That Elusive Elasticity:

A Long-Panel Approach To Estimating

The Capital-Labor Substitution Elasticity

Abstract

The elasticity of substitution between capital and labor features prominently in several areas of economic research. Although this elasticity has been the subject of an enormous number of empirical studies, a consensus estimate remains elusive. We develop an estimation strategy that filters panel data in an original way and avoids several pitfalls -- difficult-to-specify dynamics, transitory time-series variation, and positively sloped supply schedules -- inherent in investment equations that can bias the estimated elasticity. Results are based on an extensive panel containing 1,860 manufacturing and non-manufacturing firms. Our model generates a precisely estimated elasticity of approximately 0.40. The method developed here may prove useful in estimating other structural parameters from panel datasets.

That Elusive Elasticity:

A Long-Panel Approach To Estimating

The Capital-Labor Substitution Elasticity

I. Introduction

Estimating the elasticity of substitution between capital and labor has been
an important topic on the quantitative research agenda for decades. This elasticity,
σ, features prominently in several areas of economic research.   The validity of
various growth theories depends on the value of σ.   Policymakers frequently alter
price incentives for capital accumulation, and σ is a key element determining
policy effectiveness and the resulting welfare changes. Although this elasticity has
been the subject of an enormous number of empirical studies, a consensus estimate
remains elusive.

The range of estimated values for σ corresponds to an equally wide range of
implications for growth models. Values of σ near or below unity cast doubt on the
validity of the Solow growth model as conventionally formulated. Mankiw (1995,
p. 287) presents a formula for computing the impact of σ on the difference in rates
of return on capital between rich and poor countries implied by the Solow model.
When $\sigma = 4.0,$ the implied rate of return difference is only 3 percentage points.[1]
However, as σ is lowered to 1.0 or 0.5, the implied differences become implausibly
large, rising to 32 and 100 percentage points, respectively. In the Solow growth
model, Klump and Preissler (2000) show that the substitution elasticity is
negatively related to the speed of convergence toward the steady-state (if the
economy has overaccumulated capital) and positively related to steady-state per

---

[1] These computations are based on the assumptions of a 10 percent return in the rich country and
a capital elasticity in production of 2/3.

capita output.[2] If σ exceeds unity, long-run growth is possible even without any technological progress (Pitchford, 1960; Barro and Sala-i-Martin, 1995). Acemoglu (2001) shows that the relative contributions of technological change and factor accumulation in accounting for long-run growth depend on σ, which has further implications for the importance of biased technological change and the movement of factor shares.[3]

The substitution elasticity is also essential for evaluating the impact of tax policies. In a simplified version of the Ballard, Fullerton, Shoven, and Whalley (1985) computational general equilibrium (CGE) model, the change in welfare from equalizing capital tax rates across industries is 70 percent larger when the elasticity rises from 0.50 to 1.00. Similarly, Engen, Gravelle, and Smetters (1997, Table 5) show that, when the income tax is replaced by a consumption tax, the increase in steady-state net output is 79 percent higher when the elasticity of 0.50 is replaced by a value of unity. Results from the two-country model of Roeger, Veld, and Woehrmann (2000) are also sensitive to whether the elasticity is 0.50 or 1.00; a one percentage point cut in one country's corporate tax rate leads to a 70 percent larger increase in combined consumption with the larger elasticity. Fox and Fullerton (1991) find that, in CGE models, estimated welfare gains from tax initiatives depend much more on this elasticity than on the complex features and detailed disaggregation found in many simulation models. Starting with the seminal analysis of Harberger (1959, 1962), the substitution elasticity between capital and labor, equivalent to the user cost elasticity of capital under a CES

---

[2] However, the latter result is not robust; in a Diamond overlapping generations model, Miyagiwa and Papageorgiou (2003) show that σ and steady-state per capita output are negatively related (provided σ is sufficiently large).

[3] Furthermore, in the original article introducing the CES production function, Arrow, Chenery, Minhas, and Solow (1961) note that the impact of factor endowments on international trade and the variation of relative income shares depend on the value of this elasticity.

production technology, is central to assessing policy impacts.

Despite the substantial research energies devoted to estimating this elasticity, a consensus value remains elusive.[4] For example, in the Joint Committee On Taxation's (1997, Table 6) study of nine different tax models, elasticities range from 0.20 to 1.00. The wide range of estimated elasticities reported in the literature may be attributed to a common source. Most econometric studies rely on quarterly or annual time-series variation in investment data to identify the elasticity. Three biases may result that weigh more or less heavily in different studies. First, the specification of an investment equation requires assumptions about dynamics. While economic theory is highly informative about the determinants of the demand for the stock of capital, it is relatively silent about the demand for the flow of investment. Misspecified dynamics can bias estimates of the elasticity (Summers, 1988). Of particular importance are the nature of adjustment costs and the role of financing constraints, which have received a great deal of attention in recent years and whose effects on investment spending remain controversial.[5] Second, coefficient estimates from investment regressions may be biased if the time-series variation of investment spending largely reflects adjustments to transitory shocks and firms respond less to transitory than permanent variation because of adjustment costs. An elasticity estimated with time-series data at quarterly or annual frequencies will tend to be lower than the

---

[4] See Chirinko (1993), Hassett and Hubbard (1997), and Mairesse, Hall, and Mulkay (1999) for surveys of the empirical literature.

