8  $-14.3 \pm 2.5\%$ ) and lower  $\delta^{13}$ C values (mean 3.1 ± 0.9‰) (Fig. 8).  $\delta^{18}$ O and  $\delta^{13}$ C values for Cd 9 dolomites lie within the range of values for Fd1 and Md dolomites, -16.4 to -14.2‰ and from +3.2 10 11 to +3.9‰, respectively (Fig. 8). In addition, two samples of dolomite cement in the mudstone shows very different isotopic values, with a  $\delta^{18}$ O value of -4.5 to -3.4‰ and  $\delta^{13}$ C value of -4.6 to -2.0‰ 12 13 (Fig. 8).

14

### 15 **Rare-earth elements (REE)**

# REE concentration of the Upper Formation of the Tengger Formation dolomites and normal mudstone is summarized in Table 2, whereas the NASC-normalized (*Gromet et al., 1985*) REE profiles of dolomites and mudstone is shown in Fig. 9.

19

20 Fd1 and Fd2 dolomites have similar  $\Sigma$ REE contents and wide ranges of values relative to the 21 other types of dolomite (Table 2), with mean respective total  $\Sigma REE$  contents of 214.08 ppm (range 22 135.15 to 328.08 ppm) and 212.14 ppm (range 151.14 to 307.56 ppm). For the ratio of  $La_N/Yb_N$ , a 23 wide range of Fd1 and Fd2 dolomites (n=7) have moderate values ranging 1.02 to 1.86, but a smaller 24 subset with higher values ranging 2.22 to 3.27 (n=6) indicates light rare-earth element (LREE) 25 enrichment (Kučera et al., 2009; Wen et al., 2014). From the REE<sub>N</sub> pattern (Fig. 9A), Fd1 and Fd2 26 dolomites appear to be enriched in LREEs with a slight right-inclining distribution, and slight high 27 rare-earth element (HREE) depletion with a fluctuating HREE distribution, and display slightly 28 positive Tb and Yb anomalies, and a slightly negative Dy anomaly. Conversely, SREE contents of

1 Md dolomites lie in a relatively narrow range of 126.13 to 180.81 ppm (mean 158.32 ppm) and they 2 show a pronounced HREE enrichment ( $La_N/Yb_N = 0.54$  to 1.0). The REE<sub>N</sub> profile of Md dolomites 3 exhibit pronounced LREE depletion with a slight left-inclining distribution, and HREE enrichment 4 with a flat HREE distribution, and display slightly positive Tb and Yb anomalies, except for one 5 sample which has pronounced positive Eu and Gd anomalies (Fig. 9B). The two samples of Cd dolomite yield the lowest  $\Sigma REE$  contents with mean value of 93.23 ppm and show a slight LREE 6 7 enrichment ( $La_N/Yb_N = 1.39$  to 1.93). The REE<sub>N</sub> profile of Cd dolomite shows slight LREE 8 enrichment with a flat distribution, and a slight HREE depletion with a weak right-inclining 9 distribution, and displays pronounced positive Eu and Tb anomalies and negative Dy and Er 10 anomalies (Fig. 9C). No dolomite types show a positive Eu anomaly (Eu/Eu\* mean 0.89) except for 11 Cd dolomite, which has a slightly positive Eu anomaly (Eu/Eu\* mean 1.21), and all exhibit a very 12 slightly negative Ce anomaly (Table 2).

Mudstone in the study area, considered as the background lacustrine sediment, yields stable
 ΣREE content ranging from 203.20 to 257.21 ppm (mean 233.64 ppm). The mean of La<sub>N</sub>/Yb<sub>N</sub> ratio
 is 1.30 suggesting a weak HREE enrichment. The mudstones show a relatively flat REE distribution
 with slight HREE depletion, with a slightly negative Eu and positive Yb anomalies (Fig. 9D).

17

### 18 Fluid-inclusion microthermometry

19 Microthermometric measurements focused on primary two-phase (liquid and vapour) fluid 20 inclusions from the dolomites. Because of their small size, fine-crystalline dolomites are not suitable 21 for microthermometry. Fluid inclusions from Md dolomites show irregular to elongate shapes with 22 a size range of 4 to 12  $\mu$ m (Fig. 10A). These have a wide range of homogenization temperature ( $T_{\rm h}$ ) 23 from 167 to 283°C, but a negatively skewed distribution with 55% yielding temperatures between 24 160 and 200°C (Fig. 11A). Their ice-melting temperatures ( $T_m$ ) vary widely from -21.2 to -8.1°C, 25 and calculated salinities of the fluids from which the dolomite formed are in the range from 11.8 to 26 23.2 eq. wt. % NaCl (Bodnar, 1993) (Table 3; Fig. 11C). The coarse dolomite cement contained no 27 workable primary inclusions, probably because of dissolution and recrystallization, which removed 28 the inclusions in the weakest parts of crystal. For this reason, no coarse dolomite could be analyzed 1 for their inclusions.

2

Natrolite, which occurs in association with dolomite, is also suitable for microthermometric studies. Primary inclusions in natrolite are relatively large (8 to 20  $\mu$ m) and have regular and elongated shapes (Fig. 10B). Natrolite inclusions have rather higher homogenization temperatures ( $T_h$  from 232 to 351°C; Table 3; Fig. 11B) and their ice-melting temperatures range from -25.2 to -16.9°C, suggesting a salinity of 19.8 to 25.7 eq. wt. % NaCl (Table 3; Fig. 11C). Thus both homogenization temperatures and salinity of the fluids precipitating the natrolite appear to be distinctly higher than those from which the dolomite formed.

