17 **| Abstract**

18 Recent studies provided an increasingly detailed understanding of how visual objects categories  
19 like faces or bodies are represented in the brain. What is less clear is how a given task impacts the  
20 representation of the object category and of its attributes. Using (fMRI) we measured BOLD  
21 responses while participants viewed whole body expressions and alternatively performed an  
22 explicit (emotion) or an implicit (shape) recognition task. Our results based on multivariate  
23 methods, show that the type of task is the strongest determinant of brain activity and can be  
24 decoded in EBA, VLPFC and IPL. Brain activity was higher for the explicit task condition in the  
25 first two areas without evidence of emotion specificity. This pattern indicates that during explicit  
26 recognition of the body expression, body category representation may be strengthened, and  
27 emotion and action related activity suppressed. Taken together these results indicate that there is  
28 important task dependent activity in prefrontal, inferior parietal but also ventral visual areas and  
29 point to the importance of the task both when investigating category selectivity and brain correlates  
30 of affective processes.

## | Introduction

There is increasing evidence that the brain encodes stimulus information in high-dimensional representational spaces based on the joint activity of neural populations ([Averbeck, Latham, and Pouget 2006](#); [Haxby, Connolly, and Guntupalli 2014](#); [Kriegeskorte et al. 2008](#)). This encoding process may be dynamic, relatively task sensitive and at the service of different and complex behavioral goals ([Hebart et al. 2018](#)). The emerging network picture is a change from more static views of category representation favoring dedicated functional areas ([Betzel 2020](#)). Understanding how the brain dynamically represents a familiar object category like the human body and its attributes like the emotion expression is particularly relevant as the behavioral impact of perceiving a body may vary substantially with the participants' task as well as with the expression the body displays. Here we address a central question about the impact of task type on brain activity. We investigate whether task type can be decoded in prefrontal as well as in body selective areas EBA and FBA. Secondly, to understand the nature of the task effects we ask whether they are sensitive to the emotion expression of the body.

First, it is currently an open question to what extent specific body attributes, like identity or emotional expression, influence the activity and selectivity of body areas in ventrotemporal cortex, EBA and the more anterior FBA ([de Gelder and Poyo Solanas 2020](#); [Peelen and Downing 2017](#); [Ross and Atkinson 2020](#)). Studies of body expression perception have systematically reported an impact of emotional expression on activity in EBA and FBA ([Peelen and Downing 2007](#); [Pichon, de Gelder, and Grezes 2009, 2012](#); [Hadjikhani and de Gelder 2003](#)). Different from EBA, FBA has been suggested to have a bigger involvement in identity and emotion processing through its connections to other areas, like the amygdalae ([Orgs et al. 2015](#)). EBA and FBA may also have different roles for different emotions. For example, Peelen and colleagues found that fear significantly modulated EBA but not FBA while no difference was found in activity patterns for

1 other expressions ([Peelen et al. 2007](#)). Such emotion specific differences have been related to  
2 differences in attention, arousal etc. For example, it has been shown that the strength of emotion  
3 modulation in FBA is related, on a voxel-by-voxel basis, to the degree of body selectivity and is  
4 positively correlated with amygdala activation ([Peelen et al. 2007](#)). Most interestingly, the fact that  
5 EBA seems more sensitive to fearful body expressions than FBA makes more sense from a survival  
6 point of view, since EBA has been suggested to be the interface between perceptual and motor  
7 processes ([Orgs et al. 2015](#)).

8  
9 Second, it is poorly understood whether expression sensitivity of the body areas itself varies with  
10 the task, ie. whether the specific task changes how a body area represents the emotion of the body  
11 stimulus. It has been argued that the task impacts processing in prefrontal and parietal areas but  
12 not necessarily in ventral temporal category selective areas ([Bugatus, Weiner, and Grill-Spector  
13 2017](#); [Tsotsos 2011](#); [Bracci, Daniels, and Op de Beeck 2017](#); [Xu and Vaziri-Pashkam 2019](#)). More  
14 specifically, the task may require explicit recognition of a body attribute like the emotional  
15 expressions as opposed to incidental or implicit perception where no recognition of the expression  
16 is asked for. A classic example of implicit processing task is a gender recognition used for  
17 measuring implicit processing of facial expressions (e.g. ([Vuilleumier et al. 2005](#)) or a color  
18 monitoring task used or implicit perception of body expressions ([Pichon, de Gelder, and Grezes  
19 2012](#)). For instance, we observed increased activity in FBA and EBA when participants performed  
20 an emotion versus a color-naming tasks with whole body videos ([Pichon, de Gelder, and Grezes  
21 2012](#); [Sinke et al. 2012](#)). Implicit processing is also related to exogenous attention or stimulus  
22 driven attention, a well know source of representational dynamics ([Carretie 2014](#)). Affective  
23 stimulus attributes modulates the role of attention as shown for example with findings that bodies  
24 with fear expressions have different effects on saccades than neutral bodies ([Bannerman et al.  
25 2009](#)) and in hemispatial neglect patients, contralesional presentation of fear body expressions  
26 reduces neglect ([Tamietto et al. 2015](#)). In an effort to disentangle the effects of attention and task,  
27 ([Bugatus, Weiner, and Grill-Spector 2017](#)) showed that attention has an influence on category  
28 representation in high level visual cortex and in prefrontal cortex, while task did influence activity  
29 in prefrontal cortex but not in high level visual cortex. As concerns stimulus awareness, activity in  
30 ventral body category representation areas is significantly reduced for unaware stimuli but stays  
31 the same in dorsal action representation areas ([Zhan, Goebel, and de Gelder 2018](#)).

1 The goal of this study was to investigate whether the type of task influences the representation of  
2 bodies and body expressions inside and outside body selective category areas during measurement  
3 of brain activity with fMRI. We used decoding analysis to discover how body areas are involved  
4 in explicit as opposed to implicit expression processing. If ventrotemporal body object categories  
5 areas (EBA, FBA) are relatively insensitive to task dynamics then they should not be among the  
6 areas where task differences are observed. Alternatively, body category representation areas may  
7 be directly involved in expression recognition or indirectly through functional connectivity with  
8 other important areas in expression processing like the amygdalae as found for faces in FFA  
9 ([Vuilleumier et al. 2004](#)) and may also obtain for bodies in FBA ([de Gelder, Hortensius, and](#)  
10 [Tamietto 2012](#)), prefrontal areas (VLPFC) and action representation areas in parietal cortex,  
11 specifically intraparietal sulcus (IPS) and inferior parietal lobule (IPL).

12  
13 Two different tasks were designed to be formally similar (similar difficulty, similar response  
14 alternatives) for use with the same stimulus materials consisting of body expressions with two  
15 different emotions and two different skin colors. One task, emotion categorization, required  
16 explicit recognition of the body expression and a forced choice between two alternatives. The other  
17 shape task required explicit recognition of a shape overlaid on the body image and a forced choice  
18 between two shape alternatives. We used multivariate decoding and RSA in order to decode  
19 stimulus and task related information in locally defined patterns of brain activity ([Connolly et al.](#)  
20 [2012](#); [Connolly et al. 2016](#); [Huth et al. 2012](#); [Kriegeskorte et al. 2008](#); [Mitchell et al. 2008](#); [Nastase](#)  
21 [et al. 2017](#); [Oosterhof et al. 2010](#); [Sha et al. 2015](#)). Our goal was to answer the question whether  
22 activity in body category representation areas EBA and FBA would be critical for the difference  
23 between the emotion vs the shape task and whether this difference could also be decoded in other  
24 areas possibly in amygdalae. The alternatively outcome would be that the task cannot be decoded  
25 in the category areas and similar activity in those areas, indicating that category representation is  
26 independent from the actual task requirements. To anticipate, our results show that the difference  
27 between the two tasks can be decoded in EBA, VLPFC and IPL and that task sensitivity is clearly  
28 seen both in category selective areas in the higher visual cortex and in the VLPFC.

## 1 | **Materials and Methods**

2

3 The present study uses brain and behavioral data previously collected and described in ([Watson](#)  
4 [and de Gelder 2017](#)) but now analyzed from a different theoretical perspective and with fully  
5 different methods.

6

### 7 | **Participants**

8 Data of twenty Caucasian participants were used for the current study (8 males, mean age  $\pm$   
9 standard deviation=22  $\pm$  3.51 years). Participants were naive to the task and the stimuli and  
10 received a monetary reward for their participation. Written informed consent was provided before  
11 starting the protocol. The scanning session took place at the neuroimaging facility Scannexus at  
12 Maastricht University. All procedures conformed with the Declaration of Helsinki and the study  
13 was approved by the Ethics Committee of Maastricht University.