[5] Regarding adjustment costs, see the surveys by Hamermesh and Pfann (1996) and Caballero (1999). Regarding financing constraints, see the survey by Hubbard (1998) and the controversy in Kaplan and Zingales (1997, 2000) and the reply by Fazzari, Hubbard, and Petersen (2000). Chirinko, Fazzari, and Meyer (1999) show that excluding cash flow (a variable typically included to capture financing constraints) from an investment equation using annual data biases upward the estimated user cost elasticity.

"true" long-run elasticity.[6] Third, if the supply curve of investment is upward sloping, as is more likely in the short to medium-run, studies incorrectly maintaining a perfectly elastic supply schedule will tend to understate demand elasticities (Goolsbee, 1998).[7] While the misspecification of dynamics has an indeterminate effect, the estimated elasticity will be biased toward zero by transitory time-series variation and positively sloped supply schedules.

These potential problems all stem from a common source -- the use of investment data as the measure of capital formation. We avoid these problems by developing an approach that relies directly on capital stock data and exploits in an original way the substantial information available from panel data. We focus on the first-order condition relating the long-run desired capital stock (K^*) to the long-run desired values of output (Y^*) and the user cost (C^*). This specification underlies virtually all investment studies since Jorgenson's (1963) path-breaking work on the neoclassical model of capital accumulation and can be represented as follows:

(1) $K^* = G[\underset{+}{Y^*}, \underset{-}{C^*}].$

The difficulty with estimating (1) is that the desired values are not readily observable. We use panel data, long in the time dimension, to estimate the variables in (1) as time-averages within firms. With empirical counterparts to K*, Y*, and C* defined, it is straightforward to estimate G[.]. To account for firm effects and productivity shocks, we specify equation (1) in growth rates. Our econometric model regresses the growth rate of the capital stock on the growth

---

[6] This point has been noted by, among others, Eisner (1967), Lucas (1969), Berndt (1976), Shapiro (1986b), and Kiyotaki and West (1996).

[7] This conclusion has been challenged by Hassett and Hubbard (1998) and Whelan (1999).

rates of the user cost and output across firms. Cross-sectional variation provides identification. This relatively simple, yet fully rigorous, approach estimates technology parameters immune to the biases discussed above.

Our study proceeds as follows. Section II introduces the estimation strategy. The econometric equation is derived from the firm's profit-maximization problem, and long-run values of the variables entering the regression equation are measured as time-averages. Our estimation strategy accounts for a variety of productivity shocks, omitted variables, and firm fixed effects, and uses panel data in a way that differs substantially from prior panel studies. We demonstrate with spectral analysis how our estimator places relatively more weight on low frequency movements than the traditional investment model. Section III discusses the panel dataset containing, 1,860 firms for the period 1972 to 1991, and the construction of the variables. Section IV presents our OLS and IV results. Both techniques yield similar estimates of the substitution elasticity of approximately 0.40. This estimate is higher than the elasticity of 0.25 reported by Chirinko, Fazzari, and Meyer (1999) based on the same dataset but using an investment model. Thus, the three problems affecting investment equations -- difficult-to-specify dynamics, transitory time-series variation, and positively sloped supply schedules -- impart a discernible bias toward zero. Nonetheless, the elasticity remains far from unity, the value defining the frequently used Cobb-Douglas production function and determining the cut-off at which tax incentives become cost effective (in a static sense). Section IV also assesses the importance of measurement error, offers an alternative interpretation of our estimator in terms of a low-pass filter, examines the sensitivity of the estimates to various subsets of the sample, and compares our approach to related work with panel data. Section V offers a summary and conclusions.

II. Estimation Strategy

Our econometric model follows directly from the behavior of a firm that maximizes its discounted flow of profits over an infinite horizon. We analyze the firm's choices in long-run equilibrium, thus eliminating the need to model adjustment costs, delivery lags, vintage effects, and expectations. Under these assumptions, the firm always produces its long-run desired level of output with its long-run desired mix of inputs. The critical consequence is that the firm's dynamic optimization problem is transformed into a static problem. To determine the firm's demand for capital, we need only calculate the marginal product of capital evaluated at the long-run levels of inputs and output.

We assume that production possibilities are described by the following CES technology,

$$(2) \quad Y^*_{f,t} = \{\omega(K^*_{f,t}{}^{[(\sigma-1)/\sigma]}) + (1-\omega)(X^*_{f,t}{}^{[(\sigma-1)/\sigma]})\}^{[\eta\sigma/(\sigma-1)]} U_{f,t},$$

where $Y^*_{f,t}$ is long-run desired real output for firm f at time t, $K^*_{f,t}$ is the long-run desired real capital stock, $X^*_{f,t}$ is the long-run desired level of all other factors of production, and $U_{f,t}$ represents a stochastic productivity shock.[8] An attractive feature of the CES technology is that it depends on only three parameters characterizing returns to scale (η), the distribution of factor returns (ω) and, of particular importance for this study, substitution possibilities between the factors of production (σ). The CES function is strongly separable, and it can be expanded to include many additional factors of production (e.g., intangible capital) without affecting the estimating equation derived below. This feature gives the CES

---

[8] The limiting value of (2) as $\sigma \rightarrow 1$ is the Cobb-Douglas production function under the additional assumption that $\eta=1$.

specification an important advantage relative to other technologies that allow for a more general pattern of substitution possibilities (e.g., the translog, minflex-Laurent). Our approach does not require price and quantity data on the other factors of production (with limited availability and reliability at the firm level) to recover the key parameter of interest.