10

## 11 **DISCUSSION**

12 Four main types of dolomite were recognized in the Tengger Formation: Fd1 dolomites form a 13 matrix that supports synchronously deposited white scattered grains of natrolite, analcine and Fe-14 bearing magnesite; massive or laminated Fd2 dolomites without synchronously deposited grains; 15 Md dolomites are limited to laminae and bands which exhibit deformation structures; Cd dolomites 16 are restricted to fracture infills. This study considers the Tengger Formation dolomites as primary 17 products of direct precipitation during sedimentary and/or penecontemporaneous stages from 18 hydrothermal fluids. These fluids have supplied magnesium for dolomite generation (e.g. Last and 19 Deckker, 1990) and resulted in their high iron content.

20

### 21 Genetic model for syn-sedimentary hydrothermal dolomites

It is proposed that the input of hydrothermal fluids associated with volcanism at the base of the lake were synchronous with deposition and could have altered physical and chemical conditions sufficiently to facilitate the deposition of dolomites. The geochemical potential of hydrothermal fluids to form fault-related dolomites in the subsurface has been previously demonstrated, for example by *Nader et al. (2004)* and *Eickmann et al. (2009)*. In the Baiyinchagan Sag, such hydrothermal fluids discharged from faults and fractures into the bottom of the lake would have resulted in mixing with lake water in the presence of unconsolidated normal lacustrine terrigenous sediments. This mixing, together with a decrease in pressure and temperature of the hydrothermal fluid, would have driven the sequential precipitation of the various dolomites and associated minerals, forming the deposits observed in the cores. These dolomites should be called hydrothermal, because they apparently formed at higher than ambient temperature (*Machel and Lonnee, 2002*).

6

7 The vertical alternation between dolomite and mudstone/siltstone suggests that the 8 hydrothermal fluid was introduced into the lake in pulses, with active hydrothermal phases 9 alternating with periods of reduced activity or cessation of hydrothermal discharge. The lateral 10 distribution of dolomites (Fig. 2) suggests rapid decay in precipitation potential with distance from 11 the source of hydrothermal fluids (e.g. Dekov et al., 2014; Lopez et al., 2017). Firstly, the onset of 12 hydrothermal activity was marked by formation of laminae or bands of Md dolomites intercalated 13 with unconsolidated lacustrine sediments layers, giving way up-section to deposition of intermixed 14 muds/silts and Md dolomites. The resulting localized buildup of dolomites associated with discharge 15 of hydrothermal fluid resulted in syn-sedimentary deformation and folding, even syn-depositional 16 brecciation of a number of earlier consolidated rocks such as white laminae and bands, with either 17 local redeposited or transport over a short distance. This would have been followed by a period 18 increased input of hydrothermal fluid, leading to greater upwelling and mixing within the lake. Local 19 to the hydrothermal vents, highly idiomorphic natrolite, analcime, pyrite and/or dolomite and 20 magnesite precipitated, within distinctly shaped grains. More distal from the vents, mixing of 21 hydrothermal fluids with a higher fraction of lake water resulted in Fd1 and Fd2 dolomites and very 22 fine analcime and natrolite precipitates inter-mixed with sediments redeposited in the lake sourced 23 from the surrounding basin. Subsequently, during periods when hydrothermal discharge ceased, 24 normal lacustrine mudstones and/or siltstone deposits accumulated, and no dolomites were formed. 25 Thus, the hydrothermal fluids supplied the basic components for the formation of dolomites, and 26 the lake served as a depositional environment for these components (in the form of the different 27 dolomites, natrolite, analcime and magnesite). The dolomites of the Tengger Formation formed 28 under the influence of both hydrothermal fluids and lake water, and can best be referred to as synsedimentary hydrothermal dolomites. This system may have been comparable to subaqueous
 exhalative systems thought to have formed carbonate chimneys in alkaline lakes of Afar (e.g. *Dekov*,
 *et al.*, 2014) and at depth of more than 600 m in the South China Sea (*Sun et al.*, 2015).

4

# 5 Evidence in support of syn-sedimentary hydrothermal dolomite formation

The proposed model of syn-sedimentary hydrothermal dolomites is supported by four separate lines
of evidence: the large-scale tectonic and depositional environment, the petrography and occurrence
of dolomites, associated minerals, and dolomite geochemical composition.

9

### 10 Tectonic and depositional setting

11 Continental rifting generated a lake basin within which muddy sediments accumulated, with a series 12 of basin-bounding normal faults along which hydrothermal fluid circulated. Although there was 13 little apparent volcanism in the Baiyinchagan Sag during the Early Cretaceous, abundant andesite, 14 rhyolite, and pyroclastic rock was produced in the eastern part of the Erlian Basin (e.g., the 15 Honghaoershute and Saihantala sags; Lu et al., 2011; Ji et al., 2012; Li et al., 2014). This suggests 16 that the study area was under the indirect influence of volcanism. The extensional tectonics and volcanic activity gave rise to an abnormally high local geothermal gradient of *ca* 83°C.km<sup>-1</sup> in the 17 18 Baiyinchagan Sag (Liu and Zhang, 2011), significantly steeper than the current geothermal gradient of ca 35°C.km<sup>-1</sup> (Ren, 1998; Zhao et al., 2001). The proximity of the dolomite to the fault zones 19 20 suggests that the complex network of faults and fractures acted as conduits for migration of 21 hydrothermal fluids (Fig. 2). The active tectonic regime and high heat flux would have both 22 enhanced the permeability of fault/fracture network and provided a drive for convection of 23 hydrothermal fluids (*Nader et al., 2004; Hollis et al., 2017*). The very high fluid temperature (≥300 °C) would be both thermodynamically and kinetically favourable for dolomite generation. 24

1

#### 2 Dolomite texture, structure and composition

The contrasting textures and the high iron content of the different types of dolomite provide direct
evidence for formation from hydrothermal fluids, and associated sedimentary structures point
clearly to a primary origin.