14

### 15 | **Stimuli**

16 Stimuli consisted of still images of angry and happy body postures of black African and white  
17 Caucasian ethnicity. The set of black body expressions was obtained by instructing black African  
18 participants, all residents of Cape Town, South Africa, to imagine a range of daily events and show  
19 how they would react to them nonverbally. The set of white affective body stimuli (five males  
20 each expressing anger and happiness) were selected from a set previously validated ([Stienen,](#)  
21 [Tanaka, and de Gelder 2011](#); [Van den Stock et al. 2011](#)). Both sets were pre-processed with the  
22 same software and underwent the same post-selection procedure. Photographs were captured using  
23 a Nikon V1 35mm camera equipped with a Nikon 30-100mm lens on a tripod, and under studio  
24 lighting. The stimulus set consisted of 20 affective bodies (2 races (Black, White) x 2 emotions  
25 (Angry, Happy) x 5 identities). The photos showed the entire body, including the hands and feet.  
26 For behavioral validation of the images ten white European participants were then asked to  
27 categorize the emotion expressed in a given picture (neutrality, anger, happiness, fear, sadness,  
28 disgust). All emotions were recognized above 70%. Based on these results five male identities  
29 were chosen, with photos of the same identity expressing both anger and happiness. Ten upright  
30 white and black (20 in total) affective body images were selected for the final stimulus set. Pictures

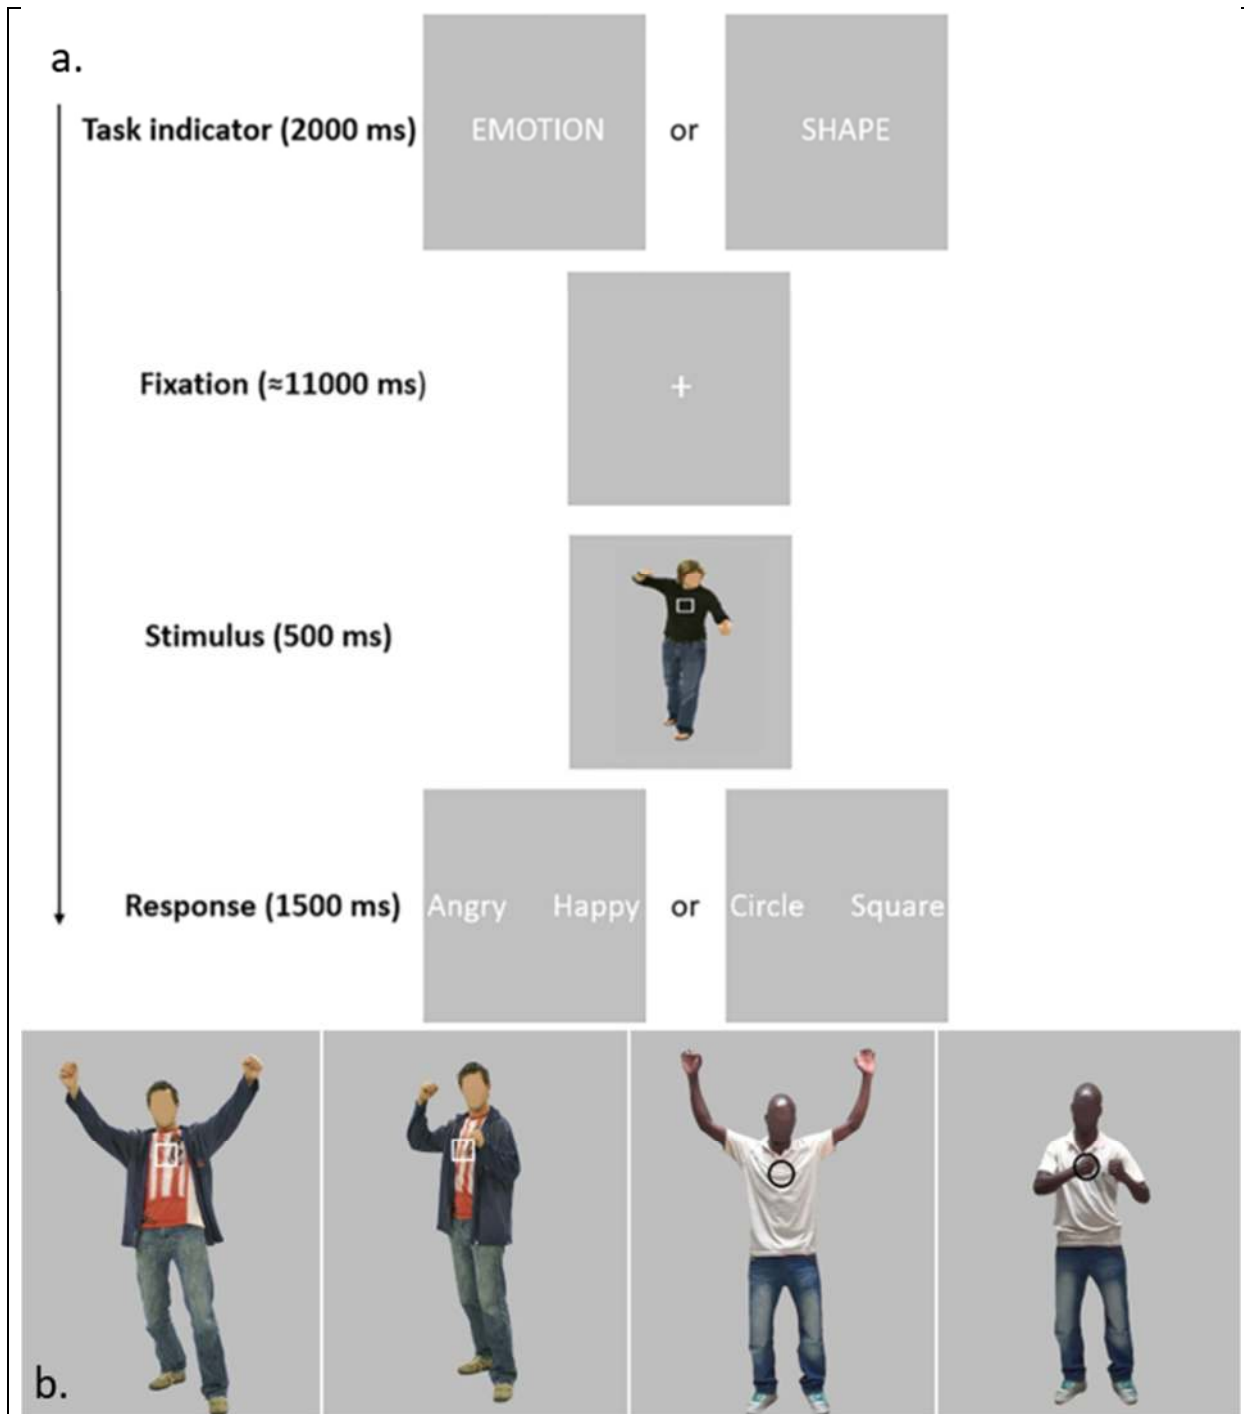

1 were edited using Adobe Photoshop CC 14 software (Adobe System Incorporated) in order to blur  
2 the faces using an averaged skin color; thus, there was no information in the face.

3

#### 4 | **fMRI Acquisition and Experimental Procedure**

5 Participants were scanned using a Siemens 3T Prisma scanner. Padding and earplugs were used to  
6 reduce head movements and scanner noise. Stimuli were projected to the center of a semi-  
7 translucent screen at the back of the scanner bore that participants could see using a mirror mounted  
8 on the head coil. The experiment comprised two categorization tasks that followed a mixed  
9 block/event related design of four separate runs. Each run consisted of a presentation of emotion  
10 (A) and shape (B) blocks (AB – BA – BA – AB) and in each block stimuli were presented in a  
11 slow event related manner. The two different tasks were designed to provide information on  
12 explicit and implicit emotion perception. For the emotion block, participants were instructed to  
13 respond on whether the emotion expressed was anger or happiness. In the shape block, participants  
14 judged whether the stimulus contained a circle or a square which was superimposed on the body.  
15 The task was indicated on the screen for 2 s before each block began. The trials in each block were  
16 separated by a fixation cross on a gray background that appeared for 10 or 12 s (in a pseudo-  
17 random order). Following the fixation cross, a body image was presented for 500 ms (during each  
18 trial the participants were instructed to fixate) followed by a response screen lasting 1500 ms,  
19 showing the two response options on the left and right of the fixation cross and corresponding to  
20 the index and to the middle finger respectively. The side of the response options were randomized  
21 per trial to avoid motor preparation. Each stimulus was presented twice in each run, once during  
22 the emotion task and once during the shape task. Thus, each run consisted of 40 trials (+ 2 task  
23 indicators), see Fig. 1.

24

**Figure 1. (a) Examples of explicit and implicit trials.** During the experiment a task indicator appeared (2000 ms) showing which task (explicit emotional evaluation or implicit emotional evaluation) the participants were asked to perform. The task indicator was followed by a fixation period, the stimulus (white happy/angry, or black happy/angry) and a response window. Participants responded via two buttons pressed by the index finger (word on the left) and the

middle finger (word on the right), with randomization of the response options in order to avoid motor preparation ([Watson and de Gelder 2017](#)).

**(b) Example of different angry (happy) poses.** Four different examples of unique affective body poses depicting happiness (first picture and third picture from the left) and anger (second picture and fourth picture from the left). Participants were asked to recognize the emotion in the explicit task and name the shape (square/circle superimposed) in the implicit task.

1

## 2 | **MRI acquisition and Data Preprocessing**

3 A T2\*-weighted gradient echo EPI sequence was used to acquire the functional data covering the  
4 whole brain with  $2 \times 2 \times 2 \text{ mm}^3$  resolution (64 slices without gaps, TR = 2000 ms, TE= 30 ms, flip  
5 angle=  $77^\circ$ , multiband acceleration factor = 2, FOV = 160 x 160 mm, matrix size = 100 x 100).  
6 Furthermore, a T1-weighted MPRAGE sequence was used for each participant ( $1 \times 1 \times 1 \text{ mm}^3$ ,  
7 TR=2300 ms, TE= 2.98 ms). Preprocessing was performed using BrainVoyager software  
8 (BrainVoyager QX) (Brain Innovation B.V., Maastricht, the Netherlands). For each run a slice scan  
9 time correction using sinc interpolation was performed, data from each run was motion-corrected  
10 by realigning to the first volume of the first run using sinc interpolation. A two-cycle temporal  
11 high-pass filtering was applied in order to remove low frequency linear and quadratic trends.  
12 Notice that no spatial smoothing was performed at this stage. The anatomical data, after the skull  
13 removal and inhomogeneity correction, were spatially warped to MNI space (MNI-ICBM 152),  
14 and the functional data were then co-registered to the anatomical data in the new space using the  
15 boundary based registration algorithm ([Greve and Fischl 2009](#)).