Differentiating (2) with respect to capital, we obtain the following relation for the marginal product of capital $(\partial Y^*_{f,t} / \partial K^*_{f,t})$,

$$(3) \quad \partial Y^*_{f,t} / \partial K^*_{f,t} = (\eta\omega) \, Y^{*[1+(1-\sigma)/\sigma\eta]}_{f,t} \, K^{*-[1/\sigma]}_{f,t} \, U^{[(\sigma-1)/\sigma\eta]}_{f,t} \, .$$

Profit-maximization implies that this marginal product of capital equals the Jorgensonian user cost of capital $(C^*_{f,t})$, which combines interest, depreciation, and tax rates with relative prices (an exact specification of the user cost is deferred to Section III). Setting $\partial Y^*_{f,t} / \partial K^*_{f,t}$ equal to $C^*_{f,t}$ and rearranging (3), we obtain the following expression for the long-run desired capital stock,

$$(4) \quad K^*_{f,t} = \Psi \, C^{*[\alpha]}_{f,t} \, Y^{*[\beta]}_{f,t} \, U^{[\zeta]}_{f,t} \, ,$$

$$\Psi = (\eta\omega)^\sigma,$$
$$\alpha = -\sigma,$$
$$\beta = (\sigma\eta+1-\sigma) / \eta,$$
$$\zeta = (\sigma-1)/\eta.$$

Note that, with a CES production function, the user cost elasticity of capital is equivalent to the substitution elasticity between capital and other inputs (multiplied by minus one).

The central difficulty with estimating (4) is the that the long-run values are not observed. Most previous research addresses this problem by differencing the log of (4) to obtain an equation for investment. As discussed in the Introduction,

however, this approach relies on the modeling challenges associated with investment data, and may therefore generate biased estimates. To avoid these potential problems, we measure the capital stock directly and then estimate the long-run desired levels of capital, output, and the user cost as time averages over several years. We refer to the years over which an average is computed as an interval. As shown in Figure 1 for a representative variable $W_{f,t}$ ($W_{f,t} = \{K_{f,t}, Y_{f,t}, C_{f,t}\}$), we divide our sample into three intervals indexed by a τ subscript, $\tau = 0,1,2$. The intervals are 1972-1977 ($\tau=0$), 1978-1984 ($\tau=1$), and 1985-1991 ($\tau=2$). We assume that $W^*_{f,t}$ equals $W_{f,\tau}$, where the latter is the mean of $W_{f,t}$ over an interval. As we will discuss below, the $\tau=1$ and $\tau=2$ intervals are used for parameter estimation; the $\tau=0$ interval is used only to form instruments and define classifications that split the sample.

With the variables in (4) defined in terms of the $\tau=1$ and $\tau=2$ intervals, we take logs, and obtain the following equation,

(5) $\quad k_{f,\tau} \;=\; \alpha\, c_{f,\tau} \;+\; \beta\, y_{f,\tau} \;+\; \psi \;-\; u_{f,\tau},$ $\qquad\qquad \tau = 1,2.$

$$
\begin{aligned}
k_{f,\tau} &= \ln[K_{f,\tau}] = \ln[K^*_{f,t}], \\
c_{f,\tau} &= \ln[C_{f,\tau}] = \ln[C^*_{f,t}], \\
y_{f,\tau} &= \ln[Y_{f,\tau}] = \ln[Y^*_{f,t}], \\
\psi &= \ln[\Psi],
\end{aligned}
$$

where $u_{f,\tau}$ is an error term that follows directly from the technology and represents productivity shocks. We model productivity shocks as follows,

(6) $\quad u_{f,\tau} = \zeta\,[v_f + v_i + w_\tau + w_{i,\tau} + w_{f,\tau}].$

The productivity shock is decomposed into firm-specific (v_f) and industry-specific (v_i) components, as well as components that vary over the τ intervals, w_τ, $w_{i,\tau}$ and

$w_{f,\tau}$. With this error structure, estimates can be obtained by differencing (5) and (6) between the τ intervals,

(7) $\Delta k_{f,\tau} = \alpha \, \Delta c_{f,\tau} + \beta \, \Delta y_{f,\tau} + \Delta \psi - \Delta u_{f,\tau},$

$\Delta k_f = -\sigma \, \Delta c_f + \beta \, \Delta y_f - \gamma - \lambda_i - \Delta w_f.$

$$
\begin{aligned}
\sigma &= -\alpha, \\
\eta &= (1-\sigma) / (\beta - \sigma), \\
\gamma &= \zeta \, \Delta w_\tau, \\
\lambda_i &= \zeta \, \Delta w_{i,\tau}, \\
\Delta w_f &= \Delta w_{f,\tau}.
\end{aligned}
$$

Because there are only two intervals, first-differencing eliminates the temporal dimension to the model, and τ subscripts have been omitted in the final equation. Consequently, the parameters are estimated in a cross-section regression. Fixed firm and industry effects are eliminated by differencing, and fixed interval effects (notably, biased technical change) are captured by the constant (γ). Industry effects that vary across intervals are captured by industry dummies (λ_i).