6

Fd1 and Fd2 dolomites are microcrystalline (2 to 10 µm) and occur as non-planar to planar-7 8 subhedral crystals. This indicates that nucleation rate is higher than growth rate, which is 9 characteristic of a high density of nucleation sites in a substrate and/or formation at relatively low temperature (<50 to 100°C) (Gregg and Sibley, 1984). Conditions commensurate with rapid-10 11 precipitation of fine-crystalline dolomite, such as high dolomite supersaturation and presence of 12 precursor carbonates, are generally viewed as occurring in near-surface evaporative and/or shallow-13 burial environments (Hips et al., 2015; Lu et al., 2015; Hou et al., 2016). However, the co-14 occurrence of siliciclastic lacustrine sediments, and the apparent absence of CaCO<sub>3</sub> or abundant 15 evaporites (e.g., gypsum or anhydrite), suggest the fine-crystalline dolomites are primary chemical 16 precipitates penecontemporaneous with deposition of the lacustrine sediments. In addition, fine-17 crystalline dolomites in near-surface or shallow-burial environments tend to have a low (<2%) iron 18 content, whether formed from marine (e.g. Azomani et al., 2013; Olanipekun et al., 2014) or 19 lacustrine water (e.g. Last et al., 2012), whereas those in the Tengger Formation show significantly 20 higher FeO content (>7%) (Table 1; Fig. 7B). This provides clear evidence that the Fd dolomites 21 were not formed simply from lake water, but also involved hydrothermal fluid that was enriched in 22 iron.

23

The interfaces between the Md and Fd dolomites and the lacustrine sediments are sharp, with no evidence of recrystallization of Fd dolomite or patchy replacement. Furthermore, there is an absence of replacement textures, such as submicron calcite domains in the dolomite. Texturally, Md dolomites display crystalline aggregates composed of subhedral to euhedral crystals, which indicates multiple growth episodes of the crystals (*Rosen and Coshell, 1992*). Md dolomites are also non-cathodoluminescent and show no zonation, possibly due to slower crystallization from a stable
and homogeneous fluid (*Machel, 2004*). Laminae and bands of Md dolomites exhibit deformation
structures and brecciation, indicating a syn-sedimentary origin rather than formation during later
diagenesis. The lower FeO content (mean 4.5%) compared to the fine-crystalline dolomites (Table
1; Fig. 7B), may be result from the removal of iron from the fluid via the growth of cubic pyrite.

6

Cd dolomites are a later stage fracture infill, and are characterized by large crystal sizes and
undulatory extinction. The undulatory extinction is indicative of crystal growth at high temperatures
(>60 °C) responsible for distorted crystal lattices (*Warren, 2000*). Compositionally the Cd dolomites
are similar to the Fd dolomites, suggesting precipitation either from similar fluids, or at different
evolutionary stages of the same fluid (*Boni et al. 2000; Warren, 2000*).

12

### 13 Significance of associated minerals

14 All dolomites are associated with unusual and distinctive minerals which provide further evidence 15 for high temperature precipitation. White grains of natrolite and analcime occur evenly mixed with 16 Fd1 dolomite, or replaced by Md dolomite in the white laminae/bands. Natrolite and analcime are 17 commonly euhedral, relatively large (up to 200 µm) crystals, without remnant precursors, and display consistent chemical compositions (Table 1). This mineral assemblage is interpreted to have 18 19 precipitated from hydrothermal fluids in response to changing temperature or other physicochemical 20 conditions, rather than by replacement within a burial environment that would typically produce 21 single-component minerals such as siliceous minerals (Liu et al., 2010).

22

Fluid inclusions in the natrolite have high homogenization temperatures of 232 to 351°C, with salinity from 19.8 to 25.7 eq. NaCl wt. %, indicating formation from a high-salinity hydrothermal fluid. *Ghobarkar and Schäf (1999)* and *Kumar and Chattopadhyaya (2006)* verified under laboratory conditions that natrolite and analcime could directly precipitate from a hydrothermal fluid to produce euhedral crystals, and suggest the crystallizing temperature for analcime is ~50°C higher than that for natrolite. Similarly, magnesite associated with dolomite has been reported to have

1 formed from hydrothermal fluids at high temperatures (>180°C, Herrero et al., 2011; <500°C, 2 Hurai et al., 2011). The cubic form of the pyrite within the dolomite provides further support for 3 formation in a high-temperature environment (Fig. 5H and I). Cubic pyrite has been reported to form at temperatures up to 250 to 300°C (Murowchick and Barnes, 1987; Kouzmanov et al., 2002), 4 but at  $> 450^{\circ}$ C pyrite forms octahedron and pentagonal dodecahedron crystals (*Cai and Zhou, 1993*; 5 Graham and Ohmoto, 1994). The higher temperature and salinity of fluids forming the natrolite, 6 7 relative to that of the Md dolomites (Fig. 11C), implies changes in hydrothermal fluid from which 8 the minerals precipitated. It is proposed that the hydrothermal fluids evolved along a pathway that 9 started with the formation of zeolite, which requires higher temperature and salinity, and consumed 10 Na-Al-Si.