16

## 17 | **Univariate Analysis**

18 Using BrainVoyager (BV, v21.2) we first defined a subject-specific univariate general linear  
19 model (GLM) where each condition (emotion black angry (E\_BA), emotion black happy (E\_BH),  
20 emotion white angry (E\_WA), emotion white happy (E\_WH), shape black angry (S\_BA), shape  
21 black happy (S\_BH), shape white angry (S\_WA), shape white happy (S\_WH)) was included as a  
22 square wave of the same duration of the trial, convolved with the canonical hemodynamic response  
23 function. The 3D motion parameter estimates were included as regressors of no interest in the  
24 design matrix. For the group statistical analysis, we first performed spatial smoothing with a

1 Gaussian Kernel (3 mm) of all the functional images and then, in order to assess the variability of  
2 observed effects across subjects, we combined the individual GLM's in a random effects (RFX)  
3 GLM analysis, as is the custom in the BV pipeline. For 7 participants, only three of the five original  
4 trials for each condition were included as predictors due to an initial error in stimulus presentation,  
5 resulting in a reduced set of 96 trials out of 160 (2 emotions x 2 skin color x 2 tasks x 5 repetitions  
6 x 4 runs). To test for effects and interactions between the factors an RFX three-way repeated  
7 measures ANOVA was performed in BV on the combined individual GLM's.

8

### 9 | **Multivariate Analysis**

10 All multivariate analyses were conducted with in-house MATLAB scripts (vR2018a, The  
11 MathWorks Inc., Natick, MA, USA). First, the BOLD time course of each voxel was divided in  
12 single trials, whose temporal window (epoch) were defined between 1TR prior and 4TR after the  
13 stimulus onset, resulting in 42 trials per run (168 in total). Within each run, 2 trials represented the  
14 task indicator and therefore they were not included in the analysis. Each trial was normalized with  
15 respect to the baseline 2000 ms, before the first stimulus onset (the first TR in the trial segment).  
16 We linearly fitted the percent BOLD signal change of each voxel and each trial separately with a  
17 design matrix consisting of a constant term (intercept) and an optimized hemodynamic response  
18 function (HRF). The optimized HRF was designed to take into account potential differences in the  
19 BOLD responses (temporal delay) for a certain voxel. The optimal delay was calculated for each  
20 voxel by convolving a canonical HRF with a box-car predictor whose value was one when the  
21 stimulus was presented. The time-to-peak parameter was varied between 4.0 s and 6.0 s in steps  
22 of 0.5 s. The five resulting HRFs were fit to the percent BOLD signal change of all trials averaged  
23 and the time-to-peak giving the best fit was chosen as the optimal HRF delay of that voxel. For  
24 each trial and each voxel, we then used the resulting  $\beta$ -values as a feature in the classifier ([Gardumi](#)  
25 [et al. 2016](#)). The method provided above does not represent the standard procedure for multivariate  
26 analysis in which  $\beta$ -values from the univariate GLM are used as feature in the classifier. The  
27 traditional GLM uses a fixed parameter for the positive time to peak of the HRF and the estimated  
28  $\beta$  of the responses to each category are used for statistical inference. Although the statistical  
29 framework is not available for the optimized HRF method, the multivariate classifier can work  
30 both with the traditional GLM  $\beta$  and the HRF optimized  $\beta$ . Furthermore, the optimized HRF  
31 method has clear advantage compared to the standard framework, because it estimates with higher

1 precision the delay of the canonical HRF used to model the response (5 possible choices within  
2 the standard range of variation of the positive time to peak: 4.0 – 6.0 s).

3

#### 4 *Searchlight analysis*

5 In order to perform whole brain decoding ([Kriegeskorte, Goebel, and Bandettini 2006](#)) we  
6 implemented the method proposed by ([Ontivero-Ortega et al. 2017](#)), in which the brain is divided  
7 into spheres of searchlights and a fast Gaussian Naïve Bayes (GNB) classifier is fitted in each of  
8 them. Each searchlight has a radius of 5 voxels and is defined by a central voxel and a set of voxels  
9 in its neighborhood. The classification accuracy of the searchlight region was then assigned to the  
10 central voxel. In order to avoid overfitting, for each subject we split the data following the leave-  
11 one-run-out paradigm (4 – fold cross-validation) and computed the prediction accuracy by testing  
12 the trained classifier on left-out test data. The GNB classifier was trained to predict tasks (Emotion  
13 vs Shape), emotion (Angry bodies vs Happy bodies) or skin color (Black bodies vs White bodies).  
14 Here the responses to individual stimuli were averaged for the 8 main conditions of the experiment.  
15 The emotion and skin color effects decoding were determined both across the tasks (160 trials  
16 available for training and testing the classifier) and within the tasks (80 trials for the explicit task,  
17 80 trials for the implicit task), for 7 participants (see Univariate analysis) only 96 trials out 160  
18 were available for the analysis. Moreover, in order to determine interstimulus differences in the  
19 multivoxel patterns (MVPs), the GNB was trained to classify the 20 unique affective bodies (5  
20 identities x 2 skin color x 2 emotions).

21

#### 22 *Interstimulus decoding*

23 In order to check whether the qualitative differences in the 20 unique poses (5 identities x 2 skin  
24 color x 2 emotions) of the stimulus set were also reflected in the MVPs, a GNB classifier was  
25 trained to classify the 20 affective bodies. Specifically, for each searchlight we assigned a unique  
26 label to each different stimulus and trained the GNB to classify it following the leave-one-run-out  
27 paradigm. We then assessed the ability of the classifier to categorize the different poses on the left  
28 out data, by assigning the corresponding prediction accuracy value to the central voxel of each  
29 searchlight.

30

31

## 1 *Whole brain RSA of intra- versus inter-conditions similarities analysis*

2 In addition to decoding with a classifier, another method to detect condition effects in MVP's is to  
3 statistically test for differences between intra- versus inter-condition MPV similarities ([Peelen,  
4 Atkinson, and Vuilleumier 2010](#)). As in the GNB analysis, for each subject and for each 5 voxel  
5 radius searchlight spanning the whole brain, we built neural representational dissimilarity matrices  
6 (RDMs) by computing the dissimilarity (1 - Pearson's correlation) between the multivoxel patterns  
7 of each of the 160 trials. Next, we extracted from these RDMs the intra-condition or inter-condition  
8 elements and compared these with a two-sample t-test. This test was performed for the conditions  
9 of task, emotion and skin color separately. Furthermore, we assessed task specific differences  
10 between intra- versus inter-condition MPV similarities by extracting neural RDMs for emotion  
11 and skin condition within the explicit and implicit task separately. This was performed by testing  
12 the task specific neural RDMs (80 trials per task). As mentioned in the univariate analysis, for 7  
13 participants 2 trials for each condition were to be discarded, resulting in 96 trials (48 per each task).  
14 On a group level, for each voxel, single-subject results were tested against zero, resulting in a  
15 group two-tailed t-test.

16

### 17 | **Group Analysis**

18 For the group-level analysis spatial smoothing (Gaussian kernel of 3mm FWHM) was applied to  
19 the resulting maps of each individual. For the decoding analysis with the GNB classifiers the maps  
20 contained the classification accuracies minus chance level and for the inter- versus intra-condition  
21 MVP similarity analysis the maps represented the t-values from the t-test. Next, for all analyses, a  
22 statistical map was obtained by performing a two tailed t-test against zero over subjects. The  
23 statistical threshold for the overall activation pattern was  $q = .05$  corrected for multiple comparison  
24 using the false discovery rate (FDR).

25

### 26 | **Region of Interest Analysis**

27 We selected regions of interest (ROIs) by setting a statistical threshold of  $q(\text{FDR}) = .01$  on the map  
28 resulting from the GNB decoding on task effect (see Results). This threshold was chosen in order  
29 to obtain spatially separated sub-clusters, as the clusters at  $q(\text{FDR}) = .05$  consisted of only a few  
30 clusters spanning many anatomical regions (see Results). Additionally, a Cluster-Level correction  
31 was performed to eliminate small clusters using the Cluster-Level Statistical Threshold Estimator

1 plugin (FWHM = 1 voxel, 3000 iterations) ([Forman et al. 1995](#); [Goebel, Esposito, and Formisano](#)  
2 [2006](#)). The multi voxel patterns were then extracted from the ROI and an RSA analysis was  
3 performed for each ROI. The Representational Dissimilarity Matrices (RDMs) were built by  
4 computing a metric of distance (1 - Pearson's correlation coefficient) between the multivoxel  
5 patterns from the 8 conditions of the main experiment. We obtained group average RDM's by first  
6 computing the RDMs at the individual level and then averaging over subjects. Additionally, for  
7 each ROI, to assess the overall activation level we plotted the group average beta values from the  
8 optimized HRF model for the different experimental conditions. We extracted beta values at the  
9 individual level by averaging the multi voxel patterns of each condition and then computed group  
10 level beta values by averaging across participants.

