Abstract

Diphenylalanine (FF) peptide nanotubes (PNTs) present a unique class of self-assembled functional biomaterials owing to a wide range of useful properties including nanostructural variability, mechanical rigidity, and chemical stability. In addition, a strong piezoelectric activity has been recently observed paving the way to their use as nanoscale sensors and actuators. In this work, we fabricated both horizontal and vertical FF PNTs and examined their optical second harmonic generation and local piezoresponse as a function of temperature. The measurements show gradual decrease of polarization with increasing temperature accompanied by irreversible phase transition into another crystalline phase at about 140-150 °C. The results are corroborated by the molecular dynamic simulations predicting order-disorder phase transition into centrosymmetric (possibly, orthorhombic) phase with antiparallel polarization orientation in neighboring FF rings. Partial piezoresponse hysteresis indicates incomplete polarization switching due to high coercive field in FF PNTs.

Keywords:

diphenylalanine peptide nanotubes, piezoelectricity, second harmonic generation, phase transition

1. Introduction

Piezoelectricity is the ability of crystalline materials without a centre of inversion to produce mechanical stress/strain under an electric field or charge/voltage under a mechanical force. This property is widely used nowadays in many applications including acoustic transducers, sensors/actuators, piezomotors, accelerometers and gyroscopes, just to name a few.¹ Following current trends for miniaturization, piezoelectric materials were suggested to be the key elements of future micro- and nanoelectromechanical systems (MEMS and NEMS), where piezoelectric effect offers many advantages over electrostatic actuation.^{2,3} In view of growing interest in biomedical applications, bioorganic materials having significant piezoactivity (in particular ferroelectrics⁴) are required for further progress in the design of modern piezo MEMS and NEMS. Several biologically originated materials were identified to be piezoelectric but their piezoelectric properties were rather weak to be used in applications.^{5,6} Another challenge is to fabricate the nanostructural material such as nanotubes for the activation of piezoelectricity at the nanoscale.⁷ Recently, strong piezoelectricity (of the order of that in the classical transducer material LiNbO_3) has been discovered in bio-inspired peptide nanotubes (PNTs) made by a self-assembly process of small diphenylalanine, $\text{NH}_2\text{-Phe-Phe-COOH}$ (FF), peptide monomers.⁸ These PNTs have first been discovered from the determination of the smallest recognition motif of the amyloid- β protein, associated with over 30 diseases, mostly neurodegenerative ones such as Alzheimer's, Huntington's, Parkinson's, Creutzfeldt-Jacob and prions, but also sclerosis (Lou Gehrig's disease) and type II diabetes.⁹ They are made from amino acids, self-assembled in unique stable tubes with hydrophilic hollows,¹⁰ having high Young's modulus and chemical stability.¹¹ X-ray and electron diffraction have revealed that their room temperature crystal structure is compatible with the space group $P6_1$ ¹², allowing many physical phenomena described by the odd-rank tensor, including optical second harmonics generation, pyroelectricity, linear electrooptic effect, piezoelectricity, etc. Crucial for applications is the temperature dependence of polarization in FF PNTs, and possible phase transformation under heating above room temperature. In this work, we present our recent findings on the temperature-dependent polarization response in FF PNTs, studied via Piezoresponse Force Microscopy (PFM)¹³ and optical SHG.

Second harmonic generation (SHG) is known to be an efficient tool for studying different types of phase transitions, such as surface reconstruction of the collagen 3D configuration in teeth¹⁴, laser-induced melting,¹⁵ phase transitions in molecular monolayers,¹⁶ structural phase transition at the surface,¹⁷ etc. In ferroelectrics, diagnostics with SHG is based on the sensitivity of SHG intensity to the order parameter; therefore the temperature dependence of the square root of SHG intensity typically follows polarization behavior. In this way, various phase transitions in classical ferroelectrics¹⁸ as well as in organic materials¹⁹ were successfully identified. In organic materials, SHG is also sensitive to conformational transitions, including irreversible transformations.²⁰ The aim of this work was thus to study temperature-dependent SHG and PFM, with the focus on possible phase transitions and ferroelectricity in this material.