11

12 Cooling of the residual fluids, that were relatively enriched in Fe-Mg-Ca, favoured 13 precipitation of Fe-bearing magnesite and dolomite. Although this would result in a small reduction 14 in the total dissolved solids, the significant reduction in salinity indicated by the fluid inclusion data 15 (from 19.8 to 25.7 eq. wt. % NaCl in the natrolite to 11.8 to 23.2 eq. wt. % NaCl in the medium-16 crystalline dolomite; Fig.11C) suggests that the cooling hydrothermal fluids also mixed with and 17 were diluted by lower salinity lake water. Similar processes are inferred to result in formation of the 18 fine-crystalline dolomite and zeolite which were then mixed with terrigenous sediments, although 19 the fine texture means that changes in the precipitation path cannot be directly observed.

20

### 21 Implications of isotopes and REEs

The isotopic composition of the Fd1, Md and Cd dolomites (Fig. 8) is comparable to that of previously described subsurface hydrothermal dolomites (e.g. *Herrero et al., 2011; Haeri-Ardakani et al., 2013*), whereas the Fd2 dolomites are notably heavier, especially in oxygen. Isotopic values of Fd1 and Fd2 dolomite are distinct from those of dolomite cements in the mudstone (Fig. 8) There is little isotopic fractionation of  ${}^{13}C/{}^{12}C$  with temperature, and thus the  $\delta^{13}C$  value of the dolomite reflects that of the parent fluids (*Tucker and Wright, 1990*). Whilst texturally distinct, the  $\delta^{13}C$  of

most of the different dolomites in the study area lie within the range +2% to +4%, with the 1 2 exception of some Fd2 dolomites with heavier  $\delta^{13}$ C. The latter are interpreted to result from abundant degassing of light CO<sub>2</sub> from ascending hydrothermal fluids reflecting a pressure reduction 3 (*Kele et al.*, 2008). The  $\delta^{18}$ O values of the dolomites reflect both the temperature and the 4 5 composition of the parent fluids, suggesting that precipitation takes place under isotopic equilibrium 6 (Matthews and Katz, 1977; Horita, 2014). Many high-temperature hydrothermal dolomites are interpreted to form from fluids with negative  $\delta^{18}$ O values (Fig. 8) (*Boni et al., 2000; Gasparrinia et* 7 8 al., 2006; Martín-Martín et al., 2015; Hou et al., 2016).

9

10 Given the formation temperature of Md dolomites from fluid inclusions ( $T_h=167$  to 283°C), the method of Land (1983) is used to calculate the fractionation factor between the dolomite and the 11 parent fluids. This suggests  $\delta^{18}$ O values of the parent fluid of +3 to +4‰ SMOW, and formation of 12 13 texturally distinct dolomites from fluids at different temperatures. The highest temperature of 14 formation is for the Cd dolomite (~182 to 221°C), with the Fd1 dolomite formed at temperatures 15 (~141 to 282°C) that were significantly higher than the Fd2 dolomites (~81 to 124°C). The 16 variations in the calculated formation temperatures could be explained by changes in the ratio of 17 lake water (mean annual temperature about 20°C; Chen, 2010) mixing with hot hydrothermal fluids that ascended rapidly from depth. The progressive decrease in  $\delta^{18}$ O values is consistent with that 18 19 observed in hydrothermal carbonate chimneys (Eickmann, et al., 2009; Dekov, et al., 2014), in which 20 different carbonate minerals formed in evolved hydrothermal fluids.

21

The detailed mixing process of hydrothermal fluids also can be revealed by the REEs in the Tengger Formation dolomites. The total REE ( $\Sigma$ REE) content of the dolomites are far higher than those of dolomites of evaporative, reflux, or burial origin (which typically do not exceed 100 ppm; e.g. *Haeri-Ardakani et al., 2013; Liu et al., 2017*) and most samples  $\Sigma$ REE contents are within the range reported for hydrothermal dolomites (30 to 300 ppm) (*Kučera et al., 2009*). The Cd dolomites that are interpreted to have precipitated from hydrothermal fluids to infill fractures exhibit compositions close to a hydrothermal end-member and are characterized by the lowest  $\Sigma$ REE