Equation (7) is the basis for our estimation; it relates long-run growth in the capital stock to long-run growth in the user cost and output across firms. Cross-sectional variation in the data identifies the parameters. Of course, the capital and output growth variables have cross-sectional variation. The user cost consists of three multiplicative terms—the relative price of capital to output, tax adjustments, and the opportunity cost of holding depreciating capital. The growth in the relative price and tax terms vary substantially across firms because of differences in the asset composition of firms' capital stock. For example, the relative price of capital for industries that use high-tech equipment declines more than the relative price for low-tech industries. This variation allows us to estimate the parameter of central interest in this study, the elasticity of the capital stock with respect to its user costs,

σ. Additionally, we can recover the returns to scale elasticity, η, as a non-linear combination of the estimated σ and β parameters.

In contrast with prior studies that use investment data, our estimation strategy emphasizes low frequency variation. We estimate the long-run values of the regression variables by taking averages over several years (intervals), and then difference the data to control for a variety of firm and industry effects. This "interval-difference estimator" contrasts with the standard investment regression derived by differencing untransformed annual data, which we refer to as "the year-difference estimator." Because it averages over several years, the interval-difference estimator places substantially more weight on the lower frequencies in the data. To see this point more rigorously, it is instructive to interpret both estimators in the frequency domain. The spectra for the interval-difference and year-difference estimators are plotted in Figure 2. These spectra are normalized so that the area under each curve equals unity, and they should be interpreted relative to each other for any arbitrary input series.[9] Figure 2 clearly demonstrates that the lower frequencies receive much more weight for the interval-difference estimator ($I(\omega)$) relative to the year-difference estimator ($Y(\omega)$). Thus our interval-difference estimator emphasizes low frequency variation that will lead to better estimates of σ.

Consistency of the OLS parameter estimates depends on the relation between the stochastic element, Δw_f, and the regressors, especially Δy_f. This

---

[9] We rely on the fundamental result from spectral analysis that the spectrum of a transformed series (the interval-difference or year-difference series) is the product of the spectrum of the input series (e.g., the capital/output ratio) and a nonnegative scalar that depends on the frequency, ω. Following the development in Sargent (1979, Chapter XI) and using a first-order approximation for the log of a variable, the scalars for the interval-difference ($I(\omega)$) and year-difference ($Y(\omega)$) series are as follows:
$I(\omega) = (1/7)^2 * (1 - COS(7\omega)) * 2 * (1 - COS(2*4*\omega)) / (1 - COS(\omega))$ (for an interval of seven years) and $Y(\omega) = 2 * (1 - COS(\omega))$ for $\omega \varepsilon [0,\pi]$. These are the functions plotted in figure 2.

correlation is not likely to be a problem for two reasons. First, Δw_f is that part of the productivity shock that remains after accounting for all fixed and industry effects. Major technological changes (e.g. telecommunications, computing, the internet) are likely to have their largest effects on all firms (captured by γ) or on all firms in an industry (captured by λ_i) with only a small residual impact that is firm specific. Second, only part of the productivity shock enters the error term. As noted by Shapiro (1986a), including output in a factor demand equation can completely absorb the productivity shock. When the elasticity of substitution is unity, ζ equals zero, and $u_{f\tau}$ vanishes (cf. equations (4) and (6)). When σ deviates from unity, the impact of the productivity shock is nonetheless diminished by ζ (provided returns to scale are not decreasing too sharply). Despite these arguments that OLS estimates will not be appreciably affected by Δw_f, we present two alternative estimates that are robust to simultaneity. First, we impose constant returns to scale ($\eta=1$ implying $\beta=1$). Thus, Δy_f, the variable most likely to be correlated with Δw_f, no longer appears as a regressor. Second, we present IV estimates and Hausman tests using the variables in the $\tau=0$ interval as instruments. This procedure accounts for possible endogeneity between the error term and the Δy_f and Δc_f regressors.