2. Experimental details

FF PNTs were self assembled by dissolving the FF dipeptide from the lyophilized form (Bachem, Switzerland) in 1,1,1,3,3,3-hexafluoro-2-propanol at a stock concentration of 100 mg/ml. For horizontal tubes, 2 μ l of the stock solution was diluted with 98 μ l of dd-H₂O. The diluted solution was deposited onto Au- or Pt-coated silicon substrates and left overnight for drying. For vertical tubes, 30 μ l of the stock solution was cast directly on a substrate with an area \approx 2 cm² and left for complete evaporation for 12 hrs.²¹ The local piezoresponse measurements were performed with a commercial AFM (Ntegra Prima, NT-MDT) equipped with external function generator and lock-in amplifier as already described elsewhere.⁸ We used doped Si cantilevers with the spring constants of 0.5 - 1 N/m. Ac voltage of 2 V amplitude and frequency 5 kHz was applied to the counter electrode while the tip was grounded. For the SHG measurements, the beam of a Ti:sapphire laser (790 nm with a pulse width of about 100 fs, a repetition rate of 80 MHz, and an average power of 15 mW) was focused onto a spot of about 50 μ m diameter. Reflection geometry was used at a 45° incidence. Both fundamental and SHG waves were polarized with the electric field vector in the incidence plane (p-in, p-out). The SHG signal at 380 nm was filtered by a colour filter (BG39) and detected by a photomultiplier tube in a photon counting mode. SHG images filtered by BG39 were taken with CCD camera using optical microscope (magnification x45) under

femtosecond laser irradiation. CCD camera was then mechanically scanned to acquire the SHG image with the resolution of a few μm .

3. Results and discussion

Figure 1 shows representative SEM and PFM images of the fabricated PNTs assembled horizontally and vertically on metallized substrates as described above. A variety of tubes of different lengths, diameters, and orientations was observed. Strong piezoelectric contrast was observed on both horizontal (via lateral PFM signal, inset to Fig. 1a) and vertical tube assemblies (via vertical PFM, inset to Fig. 1b). These results confirm already published data⁸ on horizontal tubes where only shear piezoelectric coefficient (d_{15} ~60 pm/V on sufficiently big tubes) could be measured. The estimate of the effective longitudinal piezoelectric coefficient d_{33} in vertical tubes yields values in excess of 30 pm/V, i.e. it exceeded that for LiNbO_3 .²² Figure 2a represents the variation of the average shear PFM contrast with increasing temperature measured on horizontal tubes. The contrast gradually decreases with temperature demonstrating monotonous d_{15} dependence and ultimate disappearance of piezoresponse at the temperature of ~ 150 °C. It should be noted that the contrast becomes irreversible if the sample is heated above 100 °C, i.e., it is not recovered after cooling down to room temperature and remained practically zero after heating up to 140-150 °C. This hints to the possible phase transformation to another phase on heating, as no visible degradation of the topography was found. Figure 2b shows the temperature dependence of SHG intensity measured on vertical tubes (both heating and cooling runs). The results are, in general, consistent with the temperature-dependent PFM contrast measurements, however, many more details were observed on the temperature curve. A clear cusp on the SHG intensity curve at about 50 °C is followed by the significant reduction of the intensity until a plateau between 100 and 120 °C is reached. Finally, the SHG signal drops down at ~ 130 °C (irreversibly as evidenced by the cooling curve). It should be noted that these data are consistent with the recent studies of thermal stability of PNTs via differential thermal gravimetry (DTG).²³ These measurements revealed that FF PNTs exhibit a clear weight loss at temperatures close to ~ 50 °C (anomaly seen also with SHG, Fig. 2b) and at ~ 140 °C. The rearrangement of the crystalline structure of PNTs at 50 °C (as evidenced by the anomaly of the SHG signal) can be due to the phase transition between

two piezoelectric phases as confirmed by the existence of piezoresponse both below and above this temperature (Fig. 2a). The details of this phase transition are outside the scope of this paper and will be reported elsewhere. In general, the apparent decrease of the piezoelectric contrast and SHG intensity (Fig. 2) with temperature is a clear signature of the irreversible phase transformation into a high-symmetry phase as often observed in molecular crystals.^{24,25}