1 content of all the dolomites (Fig. 9C). The higher SREE contents of the other Tengger Formation 2 dolomites, and the shape of their REE<sub>N</sub> profiles, suggest there was an enhanced influx of REEs. 3 Michard (1989) suggested that a decrease in fluid pH may increase  $\Sigma REE$  content, and laboratory 4 experiments (Pourret et al., 2007) demonstrated that enhanced alkalinity can lead to HREE 5 enrichment. Thus hydrothermal fluids with higher alkalinity could have produced the Md dolomites, 6 resulting in more pronounced HREE enrichment (Fig. 9B). Increased mixing with lake water would 7 decrease the pH of the hydrothermal fluid, accounting for the higher  $\Sigma REE$  of Md dolomites. The 8 pH and alkalinity would continue to decrease as the fraction of lake water increased, resulting in 9 precipitation of Fd1 and Fd2 dolomites with higher REE contents and greater HREE depletion (Fig. 10 9A). There may also be a REE contribution from the non-carbonate fraction, such as siliciclastics 11 which make up more than 5% of the deposits and are typically REE-rich (Banner et al., 1988). The 12 association of Fd1 and Fd2 dolomites with normal lacustrine sediments (feldspars and clays) may 13 also contribute to their relatively higher  $\Sigma REE$  content. Moreover, all dolomites show similar Eu 14 and Ce anomalies, indicating formation under stable redox conditions, such as would be expected 15 with deposition in a deep lake. The Fd1, Fd2 and Md dolomites could have inherited a positive Tb 16 and negative Dy anomaly from a hydrothermal fluid, and a positive Yb anomaly from lake water, 17 because the chemical features of other REEs change systematically along the REE series of parent 18 fluids rather than environment (Sholkovitz and Shen, 1995).

19

20 The supporting evidence above provides clear evidence that the dolomites of the Tengger 21 Formation formed under the influence of both hydrothermal fluids and lake water, with the different 22 dolomite types reflecting different degrees of mixing between two fluids. Theses dolomites thus 23 show important differences from those found in the Tarim and Sichuan basins that appear to have 24 result from alteration of limestone by hydrothermal fluids. The latter are identified as products of a 25 replacement reaction based on preservation of depositional textures and development of zebra and 26 brecciated textures, none of which are seen in the Tengger Formation dolomites, as well as 27 geochemical features inherited from the precursor limestone (e.g. Dong et al., 2016; Feng et al.,

1

# 2 CONCLUSIONS

Based on petrographic features, elemental composition, oxygen and carbon isotopic composition,
REE contents and fluid inclusion properties, the following conclusions are drawn about the Tengger
Formation dolomites in the Baiyinchagan Sag of the Earlian Basin.

6

Fe-bearing magnesite, pyrite and barite.
Four different types of dolomite can be recognized: fine-crystalline dolomite present either
as white matrix-supporting grains (Fd1) or as dolomitic mudstone (Fd2); medium-crystalline
dolomite (Md) composed of white laminae and bands; and rare coarse dolomite (Cd) occurring
as saddle dolomite filling fractures. Importantly, dolomites are mixed or interbedded with
lacustrine terrestrial sediments, suggesting synchronous deposition, and co-occur with natrolite,

13

142The fine-crystalline dolomites (Fd1 and Fd2) have a similar geochemical composition to15the Cd dolomite in terms of a high FeO content, while the Md dolomites have the highest CaO16and MgO contents and lowest FeO contents. This demonstrates that the Tengger Formation17dolomites must have formed under the influence of Fe-rich and Mg-rich hydrothermal fluids.

18

19 The Md dolomites precipitated at high temperatures from hydrothermal fluids that mixed 3 20 with a relatively minor amount of lake water local to the vents, that may thus have had a higher 21 alkalinity than the fluids that formed the Fd dolomites. As the hydrothermal plume expanded 22 within the lake the fluids would have retained a relatively high but decreased alkalinity, 23 producing the Fd1 dolomites accompanied by white grains. Mixing of increasing amounts of 24 lake water with the hydrothermal fluid, would have reduced temperatures still further and 25 precipitated the Fd2 dolomites. At a later stage high temperature Cd dolomite precipitated 26 locally to fill fractures.

27

28

4 A combination of the geological setting and the petrography and geochemistry of the

1 dolomites, suggests strong localized discharge of very high-temperature saline-alkaline 2 hydrothermal fluids through boundary faults and accompanying fractures, under an abnormally 3 high heat flux. This hydrothermal fluid mixed with cold lake water, creating conditions favourable to the precipitation of dolomite and associated minerals. The chemical and physical 4 5 processes that lead to accumulation of the Tengger Formation thus reflect both hydrothermal 6 and sedimentary processes. The hydrothermal fluids would have supplied the basic chemical 7 components for formation of the dolomites, while the lake water moderated the composition 8 and temperature of the hydrothermal fluid and served as a depositional environment.

9

### 10 ACKNOWLEDGEMENTS

We are grateful to the staff from Zhongyuan oil field for kind assistance in collection of core samples,
and others who are helpful for laboratory work. We thank the anonymous reviewers and Associate
Editor Cathy Hollis for constructive and thoughtful comments that helped improved the manuscript.
This study was supported under grants from the National Science Foundation of China (Grant No.
41472094, 41502099).

#### 1 Figure and captions

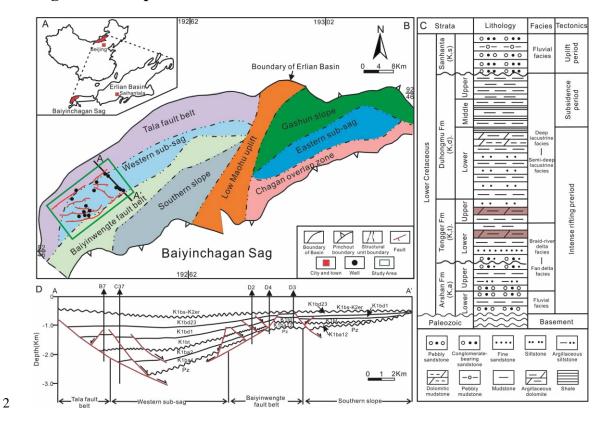

Fig. 1. (A) Location of the Baiyinchagan Sag in the Erlian Basin of northern China; (B) Simplified
structure map of the Baiyinchagan Sag; (C) Detailed stratigraphic column of the Lower Cretaceous
in Baiyinchagan (after drilling data of *Zhongyuan Oilfield, 2008*); (D) Structural cross section of a
half-graben in the westernmost area of the basin (modified from *Wang, 2006*).