11

## 1 | **Results**

### 2 | **Behavioral analysis**

3 To test for any difference in performance between the two emotion and shape tasks we performed  
4 a three-way repeated measure ANOVA on accuracies and response times completing the previous  
5 results (Watson and de Gelder 2017). For each subject we averaged the 8 conditions over  
6 repetitions. The analysis on the accuracies revealed a main effect of the three factors task, skin and  
7 emotions ( $F(1,19) = 40.06, p < .001$ ;  $F(1,19) = 28.88, p < .001$ ;  $F(1,19) = 14.08, p = .001$ ). In order  
8 to check the direction of the effect, a paired sample t-test was performed. The latter revealed that  
9 the mean accuracy for the emotion task was significantly smaller than the mean accuracy for the  
10 shape task (mean emotion =  $.893 \pm .156$ , mean shape =  $.986 \pm .027$ ,  $t(79) = -5.050, p < .001$ ).  
11 Likewise, we found that the mean accuracies for the angry poses and the black poses (averaged  
12 across the tasks) were significantly lower than the mean accuracies for the happy poses and the  
13 white poses respectively (mean angry =  $.910 \pm .158$ , mean happy =  $.969 \pm .052$ ,  $t(79) = -3.243, p$   
14  $= .002$ ; mean black =  $.911 \pm .155$ , mean white =  $.968 \pm .063$ ,  $t(79) = -2.904, p = .005$ ). The  
15 complete results are reported in the supplementary material (see Table S2, S4, S5).

16 The analysis on the response times showed a main effect of task and emotion ( $F(1,19) = 34.58, p$   
17  $< .001$ ;  $F(1,19) = 6.76, p = .018$ ). A paired sample t-test revealed that the mean response time for  
18 the emotion task was significantly greater compared to the shape task (mean emotion =  $843.01 \pm$   
19  $111.77$  ms, mean shape =  $717.35 \pm 85.44$  ms,  $t(79) = 8.63, p < .001$ ) and the mean response time  
20 for the angry was significantly higher than the happy conditions (mean angry =  $796.61 \pm 130.25$   
21 ms, mean happy =  $763.75 \pm 101.37$  ms,  $t(79) = 2.94, p = .004$ ). Furthermore, task affects the  
22 response times for the emotion conditions and for the skin conditions ( $F(1,19) = 4.66, p = .044$ ;  
23  $F(1,19) = 30.33, p < .001$ ). When participants explicitly named the emotion, we found a significant  
24 difference in the response times with more time needed to name an angry compared to a happy  
25 image (mean angry =  $873.65 \pm 114.80$  ms, mean happy =  $812.37 \pm 101.01$  ms,  $t(39) = 3.23, p =$   
26  $.002$ ). This difference was not significant during the shape categorization task. For the emotion  
27 categorization condition response times were longer for the black stimuli (mean black =  $875.30 \pm$   
28  $102.18$ ms, mean white =  $810.72 \pm 112.82$  ms,  $t(39) = 4.25, p < .001$ ). In contrast, for the shape  
29 categorization task mean response time for white conditions were longer than for the black stimuli  
30 (mean black =  $706.04 \pm 84.37$  ms, mean white =  $728.66 \pm 86.06$  ms,  $t(39) = -2.28, p = .002$ ). The  
31 complete results are reported in the supplementary material (see Table S3, S6, S7). Taken together

1 these behavioral results show significant differences between conditions, but the actual order of  
2 magnitude is such that, at this very high accuracy level, this difference although statistically  
3 significant does not reflect a substantial, meaningful behavioral distinction between the tasks.  
4 Moreover, these are not reaction times as a delayed naming task was used.

5  
6 | **Analysis of condition effects in activation level**

7 In the univariate analysis we tested the effect of the 3 main factors (task: Explicit vs Implicit;  
8 emotion: Angry vs. Happy; skin color: Black vs. White) and their interactions, and in order to  
9 determine the direction of the effect we computed a two-tailed t-test on each pairwise contrasts.  
10 We found significant higher responses for the explicit task in lateral occipito-temporal cortex  
11 (LOT), medial superior frontal gyrus (MSFG), bilateral ventrolateral prefrontal cortex (VLPFC)  
12 and bilateral anterior insular cortex (AIC). Higher activation levels for the implicit task were found  
13 in bilateral superior temporal gyrus (STG), right middle temporal gyrus (MTG), right inferior  
14 parietal lobule (IPL), bilateral marginal sulcus (MS) and left anterior cingulate cortex (ACC) (see  
15 Fig. 2a and Table 1). The contrast Angry vs. Happy bodies for all trials as well as for the emotion  
16 task trials only, revealed higher activation for happy bodies in the primary visual cortex (MNI: -  
17 13, -81, -9;  $t(19) = -8.01$ ,  $p < .001$ ) (see Fig 2b). No significant differences in activation levels were  
18 found for Black vs. White bodies. The ANOVA showed that the only interaction which gave above  
19 threshold ( $q(\text{FDR}) < .05$ ) clusters was the one between emotions and skin color (table S1 in  
20 supplementary material) see also ([Watson and de Gelder 2017](#)) for the details.

1

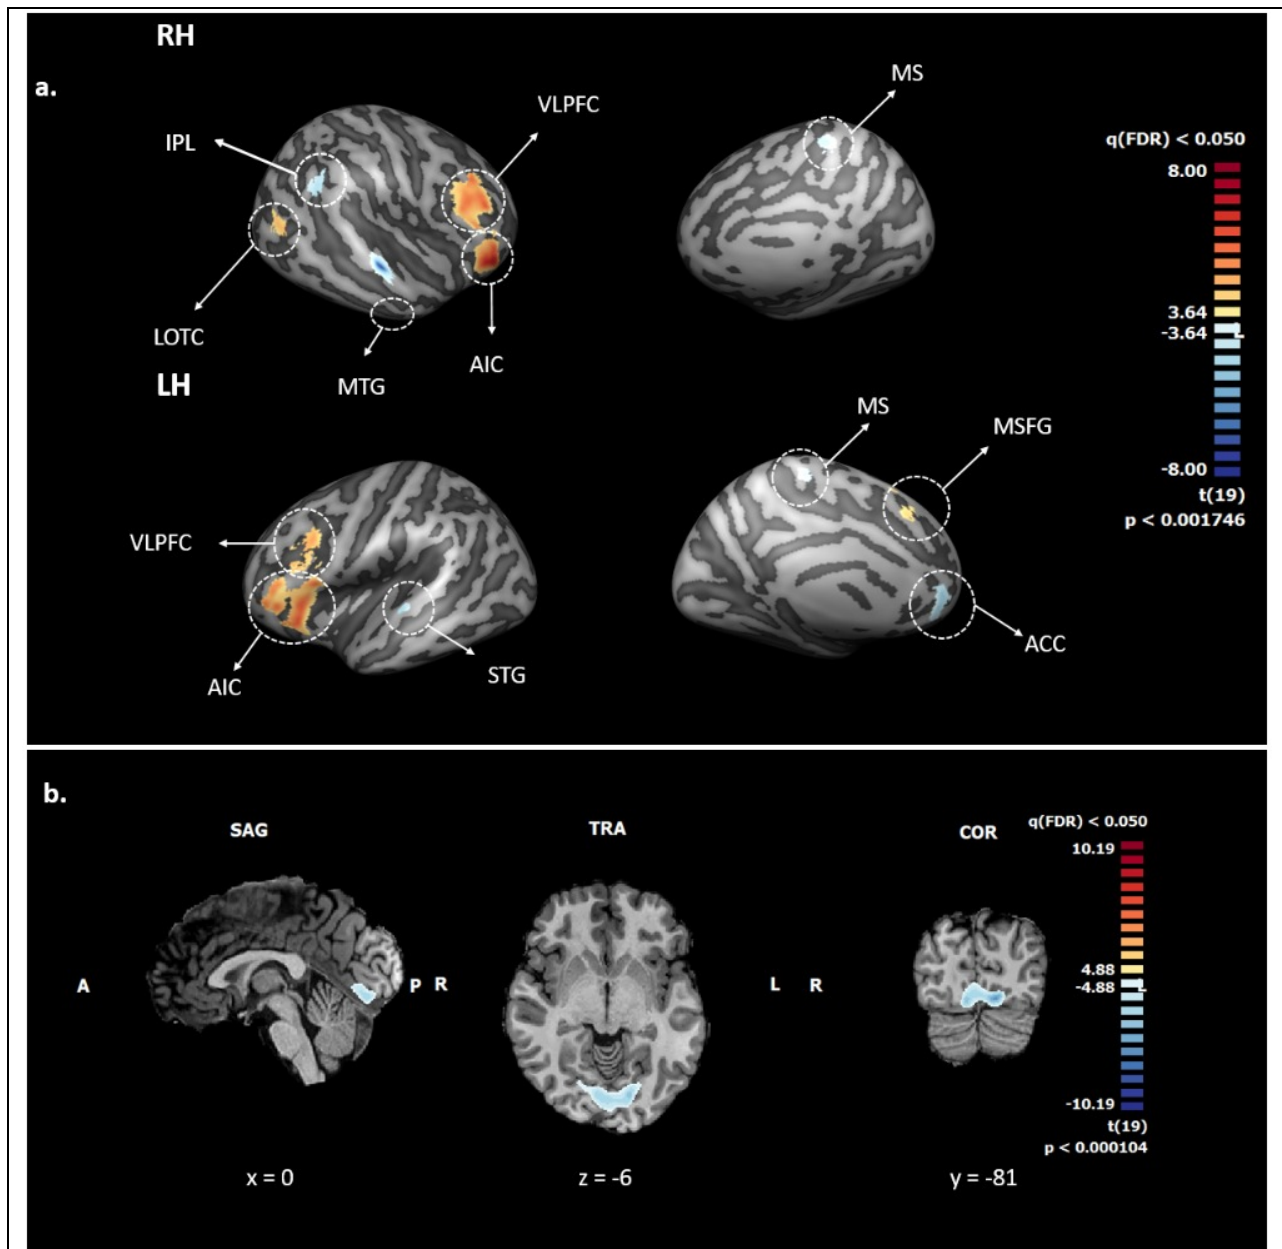

**Table 1. Whole Brain Group level univariate results of Explicit vs. Implicit conditions.** The table shows the regions where greater activity was found for the explicit conditions ( $t > 0$ ) and the implicit conditions ( $t < 0$ ). The t-map was thresholded at  $q(\text{FDR}) < .05$  and cluster size corrected. Peak voxel coordinates (MNI) and corresponding t value of each surviving cluster are reported. The degrees of freedom for the t-test were 19 while for the ANOVA 1 and 19. All the results were significant at  $p < .001$ .