Figure 3 shows typical x-ray diffraction patterns of the studied vertical PNTs before and after temperature annealing at 150 °C during 1 hour. In virgin samples (grown at room temperature) all observed peaks correspond to the expected hexagonal structure already reported for FF PNTs ($a=24.071 \text{ \AA}$, $c=5.456 \text{ \AA}$, $\alpha=120^\circ$, space group $P6_1$).¹² The diffraction peaks for annealed PNTs are apparently different, belonging to another crystalline phase. All diffraction peaks after annealing could be explained based on the appearance of an orthorhombic structure with the unit cell parameters: $a=5.210 \text{ \AA}$, $b=24.147 \text{ \AA}$, $c=41.072 \text{ \AA}$ (see Table 1 of the Supplementary Material section for more details). The possible phase transition between hexagonal and orthorhombic phases upon annealing is illustrated in Figs. 4b and 4c, where it is shown how the initial hexagonal unit cell could be transformed into the orthorhombic one via a small deformation of the FF rings. The mainframe of the FF PNT structure consists of the FF rings (Fig. 4a), formed from six individual FF molecules (6FF), in accordance with Ref. 12. Each ring possesses a dipole moment P_s along tubular OZ axis perpendicular to ring plane and form the hexagonal structure¹² from four rings (Fig. 4a, right). It is suggested that for the hexagonal structure all 6FF rings (A, B, C, and D) have the same orientation as the individual P_s (Fig. 4b), this being compatible with the total large dipole moment and strong piezoresponse in PNTs grown at room temperature.⁸ Antiparallel orientation of P_s for the neighboring 6FF rings (A and C opposite to B and D) produces novel orthorhombic structure with zero total polarization (Fig. 4c) for annealed tubes.

To understand further the molecular structure of the FF PNTs and possible mechanisms of their self-assembly and phase transitions, we performed molecular modeling and molecular dynamic (MD) simulations using HypeChem 7.52.²⁶ The isolated ring with six dipeptides as well the parallel stacking of two rings (see Fig. S1 of the Supplementary Material section) were studied by the geometry optimization of the total energy and MD runs using molecular mechanics (MM) methods (BIO CHARMM) in combination with first principle quantum approach (*ab initio* and PM3 semi-empirical). It was found that 6FF forms ordered rings (hexagonal structure, $P6_1$) with inner and

outer diameters of ~ 10.5 and 25 Å, respectively, connected by N-H...O hydrogen bonds with O-H lengths of ~ 1.65 Å. This is in full agreement with the results of Ref.12. Further, we calculated the dipole moment being ~ 1.3 Debye for a single 6FF ring, directed along the OZ hexagonal axis corresponding to a spontaneous polarization $P \approx 0.24$ $\mu\text{C}/\text{cm}^2$. This data also corresponds to the reported values for isolated FF units¹² (Fig. 4a). Figure S1 represents the model of parallel double-stacked 6FF units. In this case, the optimization with BIO CHARMM (after PM3 calculations) leads to a large dipole moment $D_t \sim 42$ Debye ($P \sim 4.0$ $\mu\text{C}/\text{cm}^2$). After additional PM3 semi-empirical optimization it further increases up to $D_t \sim 52$ Debye and the estimated polarization value reaches ~ 5 $\mu\text{C}/\text{cm}^2$. On the basis of this model we performed MD runs and simulations at different temperatures. The result is fully consistent with the experimentally obtained SHG and PFM data, i.e., the average dipole moment gradually decreases as a function of temperature (cf. calculations with experimental data in Fig. 2b). The polarization is about 5 $\mu\text{C}/\text{cm}^2$ at 25 °C and decreases to ~ 2 $\mu\text{C}/\text{cm}^2$ at 100 °C. The results for a parallel stacked FF ring model correspond to the hexagonal phase and the experimentally observed large dipole moment and high piezoelectric coefficient in virgin structures, while the antiparallel orientation of neighboring tubes correspond to the orthorhombic phase with a very small total dipole moment, as is shown in Fig. 2b. Moreover, this result made us believe that the dipole ordering along OZ hexagonal axis for the hexagonal phase is due to a cooperative dipole effect (as common to ferroelectric systems, while the orthorhombic phase is similar to antiferroelectrics), and polarization switching is possible if a high-enough electric field is applied along this axis.