This econometric model is robust to four potentially important distortions. First, the parameter estimates are robust to trending variables. See Appendix A for formal consideration of this issue and the role played by differencing in eliminating firm-specific trends. Second, the estimates are unlikely to be influenced by additional factors that may affect the specification of the production function or the first-order conditions. For example, the estimating equation is robust to including additional factors of production. Markups that vary across firms are captured by a firm-specific fixed effect eliminated by differencing. Moreover, the information processing revolution may have led to biased technical

change over the past 20 years. In terms of the CES technology, biased technical change is represented by temporal variation in ω and, like w_τ, will be reflected in the constant. Third, studies implementing the Jorgensonian framework have often been criticized for failing to distinguish between desired output and actual output (e.g., Coen, 1969; Hall, 1995). By using time-averages in the econometric equation, we recognize this important distinction. Fourth, the estimates are unlikely to be affected by measurement error in the capital stock. Classic measurement error will be part of the error term, and hence innocuous. A plausible situation where measurement error may be systematic arises when an increase in the pace of technological change effectively increases the depreciation of fixed capital through obsolescence, an effect not captured in our fixed depreciation rate assumption. However, an increase in depreciation rates would lead to a systematic overstatement of capital in $\tau=2$, and would be captured by the constant. If omitted variables or measurement error are both firm-specific and interval-varying, consistent estimation becomes an issue. In this case, the IV estimates in Section IV.E, coupled with the measurement error analysis in Section IV.C, provide a useful safeguard to check the parameter estimates.

In sum, the estimation strategy developed here collapses the time dimension of firm panel data by defining three intervals and then time-averaging the data within an interval. The first interval is used to form instruments or sort variables into contrasting classes. The second and third intervals are used for estimation. Identification is provided by the cross-firm variation in capital, output, and user cost growth. A variety of productivity shocks, omitted variables, and fixed firm effects are accounted for by estimated parameters or differencing. Production function parameters are thus estimated in a cross-section of time-averaged, differenced firm data. This econometric model does not *solve* the estimation problems inherent with investment models – difficult-to-specify dynamics,

transitory time-series variation, and positively sloped supply schedules – that may bias estimates of the elasticity. Instead, our approach *avoids* these problems by exploiting panel data with a method that emphasizes low-frequency variation and estimating directly the first-order condition for capital.[10]

---

[10] Of course, this approach requires the construction of an empirical measure of the capital stock which is not readily available in accounting data. This task is challenging as indicated by our capital stock measurement algorithm described in appendix B. It may also introduce measurement error, as we address in section IV.C. For this reason, among others, we view our approach as complementary to studies that estimate the user cost elasticity from investment equations with investment data that may be obtained directly from accounting statements.

III. The Panel Dataset

Our estimation method requires a panel dataset that is long in both the cross-section and time-series dimensions and that contains cross-sectional variation in the user cost that is key for identification. We link data sources from the Compustat Industrial Database maintained by Standard and Poors (containing financial statement data) and Data Resources, Inc. (DRI, containing user cost and industry data). In this section, we discuss the construction of the variables used for regression estimates of equation (7), for instruments, and for sorting firms into contrasting classes.

For the user costs (C), we have data for 26 different capital assets (24 types of equipment and two types of structures). The basis for these user costs, from Hall and Jorgenson (1967) and modified by DRI, is:

$$(8) \qquad C_{i,j,t} = [p^I_{j,t} / p^Y_{i,t}] [(1 - m_{j,t} - z_{j,t}) / (1-tx_t)] [r_t + \delta_j]$$

where $p^I_{j,t}$ is the asset-specific purchase price for asset j at time t, $p^Y_{i,t}$ is the industry i output price at time t, δ_j is the asset-specific economic depreciation rate, and tx_t is the income tax rate. The investment tax credit ($m_{j,t}$) and the discounted value of tax depreciation allowances ($z_{j,t}$) also vary across assets. The financial cost of capital (r_t) is a weighted average of the cost of equity (the dividend-price ratio for Standard & Poor's Composite Stock Price Index plus an expected long-run growth rate of 2.4 percent, with a weight of 0.67) and the cost of debt (average yield on new issues of high-grade corporate bonds adjusted to a AAA basis, with a weight of 0.33). The nominal cost of debt is reduced by its tax deductibility and the expected inflation rate, defined as a weighted average of past GDP deflator growth rates. User costs for two- and three-digit industries are a weighted average of the asset user costs. The weights are the proportion of total capital in an

industry accounted for by each of the 26 assets.[11] This information is then merged with the firm-level Compustat data using each firm's S.I.C. code.[12]

Measurement of the capital stock (K) is important for our study. Compustat does not provide an acceptable measure of the capital stock because book values of net plant and equipment likely understate current replacement values in periods of inflation. In addition, accounting depreciation rules may not accurately reflect economic depreciation.

We measure the current replacement value of capital with a three-step, iterative algorithm.[13] First, choose a seed value. We use the book value of net plant and equipment from the firm's first observation in Compustat.[14] The nominal

---

[11] These weights are from the Bureau of Economic Analysis capital flow tables and reflect asset usage by establishment. The Compustat data reflect ownership by company. The combination of industry aggregate data for the user cost and firm data for investment and other items may induce measurement error because some firms operate in a variety of industries. To the extent that such measurement error is constant within firms, however, it will be captured in firm fixed effects.

[12] We average the quarterly DRI user cost data at the firm level to obtain an annual user cost that corresponds to the Compustat data. The averages account for differences in firms' fiscal years, and therefore introduces some firm-level heterogeneity into the user cost data.

[13] This conceptual approach has been used for firm-level panel data at least since Salinger and Summers (1983).