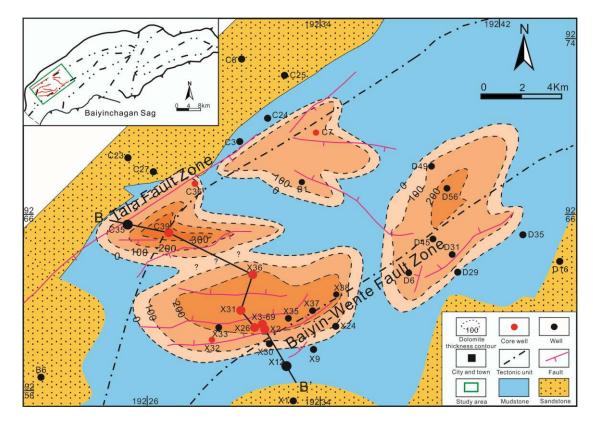

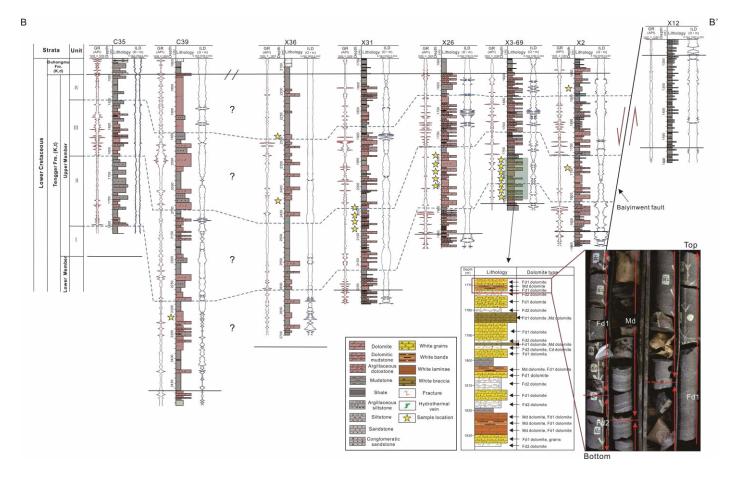

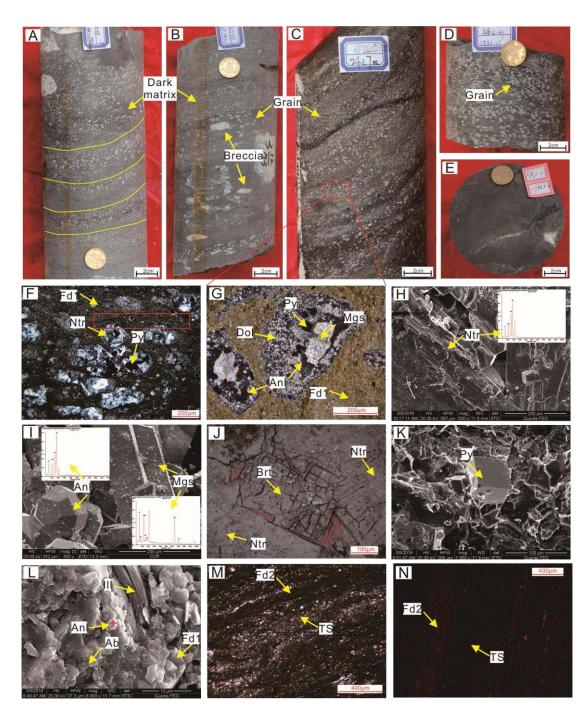

Fig. 2. Isopach map of dolomite of the Upper Member of the Tengger Formation in the study area modified from *Guo et al., (2014)*. The well log response of dolomite-bearing and redeposited terrigenous lacustrine rocks was characterized for cored wells, and used to estimate the total thickness of dolomite-bearing rocks across the basin. Shadings show very localized thickness of dolomite that range from 0 to 300 m. Wells used in cross section (Fig. 3) are shown by large black dots.

2 Fig. 3. Regional stratigraphic correlations in the Upper Member of the Tengger Formation along the NW-SE direction in cross-section B-B', the location of the section

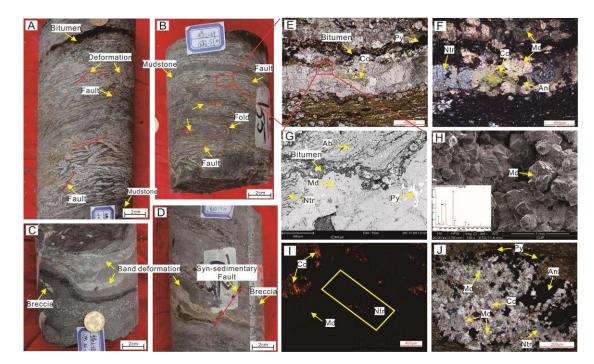

4 according to core from the Well X3-69. Photos of continuous cores located in the top of Well X3-69 show different types of dolomites with nature of their contact.