Following this idea, we attempted to measure piezoresponse hysteresis on virgin (not annealed) vertical PNTs. The simulation data has led to the conclusion that the corresponding coercive field would be very high, in the order of ~ 30 MV/cm, and have an asymmetric character as a result of the strong internal bias field. This prediction is fully consistent with the experimental result (Fig. 5) where a hysteretic-like dependence of the effective d_{33} vs. applied bias is obvious. However, the loop reveals partial switching of the polarization along the hexagonal axis with superimposed linear behaviour that could be caused by the electrostatic contribution to the piezoresponse (Maxwell stress).²⁷ Taking into account some flexibility of the PNTs at the contact point, and apparent non-local electrostatic interaction, this possibility cannot be ruled out. The results are in line with recent piezoresponse measurements in PZT nanotubes where a similar character of the piezoresponse hysteresis was found.²⁸ This signifies

that the local measurements in such complex geometries can be overshadowed by the spurious signals irrespective of the nature of the material. The polarization offset observed in the hysteresis loops (Fig. 5) could be due to the fact that the available electric field is insufficient for switching, and only a small reverse domain (unstable with time) is formed under a maximum bias. This is confirmed by the absence of any switched polarization after the consequent PFM imaging. Since the available electric field by the tip is quite low (in the first approximation $\sim 100\text{-}200$ kV/cm under the bias 10 V), this reduces the opportunities for using vertical FF PNTs as media for high density data storage. Unfortunately, higher biases destroy the tubes. Molecular simulations made under electric field were in line with the experimental observation (Table 3 of the Supplementary Material section) and showed that the antiparalle field of about 5 MV/cm is only able to decrease polarization value by about 12%.

Another important result of our simulations is the tentative explanation of the observed hexagonal-orthorhombic irreversible transformation, because the calculations show that the temperature increase leads to the strong changes in the condensation energies, in particularly modifying inter-tube interaction. The approach for the inter-tube interaction calculations with distances and determination of the condensation energies is similar to that used in Ref. 29. As a result, the inter-tube condensation energy is decreasing with temperature and, at the temperature of about 150 °C, it becomes comparable with thermal energy kT (Fig. S1, Table 2). This ultimately leads to the dissociation of PNT tubes and reorganization of their structure, so that the antiparallel orientation of the rings becomes energetically favorable at high enough temperature. All in all, the predicted re-orientation of polar molecular dipole groups in neighboring FF tubes leads to the compensation of the total polarization to almost zero value, accompanied with the symmetry change and increase of the unit cell size (see, for illustration Figs. 4 and S1 and Tables 1 and 2 of the Supplementary Material section). We believe that for FF PNTs prepared at room temperature, the parallel orientation of the polar moments related to individual nanotubes is energetically favorable; while at $T \geq 150$ °C the preferred conformation is anti-parallel leading to a doubling of the unit cell. This model is in line with the experimental XRD results (Fig. 3) and the orthorhombic structure shown in Fig. 4. Upon cooling this phase persists down to room temperature, being metastable within extended period of time. The calculated transition temperature is close to that observed by PFM and SHG experiments. AFM and SEM

data (Fig. S2 of the Supplementary Material section) indicate notable degradation of the tube surface consistent with earlier reports.³⁰