[14] Because the book value of net plant will usually be less than the replacement cost when there is inflation, the use of net plant as a seed in 1972 distorts the measurement of the replacement cost of capital. This distortion, however, is unlikely to affect the estimated parameters for three reasons. First, the distortion will disappear as new investment is added to the capital stock at current replacement value and old capital is depreciated. The early part ($\tau=0$) of our sample is used only for instruments. The effect of the seed value on the regression data, therefore, is attenuated because the capital series consist largely of new investment expenditures by the $\tau=1$ and $\tau=2$ periods. Based on the average depreciation rate of 14.8 percent, only 32.6 percent of the 1972 seed value will remain at the beginning of the estimation period in 1978. Second, a proportionate distortion of the seed value relative to the "true" replacement cost across firms is eliminated by our econometric procedure that takes logs and then first differences the capital stock data that enter the regressions. Third, any remaining random measurement error in the capital stock affects the dependent variable only and, therefore, it does not bias coefficient estimates, though it would raise standard errors.

seed value is deflated by a weighted average of investment goods price deflators, where the weights are determined by the specific capital asset mix of each industry. These are the same weights employed in the user cost computation described above. Second, subtract capital lost to (geometric) depreciation. The firm's depreciation rate is the weighted average of the rates for individual assets from DRI. Thus, there is a consistency between the depreciation rates used in constructing the capital stock and user cost data. Third, add in new investment. In most cases, this step simply adds the deflated value of the Compustat capital expenditures variable. The deflator is the weighted average of each industry's investment goods price deflators. At the micro level, however, we must take into account that a firm's capital stock may rise or decline due to acquisitions or divestitures that are not included in the capital expenditure variable. If the data indicate a significant acquisition or divestiture, we use accounting identities to calculate the impact of this activity on the capital stock. Details of the capital stock calculation appear in Appendix B.

Output (Y) is gross sales during the year reduced by cash discounts, trade discounts, and returned sales or allowances to customers. Sales will differ from output by the change in finished goods inventories. While this difference may be non-trivial in the short-run, it will have very little impact on the long-run averages used in our estimation. Nominal sales figures from Compustat are deflated by industry-specific output price indexes from DRI.

For some of the results that follow, we sort the data into contrasting sub-samples depending on whether a classifying variable averaged over the $\tau=0$ pre-estimation period (1972-1977) is above or below its median. Three variables are used as classifiers: the cash flow-capital ratio (CF/K), the size of the capital stock (K), and the Brainard-Tobin Q. Cash flow is income after taxes plus non-cash expenses, primarily depreciation and amortization. The numerator of Q is the

market value of equity plus the book value of debt less the book value of inventories. The denominator is the replacement value of the capital stock measure discussed above.

To protect against results driven by a small number of extreme observations, we exclude observations in the one-percent upper and lower tails from the distributions of the firm-specific variables.[15] Firms included in the data set must have some observations for each variable in all three of the τ intervals. Our final data set contains 1,860 firms from all sectors of the economy.

---

[15] We checked the robustness of our results when we deleted both the one-half-percent and two-percent tails. The effect on the results was negligible. Because the user cost is computed from stable industry and aggregate data, we did not delete data in the tails of the user cost variable distribution.

IV. Empirical Results

A. Cross-Sectional Variation in Growth Rates

The data for estimating the parameters in equation (7) consist of the growth in model variables between the $\tau=1$ and $\tau=2$ intervals that enter directly into the econometric model. While equation (7) is estimated with a cross-section of firms, the value of each firm observation is based on temporal variation between intervals. Statistics for the interval growth rates appear in the top panel of table 1. It is clear from the large coefficient of variation statistics for the growth in capital, output, and the user cost (2.3, 2.4, and 2.7, respectively) that there are substantial differences across firms in the regression variables. It is not surprising that capital and output growth differ across firms, but the heterogeneity in the user cost growth is remarkable relative to most other studies. We rely on this heterogeneity to identify σ in this section.[16]

B. OLS Estimates

Ordinary least squares estimates of the structural parameters from equation (7) appear in table 2. The focus of our study is on σ. In column 1, our benchmark estimate of σ is 0.367 with a standard error of 0.067. The null hypothesis that the elasticity is zero can be strongly rejected at any conventional level of significance. It is also clear, however, that our estimate of σ is much smaller than unity, the value implied by the Cobb-Douglas production function and often assumed in applied work.

As shown by equation (7), the estimated returns to scale elasticity (η) is a

---

[16] To provide a sense of the information in the data, summary statistics for the levels of the regression variables within each interval (which do not directly enter the econometric specification) are presented in the bottom three panels of table 1. The capital and output statistics are in millions of 1987 dollars.

function of the regression coefficients on the growth in both output (β) and the user cost ($-\sigma$). The OLS estimate of the returns to scale elasticity, η, is 1.135 also with a small standard error.[17] With our estimated parameter values, the primary reason that the estimated returns to scale elasticity modestly exceeds one is that the coefficient of output growth in our capital growth regression is somewhat less than unity ($\beta=0.925$). As shown in equation (7), an estimated β in the neighborhood of unity generates results for η close to constant returns for any admissible value of σ. It is interesting to note that the effect of output is much stronger here than in panel data studies using investment data (cf. Chirinko, Fazzari, and Meyer, 1999). We believe the reason for these more plausible results is that, unlike typical investment equations, our estimation method captures long-run, permanent changes in output, and is not affected by the transitory variation that may unduly influence investment regressions with annual or quarterly data.