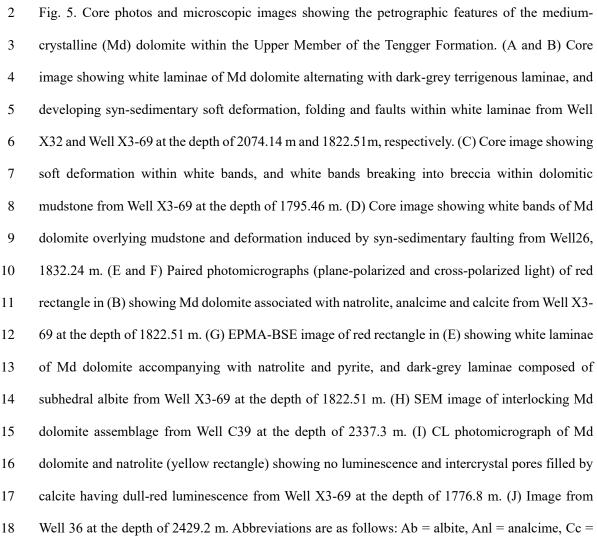

1

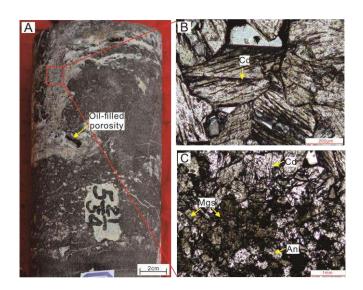

Fig. 4. Core photos, photomicrographs and SEM images showing the petrographic features of the fine-crystalline (Fd1 and Fd2) dolomite and their mineral assemblage within the Upper Member of the Tengger Formation. (A) Core showing white elongated grains composed of natrolite and analcime occurring in the dark-grey matrix of Fd1 dolomite and terrigenous feldspar, and grains gradually growing larger upwards from Well X3-69 at depth of 1795.46 ~ 1797.36 m. (B) Core showing white elongated grains, with larger white breccia clasts scattered in the matrix from Well X3-69 at a depth of 1787.14 m. (C) Core showing white small spherical grains dominated by

1 analcime and dolomite occurring in the dark-grey matrix from Well X36 at the depth of 2427.0 m. 2 (D) Core showing white irregular and droplet-shape grains made up of natrolite and Fe-bearing 3 magnesite occurring in the in the dark-grey matrix from Well X3-69 at the depth of 1832.15 m. (E) 4 Core showing Fd2 dolomite and terrigenous sediments composing massive argillaceous dolomite 5 from Well X3-69 at the depth of 1798.46 m. (F) Photomicrograph (cross-polarized light) of grains 6 of natrolite and pyrite floating in the matrix, red rectangle showing terrigenous laminae wrapping 7 around grains, from Well X3-69 at the depth of 1771.8 m. (G) SEM image showing euhedral 8 natrolite and forming assemblage from Well X3-69 at the depth of 1784.94 m. (H) Photomicrograph 9 (cross-polarized light) of red rectangle from (C) showing grains composed of analcime with 10 magnesite and dolomite from Well X36 at the depth of 2427.0 m. (I) SEM image showing octahedral 11 analcime and euhedral magnesite from Well X3-69 at the depth of 1782.2 m. (J) SEM image 12 showing cubic pyrite from Well X3-69 at the depth of 1776.8 m. (K) Photomicrograph (plane-13 polarized light) showing barite in fill of intracrystalline pore within natrolite from Well X26 at the 14 depth of 1824.3 m. (L) Photomicrograph (cross-polarized light) showing laminar structure with 15 alternation of Fd2 and terrigenous sediment layers from Well C7 at the depth of 1206.97 m. (M) 16 SEM image showing anhedral to subhedral Fd1 dolomite and anhedral albite around natrolite from 17 Well X3-69 at the depth of 1771.8 m. (N) CL image showing Fd2 dolomite with a dull red 18 luminescence commixed with terrestrial sediment minerals from Well C7 at the depth of 1206.97 m. Abbreviations are as follows: Ab = albite, Anl = analcime, Brt = barite, Dol = dolomite, Ill = illite, 19 20 Mgs = magnesite, Ntr = natrolite, Py = pyrite, TS = terrigenous sediments.

4 Fig. 6. Images showing the petrographic features of the coarse-crystalline (Cd) dolomite within the 5 Upper Member of the Tengger Formation. (A) Core photo showing massive Cd dolomite filling 6 fractures that crosscut the bedded and postdate Fd1 and Fd2 dolomite and develop into the latter 7 eventually, and develop not fully-filled voids from Well C31 at the depth of 2050.57 m. (B) 8 Photomicrograph (cross-polarized light) of red rectangle in (A) showing intercrystal pores between 9 Cd dolomite (slight blue stained with Alizarin Red-S and K-ferricyanide) from Well C31 at the depth 10 of 2050.57 m. (C) Photomicrograph (plane-polarized light) showing Cd dolomite, cloudy and non-11 planar crystals size exceeding 1 mm (slight blue stained with Alizarin Red-S and K-ferricyanide) 12 accompanied by abundant magnesite from Well C31 at the depth of 2050.57 m. Abbreviations are 13 as follows: Anl = analcime, Mgs = magnesite.