**Figure 2. (a): Whole Brain Analysis: Univariate results for Explicit vs. Implicit expression recognition task ( $q(\text{FDR}) < .05$ ).** The color map indicates regions where higher (red) or lower (blue) activation was found for the emotion recognition task (explicit) vs the shape recognition task (implicit). Statistical analysis was performed on the volume maps and the resulting brain regions, after thresholding, are mapped to and overlaid on the inflated group average cortical surface for visualization purposes. Abbreviations: ACC = anterior cingulate cortex, AIC = anterior insular cortex, IPL = inferior parietal lobe, LOTC = lateral-occipitotemporal cortex, MS = marginal

sulcus, MSFG = medial superior frontal gyrus, MTG = middle temporal gyrus, STG= superior temporal gyrus, VLPFC = ventrolateral prefrontal cortex.

**(b): Whole Brain Analysis: Univariate results for Angry vs. Happy expression recognition task ( $q(\text{FDR}) < .05$ ).** The color map indicates regions where higher (red) or lower (blue) activation was found for the angry body pose vs happy body pose averaged across the tasks. One cluster was found spanning the early visual area with higher activation for happy bodies.

1

## 2 | **Multivariate decoding of task effect**

3 The whole brain searchlight GNB analysis revealed significant above-chance classification of the  
4 explicit vs. implicit task at the group level in bilateral lateral occipito-temporal cortex (LOTG),  
5 bilateral posterior inferior temporal gyrus (PITG), posterior middle temporal gyrus (PMTG), right  
6 inferior parietal lobule (IPL), bilateral ventrolateral prefrontal cortex (VLPFC), precuneus  
7 (PCUN), posterior cingulate cortex (PCC), fusiform gyrus (FG), medial superior frontal gyrus  
8 (MSFG) and cerebellum (CB) (See Fig. 3 and Table 2 for details). Moreover, these regions  
9 overlapped substantially with the univariate GLM results as shown in Fig. 5a. Importantly, the  
10 extent and statistical significance of the multivariate GNB results were much larger than for the  
11 GLM analysis, possibly indicating that the task effect was not only expressed through the level of  
12 activation but also in different multi-voxel patterns (regardless of level of activation). We also  
13 performed an analysis of the Angry vs. Happy bodies decoding (trials of both tasks combined) and  
14 found above chance classification accuracies in the right FG (MNI: 29, -49, -20;  $t(19) = 5.80$ ,  $p <$   
15  $.001$ ), and cerebellum (MNI: 29, -43, -34;  $t(19) = 4.90$ ,  $p < .001$ ). When considering the tasks  
16 separately, we did not find any regions where emotion could be decoded. When decoding Angry  
17 vs. Happy bodies (for each task separately) and Black vs. White bodies (trials of both tasks  
18 combined, and for each task separately) the classification did not yield any above chance results  
19 at the group level.

20

**Table 2. Whole Brain Group level statistics of the classification accuracies of Explicit vs. Implicit conditions.** Results produced by the searchlight GNB tested against chance level at  $q(\text{FDR}) < .05$  and cluster size corrected (min. cluster size threshold = 176). The values of the peak voxel of

each surviving cluster is reported. The degrees of freedom were 19 and p-values were less than .001. The labels in bold represent the clusters resulting from the whole brain statistical map. Regions indicated in normal font are manually defined subregions of the main clusters displayed for completeness.

2

### 3 | Interstimulus decoding

4 The 20 bodies of the stimulus set differed in a number of ways: besides the before mentioned  
5 categories of emotion and skin color, there were also person-specific variations in the details of  
6 the body pose (e.g. anger could be expressed in a different way between stimuli). This raises the  
7 question of whether these fine-grained variations in pose are part of what is encoded in body  
8 sensitive cortex. In order to check whether these differences were also reflected in the MVPs, a  
9 GNB classifier was trained to classify the 20 affective bodies. As discussed in the univariate  
10 analysis (see Materials and Methods) for 7 participants the trial set was incomplete (12 unique

1 stimuli out of 20), therefore they were excluded from this analysis. A group two-tailed t-test against  
2 chance level was performed and the resulting t-map showed significant above chance classification  
3 accuracy (at  $q(\text{FDR}) < 0.05$ ), in cerebellum ( $t(12) = 6.84$ ,  $p < .001$ ), bilateral inferior occipital gyrus  
4 (IOG) (right  $t(12) = 5.84$ ,  $p < .001$ , left  $t(12) = 7.12$ ,  $p < .001$ ), fusiform gyrus (FG) ( $t(12) = 5.62$ ,  
5  $p < .001$ ), primary visual cortex (V1) ( $t(12) = 4.61$ ,  $p < .0018$ ) (see Fig. 4).  
6

**Figure 4. GNB decoding results for all 20 expressive body stimuli.** Above chances classification accuracies produced by the searchlight GNB,  $q(\text{FDR}) < .05$  for the interstimulus differences are shown. The color map indicates the t-value of the test against chance level accuracy. It is worth noting that IOG is different from EBA here, as the latter is located more anterior in the brain (see Table 2). Abbreviations: CB =cerebellum; EV =early visual cortex; FG =fusiform gyrus; IOG =inferior occipital gyrus.

7

## 8 | Whole brain RSA of intra- versus inter-conditions similarities analysis

9 In order to determine condition specific (task, emotion, skin) differences in the neural RDMs, we  
10 computed for each subject a task specific two sample t-test of intra-condition similarities (e.g.  
11 happy-happy, black-black, explicit-explicit) against inter-condition similarities (e.g. angry-happy,  
12 black-white, explicit-implicit). When analyzing MVP similarities within the tasks (intra) and

- 1 between the tasks (inter) we found higher intra-task similarities in bilateral VLPFC, right superior
- 2 temporal sulcus (STS), bilateral IPS and DMPFC (see Table 3). Here also, we found substantial
- 3 overlap of results with the GLM and GNB analysis, see Fig. 5b.

**Table 3. Whole Brain Group level statistics of RSA's condition specific (task, emotion, skin) effects of multivoxel similarities, at  $q(\text{FDR}) < .05$ .**

The table shows the brain regions presenting a higher intra-condition similarity (e.g. happy-happy, black-black, explicit-explicit) ( $t > 0$ ) and those with higher inter-condition similarities (e.g. angry-happy, black-white, explicit-implicit) ( $t < 0$ ). The t values refer to the peak voxel of each surviving cluster. The degrees of freedom were 19 and p-values were less than .001.

**Figure 5. (a): Whole Brain MVPA and Univariate results overlap:** Combined map of the results of tasks comparison (Emotions vs. Shape), mapped to and overlaid on the inflated group average cortical surface, for searchlight GNB (red-yellow) and univariate (blue-purple) results showing the extent of the overlap in RH for VLPFC, IPL and EBA. Abbreviations: AG = angular gyrus, DMFC = dorsomedial frontal cortex; EBA = extrastriate body area; IPL = inferior parietal lobule; VLPFC = ventrolateral prefrontal cortex.

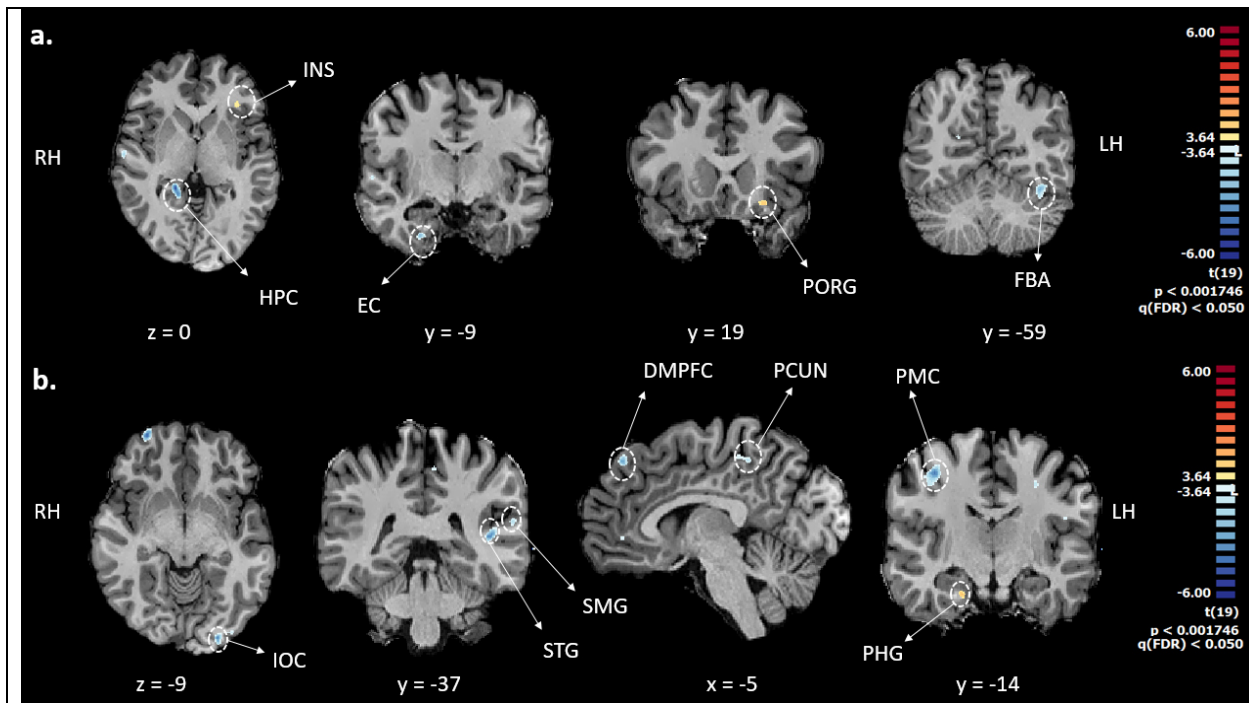

**(b): Overlap between GNB results (explicit vs implicit) and intra/inter condition similarities between the explicit and the implicit task.** Shown in light blue-purple are the resulting areas of the inter/intra task similarities analysis (task specific differences in the neural RDMs) at  $q(\text{FDR}) < .05$ . In order to qualitatively assess the overlap, we superimposed this map on the above chance classification accuracies map produced by the searchlight GNB for the explicit vs implicit expression recognition task (as in panel *a* of this figure),  $q(\text{FDR}) < .05$ , shown in red-yellow. The positive values (light blue) represent regions which show a higher intra-tasks similarity. Abbreviations: DMFC = dorsomedial frontal cortex; DMPFC = dorsomedial prefrontal cortex; EBA = extrastriate body area; IPL = inferior parietal lobe; IPS = intraparietal sulcus; VLPFC = ventrolateral prefrontal cortex.