It is already well known that FF peptides could form various supra-molecular structures. One of the most studied conformations is a hexagonal molecular nanotube structure, similar to that observed in liquid crystals (LC).^{31,32} From this point of view it is evident that the studied PNTs could be considered as an analog of a smectic C* (SmC*) phase, composed of six FF L-chiral molecules arranged as a single 6FF stable ring (one smectic disc further forms discotic-like columnar structure^{24,33}). Obviously, such molecular LC is prone to polymorphic transformations²⁵ that occur due to a very wide variation of the peptide's bond torsion angle. Some of these polymorphic phases could be metastable leading to possible irreversible phase transitions. It is worth noting that structural polymorphism exists in the amyloid fibrils related to PNTs³⁴. Similar transitions were observed in the temperature dependence of LC lipid systems³⁵ and in DNAs that change from tubular hexagonal to orthorhombic structure³⁶. It is clear that our results resemble the well-known phase transition in LC from ferroelectric-like SmC* to paraelectric SmA phase. The details of the molecular simulations and calculations of the condensation energies are reserved for future publication.

4. Conclusions

In conclusion, our measurements revealed an important feature of the polarization behavior in self-assembled diphenylalanine peptide nanotubes. As confirmed by the PFM and SHG measurements, the polarization gradually decreases from room temperature to 140 °C, and experiences irreversible phase transformation to another (probably orthorhombic) crystalline phase with zero polarization. This phase persists upon cooling to room temperature. Partial polarization switching is observed by the application of a strong electric bias to the PFM tip, but full switching is impossible due to the high coercive field. This result is in line with the fact that ferroelectric-like behavior is originated from hydrogen bonds among the FF monomers, which break upon the temperature increase. This transformation is extremely important in view of the foreseeable applications of PNTs as sensors and actuators.

Table 2. Condensation energies and optimized distances at different temperatures.

Temperature, °C	Energy of inter-ring condensation		R_{opt} of inter-ring at E min, Å	Type of inter-tube structure	Energy of inter-tube condensation E_{con}		R_{opt} of inter-tube at E min, Å
	kcal/mol	eV			kcal/mol	eV	
25	130.3	5.7	5.45	Parall	4.4	0.20	25.80
				Anti-par	4.2	0.18	26.90
100	101.3	4.4	5.50	Parall	2.5	0.10	28.50
				Anti-par	2.9	0.13	27.75

Table 3. Calculation of electric field effect for 2-rings PNT model using UHF PM3 method and HyperChem 8.0.

Simulated electric field along tube OZ-axis E_z		Dipole moment		Polarization total P	Polarizability α	
		D_{total}	D_z			
a.u.	MV/cm	Debye	Debye	$\mu\text{C}/\text{cm}^2$	$\mu\text{C}/\text{cm}^2 / V_m/E$	Å^3
0	0	42.76	-42.70	4.10	-	-
+0.001	+ 5.1422	47.71	-47.63	4.54	0.44	269.29
- 0.001	- 5.1422	37.89	-37.78	3.61	0.49	299.89

For comparison see data from literature:

- diphenylalanine (Di-Phe, FF): $\alpha \sim 33.20 \text{ \AA}^3 = 33.20 * 10^{-24} \text{ cm}^3$, $V_{\text{FF}} = 282.37 \text{ \AA}^3 \ll V_m$ (data from HyperChem 8.0)
- beta-Phenyl-L-phenylalanin : $\alpha \sim 27.7 \text{ \AA}^3 = 27.7 * 10^{-24} \text{ cm}^3$
(data from <http://www.chemspider.com/Chemical-Structure.143073.html>)