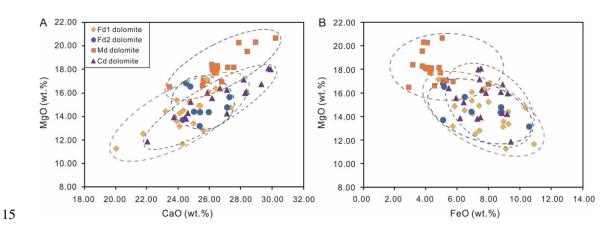

Fig. 7. (A and B) Cross-plots of major-element composition of fine-crystalline (Fd1 and Fd2),
 medium-crystalline (Md) and coarse-crystalline (Cd) dolomite within the Upper Member of Tengger
 Formation in the study area, showing relationships between MgO, CaO and FeO.

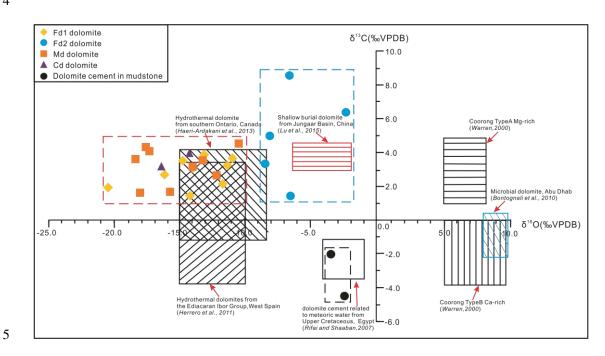

Fig. 8. Cross-plot of  $\delta^{18}$ O and  $\delta^{13}$ C stable isotopes values including the Upper Member of Tengger 6 7 Formation dolomite occurrences. Isotopic composition of Fd1 dolomite, Md dolomite and Cd 8 dolomite all lying in the red dashed box, distinguished from Fd2 dolomite lying in blue dashed box 9 and dolomite cement in mudstone lying in black dashed box. The composition of oxygen and carbon 10 isotopes are compared with other dolomites with different genesis, e.g., two hydrothermal dolomites 11 from Canada and West Spain (Herrero et al., 2011; Haeri-Ardakani et al., 2013), shallow burial 12 dolomite from Junggar Basin (Lu et al., 2015), Coorong Type A Mg-rich and Type B Ca-rich 13 dolomite (Warren, 2000), and microbial dolomite from Abu Dhabi (Bontognali et al., 2010).

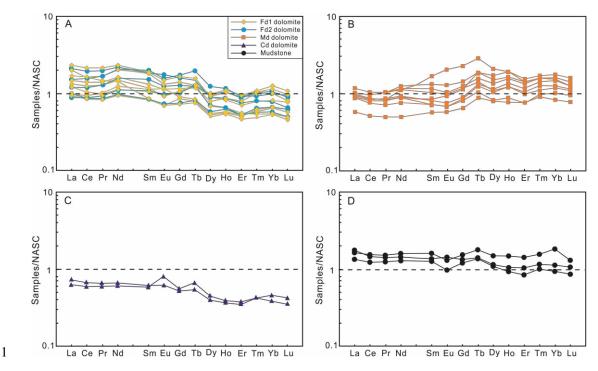

Fig. 9. The NASC normalized REE patterns of dolomites from the Upper Member of Tengger
Formation prensent in the study area. The REE<sub>N</sub> patterns are divided into four types: (A) the REE<sub>N</sub>
pattern of Fd1 dolomite and Fd2 dolomite; (B) the REE<sub>N</sub> pattern of Md dolomite; (C) the REE<sub>N</sub>
pattern of Cd dolomite; (D) the REE<sub>N</sub> pattern of mudstone.

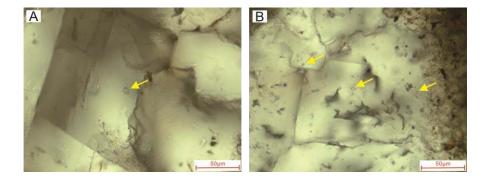

Fig. 10. Photomicrograph of fluid inclusions. (A) Isolated two-phase (liquid-vapour) primary
inclusion in Md dolomite with small vapour bubble (yellow arrow); (B) Example of two-phase
primary aqueous inclusions in natrolite (yellow arrow).

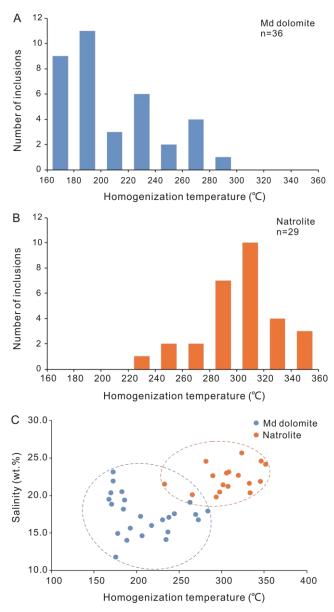

Fig. 11. (A) Histogram of homogenization temperatures of fluid inclusions in Md dolomites. (B)

3 Histogram of homogenization temperatures  $(T_h)$  of fluid inclusions in natrolite. (C) Cross-plot of

4 homogenization temperatures  $(T_h)$  and salinities of fluid inclusions from Md dolomite and natrolite,

5 showing a trend of increasing temperature and salinity from Md dolomite to natrolite.