The second column of table 2 presents results from including two-digit industry dummies in the benchmark regression (the λ_i terms in equation 7). These dummies control for industry-level productivity shocks between intervals $\tau=1$ and $\tau=2$ or, more generally, any industry-specific effects. The structural parameter estimates do not change much when the dummies are included. The σ estimate rises from 0.367 to 0.440, and η is virtually identical. The standard error of σ, however, rises by a factor of more than four. The σ estimate is therefore much less precise with industry dummies in the model. For this reason and given the

---

[17] The returns to scale elasticity is recovered from the estimated coefficients with the following formula: $\eta = (1-\sigma) / (\beta-\sigma)$ when $\beta > \sigma$. The variance of η depends in a complicated way on the variances and covariances of the estimated σ and β. We use an approximate formula based on a second-order Taylor series expansion of η about the estimated values of σ and β:
$V[\eta] = \{V[\sigma] (1-\beta)^2 + V[\beta] (1-\sigma)^2 - 2 C[\sigma,\beta] (1-\beta) (1-\sigma)\} / (\beta-\sigma)^4$, where $V[\cdot]$ and $C[\cdot]$ are the variance and covariance operators, respectively.

modest change in σ, the remaining regressions in table 2 exclude the industry dummies.

As discussed in Section II, the most likely source of correlation between the error term and the independent variables in these OLS regressions comes from the correlation between firm-specific productivity shocks embedded in the error term and firm output growth. This potential simultaneity problem can be avoided by imposing constant returns to scale (η=1 implying β=1), an assumption that removes output growth as a regressor. The third column of table 2 presents a regression with the output growth coefficient constrained to unity. The σ estimate changes only trivially when constant returns to scale are imposed (from 0.367 to 0.372).[18] These result supports our contention that σ is consistently estimated by OLS in our framework.

The final column of table 2 presents estimates based on the assumption of a Cobb-Douglas production function, which is defined by a unitary elasticity of substitution (σ=1) and constant returns to scale (η=1). Not surprisingly given the prior results for σ and η, the restrictions associated with the Cobb-Douglas are easily rejected at the one-percent level relative to the unconstrained model in the first column.

C. Measurement Error

What role might measurement error play in biasing the estimated σ downward and away from a unitary elasticity (as emphasized recently for investment models by Goolsbee, 2000)? We consider three sources of measurement error.

---

[18] While the R^2 decreases trivially from 0.564 (column 1) to 0.560 (column 3), the constraint of constant returns to scale is rejected at the one-percent level, a result driven by the large number of observations used in estimation.

First, measurement error introduced in the construction of the capital stock will have a modest effect on the estimates because the capital stock enters as the dependent variable. In situations where measurement error in the dependent variable takes the classic form or is fixed for a given firm, industry, or interval, the elasticity estimates will be unaffected.

Second, measurement error in the independent variables may arise for various reasons and can have direct and indirect effects on the estimated σ. To assess the direct effects, assume that the true value of this elasticity is unity. If the OLS estimate is inconsistent because Δc_f is afflicted with classic measurement error, the variance of this measurement error would have to account for at least 60 percent of the variance in the observed Δc_f.[19] This seems highly implausible, especially since the estimator accounts for measurement error arising from fixed firm, industry, and interval effects by differencing. An indirect effect could result from measurement error in the other independent variable. If Δy_f is measured with error, we can use the formula proposed by Rao (1973) and an auxiliary regression of Δy_f on Δc_f to assess the extent of bias on σ. Making the rather extreme assumption that one-half of the variance of Δy_f is measurement error, we obtain the somewhat surprising result that the estimated σ is biased upward toward unity. However, the bias is a trivial 0.043.[20]

---

[19] The asymptotic bias on the estimated σ is given by the following formula: $(\sigma^{\#}-\sigma') = (VAR[\xi_f]/VAR[\Delta c_f]) \, \sigma^{\#}$, where σ' and $\sigma^{\#}$ are the estimated and true values of σ, respectively, and ξ_f is the measurement error. If $\sigma^{\#}=1$, then the variance ratio must be at least equal to 0.60 given an OLS estimate of $\sigma'=0.40$.

[20] The bias on the estimated σ is $(\sigma^{\#}-\sigma') = -((\beta \, b_{\Delta y,\Delta c}) / (1-R^2_{\Delta y,\Delta c})) (VAR[\xi_f] / VAR[\Delta y_f])$, where σ' and $\sigma^{\#}$ are the estimated and true values of σ, respectively, β is from equation (7), $b_{\Delta y,\Delta c}$ is the coefficient on Δc_f, $R^2_{\Delta y, \Delta c}$ the correlation coefficient from the auxiliary regression of Δy_f on Δc_f and a constant, and ξ_f is the measurement error. We assume that one-half of the variance in the output variable is measurement error; hence, $VAR[\xi_f] / VAR[\Delta y_f] = 0.50$. We further assume that β equals its estimated value under IV of 1.402. From the auxiliary regression, $b_{\Delta y,\Delta c} = 0.061$ and $R^2_{\Delta y,\Delta c} = 0.0003$; hence, $(\sigma^{\#}-\sigma') = -0.043$.