1

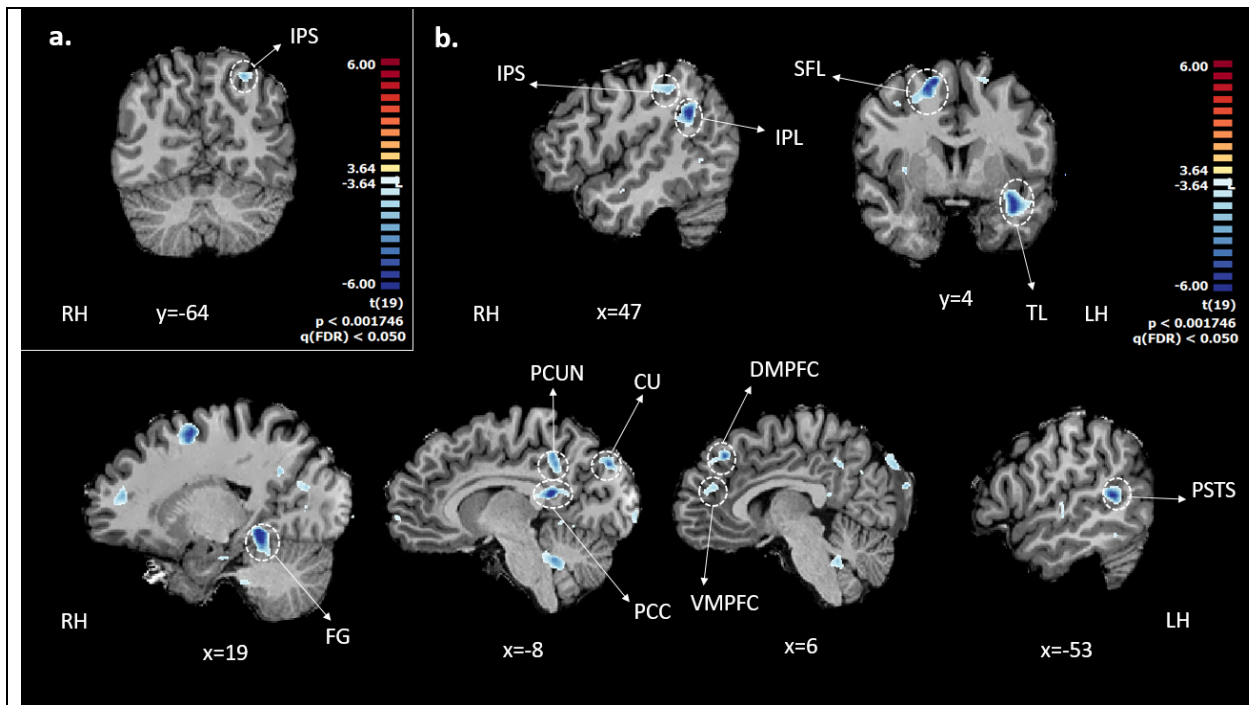

2 In the explicit emotion recognition task at  $q(\text{FDR}) = .05$ , higher similarities between same  
3 emotions (higher intra-similarities) are seen in left insula, left post-orbital gyrus, whereas higher  
4 similarities between different emotions (higher inter-similarities) were found in right entorhinal  
5 cortex, right hippocampus, left FBA (see Fig. 6 and Table 3).

6 In the implicit emotion recognition task, higher similarities were found between same emotions  
7 (higher intra-similarities) in right parahippocampal gyrus, whereas higher similarities between  
8 different emotions (higher inter-similarities) were found for dorsomedial prefrontal cortex, left  
9 precuneus, right premotor cortex, left inferior occipital gyrus, left superior temporal gyrus, left  
10 supramarginal gyrus (see Fig. 6 and Table 3).

**Figure 6. Inter/Intra emotion similarities analysis: Task specific results for affective body postures (angry, happy) in explicit (a) and implicit (b) emotion recognition.** Group results of the two-sample t-test between intra-emotions similarities against inter-emotions similarities at  $q(FDR) < .05$ . Panel a (explicit task) and panel b (implicit task) represent brain regions in which neural RDMs for same emotions are more similar than the neural patterns for different emotions (red) and vice versa (blue). Abbreviations: EC = entorhinal cortex; HPC = hippocampus; INS = insula; DMPFC = medial prefrontal cortex; PMC = premotor cortex; PORG = post-orbital gyrus.

- 1
- 2 Within the explicit task, higher similarities between different skin colors (higher inter-similarities)
- 3 were found in left IPS. Similarly, in the implicit task higher similarities between different skin
- 4 colors (higher inter-similarities) were found for DMPFC, ventromedial prefrontal cortex
- 5 (VMPFC), left precuneus, right IPS, right IPL, right superior frontal lobe (SFL), left temporal lobe,
- 6 left cuneus, left PCC, right FG, left PSTS (see Fig. 7 and Table 3).

**Figure 7. Inter/Intra condition similarities analysis: Task specific results for skin colors (black, white) in explicit (a) and implicit (b) emotion recognition.** Group results of the two-sample t-test between intra-condition (e.g. black-black) similarities against inter-conditions similarities (e.g. black-white) at  $q(\text{FDR}) < .05$ . Panel (a) and panel (b) represent brain region in which neural RDMs for same emotions are more similar than the neural patterns for different emotions (red) and vice versa (blue) for the explicit task and implicit task respectively. Abbreviations: CU = cuneus; DMPFC = dorsomedial prefrontal cortex; FG = fusiform gyrus; IPL = inferior parietal lobule; IPS = intraparietal sulcus; VMPFC = medial prefrontal cortex; PCC = posterior cingulate cortex; PCUN = precuneus; PSTS = posterior superior temporal gyrus; SFL = superior frontal lobe; TL = temporal lobe.

1

## 2 | Region of Interest Analysis

3 All three analyses on task effect (univariate GLM, multivariate GNB and RSA) revealed  
 4 convergent results spanning a number of anatomical regions (Fig. 3), e.g. VMPFC, IPL and LOTC  
 5 (including EBA). To gain a more detailed insight into the responses in these regions, we defined  
 6 several ROIs by setting a statistical threshold of  $q(\text{FDR}) = 0.01$  cluster size corrected (min. cluster  
 7 size threshold = 34) on the maps of the GNB analysis and extracting beta values from the resulting

1 clusters. For the explicit vs. implicit task decoding this revealed bilateral EBA, right IPL, right  
2 VLPFC, precuneus, and bilateral IPS, see Table 4.

3

**Table 4. Region of interest (ROIs).** Group level statistics of the classification accuracies produced by the GNB of Explicit vs. Implicit conditions tested against chance level, at  $q(\text{FDR}) < .01$  and cluster size corrected (min. cluster size threshold = 34). The values of the peak voxel of each surviving cluster is reported. The degrees of freedom were 19 and p-values were less than .001.

Brain Regions	L/R	x	y	z	t(19)
Extrastriate body area	R	54	-59	-5	7.207***
	L	-44	-66	1	9.531***

\*\*\*  $p < .000001$

4

5

6

7

**Figure 8. Details of the responses from the ROIs identified by the task based decoding, RDM and beta plots at the category level of each ROIs are shown.** The different ROIs are the result of the classification accuracies tested against zero produced by the GNB thresholded at  $q(\text{FDR}) = 0.01$  cluster size corrected (min. cluster size threshold = 34). On the left side of the panels the RDMs computed with 1-Pearson's correlations distance between the different conditions are shown. The bar charts on the right side of the panel show the mean plus standard error of the group averaged ROI beta values. The RDM for VLPFC and (right) EBA show a pattern of similarities within the explicit condition however, the same pattern is absent in the implicit condition. The condition's color labels refer to the explicit recognition task (red) and implicit recognition task (blue). Abbreviations: EBA = extrastriate body area; IPL = inferior parietal lobe; VLPFC = ventrolateral prefrontal cortex.

1

2 As shown in Fig. 8, the neural RDMs of the EBA and VLPFC ROIs show a similar structure, in  
 3 particular in the explicit task conditions (upper left half of the RDM), whereas this effect is absent  
 4 in the implicit conditions (bottom right half of the RDM). While the MVPs of the other regions  
 5 (see supplementary material, Figs S1 and S2) produce RDMs which present effects (similarities or  
 6 dissimilarities) within conditions or activation levels, they do not show the clear pattern found for  
 7 right EBA and VLPFC.

## 1 | **Discussion**

2

3 In the present study we measured the representational dynamics of explicit and implicit body  
4 expression perception and identified the brain areas that are critical for the distinction between the  
5 two tasks. Our results revealed three main findings. First, the difference between explicit and the  
6 implicit body expression processing can be decoded with high accuracy in right EBA, VLPFC and  
7 IPL. Second, the brain activity associated with explicit recognition in these areas is not emotion  
8 specific. Third, some specific effects for different emotions are observed in the implicit condition.  
9 In the sections below we discuss these findings and propose that taken together these findings  
10 suggest that the way in which object category, stimulus attributes and action are represented is  
11 dynamically organized by the requirements of each task and we clarify the functional role of body  
12 areas.

13

### 14 | *Similar task specificity across high-level visual cortex, EBA, VLPFC and IPL.*

15 The first major result of our study is that there are three areas where the difference between naming  
16 the expression or naming a shape on top of it while ignoring the expression can be decoded with  
17 high accuracy, and mainly expressed through highly similar responses for all conditions in the  
18 explicit task. Our results are consistent with previous studies that have reported task specific  
19 activity in higher visual cortex and VLPFC ([Bracci, Daniels, and Op de Beeck 2017](#); [Bugatus,  
20 Weiner, and Grill-Spector 2017](#); [Xu and Vaziri-Pashkam 2019](#); [Haxby, Connolly, and Guntupalli  
21 2014](#); [Kriegeskorte et al. 2008](#); [Pichon, de Gelder, and Grezes 2009](#)). Specifically concerning  
22 explicit tasks, increased sensitivity in higher visual areas was found in some but not in other earlier  
23 studies. A previous study ([Bugatus, Weiner, and Grill-Spector 2017](#)) found that during either a  
24 working memory, oddball or selective attention task, the task effect was limited to VLPFC and not  
25 seen in high-level visual cortex where responses were more driven by stimulus category than by  
26 the task demands. One explanation for the same task effect seen in EBA and VLPFC here is that  
27 VLPFC contains flexible category representations (here body specific neurons) when the task  
28 requires it ([Bugatus, Weiner, and Grill-Spector 2017](#)). While this may explain the task sensitivity  
29 to body expression categorization in VLPFC, it does not address the parallel finding of task  
30 sensitivity in right EBA. An alternative explanation that would clarify that similar task effects are  
31 found in EBA and VLPFC is that the explicit task effect we see here reflects selective attention.

1 Perception driven by selective attention to the expression might then have a region-general effect  
2 across EBA and VLPFC. This is in agreement with studies showing that selective attention alters  
3 distributed category representations across cortex, and particularly in high-level visual cortex and  
4 also in VLPFC ([Cukur et al. 2013](#); [Peelen, Fei-Fei, and Kastner 2009](#); [Shahdloo, Çelik, and Çukur](#)  
5 [2020](#)). These studies found effects of selective attention-based increases in category representation  
6 areas for the preferred category in visual search tasks. Our results are consistent with this to some  
7 extent as selective attention to the body expressions in the explicit task may boost body category  
8 representation in EBA. But then such an attention-based activity increase should be visible in FBA  
9 as well, or, on the assumption that EBA codes body parts and FBA whole body images, it should  
10 be clearer in FBA, unless their respective involvement with expression coding is very different.  
11 This is indeed suggested by the present results privileging EBA. On the other hand, there is  
12 evidence that category selective mechanisms in visual object areas operate outside selective  
13 attention, a process attributed to neural mechanism for attentional selection enshrined in the  
14 category selective area ([Peelen, Fei-Fei, and Kastner 2009](#)). This would lead one to expect little  
15 difference between activity in body areas between the explicit and the implicit task, contrary to  
16 what is found here. Unless, again, EBA plays a more important role in expression perception than  
17 FBA, in which case we should expect emotion specificity in EBA task activity.

18  
19

#### 20 | *Task dynamics, body and body representation in EBA.*

21 EBA and FBA are commonly viewed as ventral stream areas associated with body representation  
22 but their respective functions are not yet clear nor is their anatomy well understood ([Weiner and](#)  
23 [Grill-Spector 2012](#)). Whole body perception is attributed more to FBA than to the EBA which is  
24 seen as more involved in body parts ([Downing et al. 2001](#); [Peelen and Downing 2007](#)). Few studies  
25 have yet investigated the specific functional roles of FBA and EBA either in expression perception  
26 or in relation to task demands and available studies find no clear differences in their functional  
27 role for expression and task sensitivity. Our results contribute to clarifying this situation.

28

29 Considering their category sensitivity, a current view is that EBA encodes details pertaining to the  
30 shape, posture and position of the body and does not directly contribute to high level percepts of  
31 identity, emotion or action that are potential functions of FBA through its connections with other

1 areas ([Downing and Peelen 2011](#)). However, studies on body expressions have most often reported  
2 involvement of both EBA and FBA with the activity pattern varying with the specific expression  
3 considered but without any clear understanding of the respective functions ([Costantini et al. 2005](#);  
4 [Marsh et al. 2010](#); [Moro et al. 2008](#); [Pichon, de Gelder, and Grezes 2012](#); [Saxe, Jamal, and Powell](#)  
5 [2006](#); [de Gelder, de Borst, and Watson 2015](#); [Tamietto et al. 2015](#); [Van den Stock et al. 2015](#)).

6  
7 Recent evidence projects a more detailed view on EBA and how it could contribute differentially  
8 to body and body expression perception which is consistent with our present findings. First, an  
9 investigation aimed at sorting out the function of EBA and adjacent MT+ reported a double  
10 dissociation, with TMS over EBA disrupting performance in the form discrimination task  
11 significantly more than TMS over pSTS, and *vice-versa* for the motion discrimination task  
12 ([Vangeneugden et al. 2014](#)). Additionally, ([Zimmermann et al. 2016](#)) showed that early disrupting  
13 of neuronal processing in EBA during action planning, causes alterations in goal-oriented motor  
14 behavior. Second, in support of the differences found here, EBA and FBA show a very different  
15 profile of anatomical connectivity with other brain areas, notably with parietal areas ([Zimmermann](#)  
16 [et al. 2018](#)). Third, EBA is a complex area with important subdivisions ([Weiner and Grill-Spector](#)  
17 [2011](#)) possibly coding different features of whole body images. In line with this, ([Ross 2014](#))  
18 propose to dissociate the EBA-MT+ area as this would profile EBA more clearly as the area coding  
19 body form and clarify functional differences between EBA and FBA. In a recent study  
20 investigating detailed features of body expressions and how they are represented in the brain, major  
21 differences were found in the functional role of EBA and FBA when studied at the feature coding  
22 level ([Poyo Solanas, Vaessen, and de Gelder 2020b](#)). EBA and FBA also showed tuning to postural  
23 features of different expressions. However, the feature representation in EBA was very dissimilar  
24 to that of FBA. Similar feature representation to that seen in EBA was found in SMG, pSTS, pIPS  
25 and the inferior frontal cortex but not in FBA ([Poyo Solanas, Vaessen, and de Gelder 2020b](#)).  
26 When such findings targeting function descriptions at the feature level accumulate, more detailed  
27 hypotheses about task effects become feasible.

28  
29 Another possibility is that the effects observed in EBA reflect recognition of the body expression  
30 based on only a body part like the hands and not on the whole body. Recent evidence shows that  
31 the hands are more informative for certain emotions, including anger images used here ([Poyo](#)

1 [Solanas, Vaessen, and de Gelder 2020a](#); [Kret and de Gelder 2012](#); [Kret et al. 2017](#); [Ross and Flack](#)  
2 [2020](#)). Concerning representation in the brain ([Taylor, Wiggett, and Downing 2007](#)) found that  
3 bilateral EBA showed a preference for individual body parts such as the hands and fingers while  
4 FBA showed a preference for the whole body. ([Bracci et al. 2010](#)) showed selective response to  
5 hands over other body parts in left EBA. Our results in the explicit condition revealed right EBA  
6 instead. Since our study used whole body stimuli and not body parts, we cannot directly address  
7 this possibility.

8  
9

### 10 | *Task decoding and the role of IPL*

11 In IPL like in EBA and in VLPFC, we are able to decode the difference between the tasks, albeit  
12 less clearly and with higher beta values for the implicit condition. In the univariate results also,  
13 IPL is more active in the implicit task. IPL is a hub structure and is involved in at least four  
14 networks (the frontoparietal, default mode, cingulo-opercular and ventral attention network  
15 ([Igelström and Graziano 2017](#)). Previous studies provided clear evidence for the role played by  
16 IPL in body and emotional perception. Emotion-specific activation within parietal cortex was  
17 found for face stimuli ([Grezes, Pichon, and de Gelder 2007](#); [Kitada et al. 2010](#); [Sarkheil et al.](#)  
18 [2013](#)) and for body stimuli ([de Gelder et al. 2004](#); [Goldberg et al. 2015](#); [Goldberg, Preminger, and](#)  
19 [Malach 2014](#); [Kana and Travers 2012](#)). Significant activity was elicited in IPL for the contrast  
20 bodies expressing fear or happiness ([Poyo Solanas et al. 2018](#)). We argued previously that IPL  
21 may play the role of a hub where emotion perception is transitioned into an action response  
22 ([Engelen et al. 2018](#)). IPL receives input from the visual system ([Caspers et al. 2011](#)) and has  
23 connections to pre-motor cortex involved in action preparation ([Hoshi and Tanji 2007](#); [Makris et](#)  
24 [al. 2005](#); [Mars et al. 2011](#)).

25

26 Higher activity in IPL in the implicit task fits the role of IPL in action representation and its  
27 involvement in the transition to action preparation ([Engelen et al. 2018](#)). Explicit emotion  
28 recognition is a cognitive task and in the course of using verbal labels action tendencies triggered  
29 by the stimuli tend to be suppressed, which may be reflected in lower IPL activity ([Engelen et al.](#)  
30 [2015](#); [Igelström and Graziano 2017](#)). In line with this, there is no difference between the emotion

1 conditions in the explicit task while there is a suggestion of this in the implicit task (but this is not  
2 significant).

3

#### 4 | *The role of VLPFC*

5 Similar to the results for right EBA we found that activity in right VLPFC allows decoding the  
6 task difference, again with significantly higher beta values for the explicit task and with no  
7 difference between the expression conditions. In the whole-brain RSA, VLPFC showed higher  
8 intra-task similarity (higher similarity for same task) (see Fig. 5 and Table 3), consistent with the  
9 pattern of similarities we found in the RDMs during the ROIs analysis (see Fig. 8). The literature  
10 suggests different explanations for the role of VLPFC. One is its role in attention and decision  
11 making, another one the possibility that VLPFC contains object category representations and  
12 finally, a role of VLPFC in regulating affective processes. The latter alternative is best supported  
13 by the pattern of results.

14

15 A familiar function of VLPFC is related to theories of PFC as predominantly involved in attention  
16 and decision processes ([Duncan 2001, 2010](#)) and it associates VLPFC activity with increased task  
17 demands ([Crittenden and Duncan 2014](#)). But our two tasks were designed to be very similar in  
18 difficulty and in cognitive demands and required a simple forced choice between two alternative  
19 responses. Under these circumstances one would not expect a task related difference in VLPFC  
20 and indeed accuracies are near 100%. Similarly, attention is known to be triggered selectively by  
21 some body emotion expressions (eg. fear) more than others ([de Gelder, Hortensius, and Tamietto  
22 2012; Tamietto et al. 2015; Zhan, Goebel, and de Gelder 2018](#)). Yet we do not observe a difference  
23 between the emotions as would be expected if the VLPFC activity corresponded to endogenous  
24 attention. This speaks against the notion that VLPFC activity here reflects an effect of attention.  
25 A second explanation is that VLPFC activity reflects a task effect and not an attention effect  
26 ([Bugatus, Weiner, and Grill-Spector 2017](#)) based on the notion that VLPFC is the final stage of  
27 high level vision in the ventral pathway involved in categorization ([McKee et al. 2014; Bugatus,  
28 Weiner, and Grill-Spector 2017; Cukur et al. 2013; Peelen, Fei-Fei, and Kastner 2009](#)). However,  
29 those studies used a number of different object categories unlike the present study only using  
30 bodies and where the explicit task was expression recognition. This makes it unlikely that the  
31 present role of VLPFC reflects a task effect based on category selectivity.

1 In contrast with those two alternatives our results best support the notion that VLPFC is involved  
2 in suppression of emotion related processes that are automatically triggered by presentation of  
3 emotional stimuli. Previous studies have shown that the VLPFC is involved in downregulating  
4 emotion responses presumably based on its structural and functional connectivity to the amygdala  
5 ([Wager 2008](#)). TMS directed on VLPFC, interrupted processing of emotional facial expressions  
6 ([Chick et al. 2019](#)). The fact that beta values are higher in VLPFC for explicit recognition  
7 conditions is consistent with this explanation.

8

### 9 | *Explicit vs implicit representation of emotions.*

10 A first finding of the RSA is that decoding accuracies for emotion were overall low and did not  
11 differ between the emotion and the shape task. It is worth noting that the amygdalae are not among  
12 the areas we found to be important for task decoding. Many studies have argued that the amygdala  
13 is activated for stimuli with affective valence whether due to fear, anger or happy expressions, or  
14 overall stimulus salience and that often activity is lower under the implicit viewing conditions ([de](#)  
15 [Gelder, Hortensius, and Tamietto 2012](#); [di Pellegrino, Rafal, and Tipper 2005](#); [Habel et al. 2007](#)).  
16 Our analysis does not reveal amygdala as an area that shows differences in decoding accuracy  
17 when implicit and explicit tasks are compared. This is consistent with the literature showing  
18 activation in amygdala both in explicit as well as in implicit emotion evaluation, albeit somewhat  
19 lower in the latter condition ([de Gelder, Hortensius, and Tamietto 2012](#)). The GNB classifier used  
20 for the analysis was trained to find regions with large differences in the MVPs for the explicit and  
21 the implicit task and it is thus not surprising that we do not find amygdala with this analysis.

22 In the Intra/Inter RDMs similarities analysis (Fig. 6,7) specifically looking for emotion condition  
23 effects, we did observe an overall pattern of task and emotion representation dynamics. Overall,  
24 we find similarities and differences between the emotion conditions for the two tasks. For the  
25 explicit emotion recognition task, higher similarities between same emotions were seen in left  
26 insula and left post-orbital gyrus. Interestingly, these areas are found when body expressions are  
27 viewed consciously but not when they are unattended or neglected ([Tamietto et al. 2015](#); [Salomon](#)  
28 [et al. 2016](#)). For the implicit emotion recognition task, higher intra emotion similarities were found  
29 in right parahippocampal gyrus, which may reflect that processing expressions involves memory  
30 similarly for both expressions. For the explicit task, higher similarities between different emotions

1 presumably representing what is common to different emotions, were found in right entorhinal  
2 cortex, right hippocampus and left FBA. Concerning the latter, this suggest that FBA is involved  
3 in expression recognition but does not contribute to specific expression coding. In contrast, in the  
4 implicit task higher similarities between different emotions were found in medial prefrontal cortex,  
5 left precuneus, left premotor cortex, right inferior occipital gyrus, right superior temporal gyrus  
6 and right supramarginal gyrus. Interestingly, the latter are all areas known from studies that used  
7 passive viewing or oddball tasks and not emotion labeling or explicit recognition ([de Gelder et al.](#)  
8 [2004](#); [Grezes, Pichon, and de Gelder 2007](#); [Goldberg et al. 2015](#)).

9

10 However, we can relate the EBA and VLPFC results to the role of IPL in action perception and  
11 preparation as discussed above. The finding of task sensitive activity in IPL suggests that the higher  
12 similarities in the explicit emotion task for VLPFC and EBA are not just independently reflecting  
13 stimulus/task settings and higher activation level in the explicit emotion task. The combination of  
14 higher activation in EBA and VLPFC and lower activation in IPL suggests connections between  
15 these three areas with VLPFC possibly influencing EBA positively and IPL negatively ([Ongur and](#)  
16 [Price 2000](#); [Goldman-Rakic 1996](#); [Ong, Stohler, and Herr 2019](#); [Craig 2009](#); [Tamietto et al. 2015](#)).  
17 For explicit recognition of the body expression, category representation would be strengthened  
18 while emotion action related information would be suppressed. Further studies using connectivity  
19 measures are needed to support this hypothesis.

20

21

## 22 | *Limitations and future perspectives.*

23 As the present study used two body expressions further research is needed to conclude whether  
24 the same pattern would be observed with different emotional expressions like for example fear.  
25 Another possible limitation concerns the number of identities. However, the postures display  
26 standard expressions that are effortless recognized as can be seen in the behavioral results. And  
27 because facial identity information is blurred, individual personal identity of each stimulus is  
28 unlikely to impact the results. Another limitation of our study that the design used does not allow  
29 to measure functional relations between the critical areas observed. Further studies using  
30 connectivity measures are needed to support our suggested explanation. Finally, is worth noting

1 that two decades of neuroimaging on the brain correlates of human emotion have not yielded a  
2 clear picture of how emotions are represented in the brain and this notwithstanding hundreds of  
3 studies ([Wager et al. 2015](#)). But relatively few studies have contrasted explicit recognition and  
4 implicit perception and the few studies who did so find substantial differences ([Zhan, Goebel, and](#)  
5 [de Gelder 2018](#)). Besides the theoretical importance of the distinction, this task contrast is  
6 particularly relevant for understanding emotion perception in clinical populations like  
7 schizophrenia ([Trémeau et al. 2015](#)) and autism ([Jones, Lambrechts, and Gaigg 2017](#); [Luckhardt](#)  
8 [et al. 2017](#)). For example, in studies of autism and schizophrenia it has been reported that implicit  
9 measures are more diagnostic than explicit ones ([Hajdúk et al. 2019](#); [Luckhardt et al. 2017](#); [Van](#)  
10 [den Stock et al. 2011](#)). A better understanding of implicit emotion processing as seen in real life  
11 routines and explicit recognition as seen in questionnaires may shed new light on clinical findings  
12 and provide a rich analytical framework for investigating social cognitive disorders. Overall, this  
13 result indicates that the similarities found in explicit tasks do not map onto the pattern of the  
14 implicit ones and stress the importance of paying attention to the importance of the task both when  
15 investigating category selectivity and brain correlates of affective processes.

16  
17

## 18 | **Conclusion**

19 The main purpose of this study was to investigate how explicit and implicit emotion perception  
20 tasks affected activity in body category and emotion coding areas during the processing of whole  
21 body expressions and to assess whether the activity patterns would also reflect differences between  
22 emotional expression and skin colors. Reviewing the various alternatives for the respective role of  
23 EBA, VLPFC and IPL related to the task driven dynamics, the results suggest that right EBA may  
24 be active in response to explicit body attribute recognition, and the parallel pattern in VLPFC may  
25 itself play a role either because it also codes for body category when the task demands it and/or it  
26 plays a role in emotion regulation that may be involved when the task requires verbal naming. The  
27 clear task effects seen here indicate that understanding the issue of category representations may  
28 profit from being viewed also in the larger context of connectivity between ventral areas and other  
29 areas in the brain.