Third, the assumption that the long-run values of K and Y appearing in the model of Section II are measured as time-averages over a τ interval may not be valid because of various short-run frictions. For example, irreversibility constraints or asymmetric adjustment costs suggest the possibility that the average values of K and Y might differ from their long-run values in a frictionless model. As shown in Appendix C, these short-run frictions introduce measurement error into K and Y. The effects of measurement error on σ have been analyzed above. Measurement error can adversely affect the reported results but, with our estimation strategy, it does not appear to be quantitatively important.

D. An Alternative Interpretation

The interval-difference estimator that generated the results in Table 2 consists of two steps: 1) average the data over non-overlapping intervals of years and 2) first difference the log of the averaged data across intervals. The first part of our estimation strategy can be interpreted in terms of a low-pass filter (LPF) defined in the frequency domain.[21] A LPF allows frequencies lower than some critical frequency, $\omega^{\#}$, to pass through to the transformed series, but excludes frequencies higher than $\omega^{\#}$. Baxter and King (1999, Section II.B) present the formulas that translate restrictions from the frequency domain into the time domain. For an input series x(t) and an interval of seven years, the LPF for a critical value $\omega^{\#}$ (LPF[$\omega^{\#}$]) produces the following transformed series ($x^{\#}(t)$),

$$(9a) \qquad x^{\#}(t) = \sum_{h=-3}^{3} a(h)\, L(h)\, x(t),$$

$$(9b) \qquad a(0) = \omega^{\#} / \pi + \theta,$$

---

[21] We thank Julio Rotemberg for suggesting this interpretation of our estimator.

(9c) $a(h) = \sin(|h| * \omega^{\#}) / (|h| * \pi) + \theta,$ $h = \pm 1, \pm 2, \pm 3$

(9d) $\theta = (1 - \sum\limits_{h=-3}^{3} a(h)) / 7,$

where L(h) is a polynomial in the lag operator and θ normalizes the variance to be unity at the 0th frequency.

The estimator used for the results presented thus far can be interpreted as a limiting case of $LPF[\omega^{\#}]$. With $\omega^{\#}$ at its lower bound of zero, all of the a(h) coefficients are initially zero by (9b) and (9c). The value of θ becomes 1/7, and equal weight is given to each observation in the interval. Stationarity is not an issue because the second step of the interval-difference estimator involves a first-difference. The use of the lower bound for $\omega^{\#}$ is consistent with our objective to emphasize long-run variation.

As a robustness check on our empirical results, we experiment with an alternative assumption about the frequencies allowed to pass through to the transformed data. We assume that frequencies with periods greater than or equal to seven years define the long-run. Based on the relation between period and frequency, this implies $\omega^{\#} = 0.8976$. We replace equal weights of 0.1429 (one seventh) in our basic estimator with the weights implied by (9b) and (9c) for $\omega^{\#} = 0.8976$: $a(h=-3) = a(h=3) = 0.0194$, $a(h=-2) = a(h=2) = 0.1286$, $a(h=-1) = a(h=1) = 0.2223$, and $a(h=0) = 0.2594$. The results are presented in the fifth column of Table 2, and the estimate of σ is 0.352 (with a standard error of 0.057), which is very close to the estimate obtained when the long-run was defined in terms of $\omega^{\#} = 0$. Thus, estimates of σ are robust to definitions of the long-run, and subsequent results are based on our assumption that $\omega^{\#} = 0$.

E. IV Estimates

The OLS estimates of equation (7) are consistent under the assumption that the error term is independent of both output and user cost growth. As discussed in Section II and suggested by the results with the constant returns model in Section IV.B, these are reasonable assumptions with our estimation method. Nonetheless, we present instrumental variables estimates in table 3 to explore the robustness of our OLS results. The instruments are constructed from data in the $\tau=0$ interval. The instrument list includes the user cost ($C_{i,\tau=0}$), capital stock ($K_{i,\tau=0}$), the output-capital ratio ($(Y/K)_{i,\tau=0}$), and the cash flow-capital ratio ($(CF/K)_{i,\tau=0}$). In addition, we included the annualized growth rates of capital, output, cash flow, accounts receivable, and cash and cash equivalents defined over the $\tau=0$ interval.

The benchmark IV estimate of σ in the first column of table 3, 0.390 is almost identical to the benchmark OLS estimate from table 2 of 0.367. Not surprisingly, the standard error rises with IV, but we can still strongly reject both the hypotheses that σ equals zero or unity. Unfortunately, the IV estimates of η are not as reasonable. Because of the large coefficient on output growth (β), the point estimate of the returns to scale elasticity (η) is 0.603. The standard error of η is much larger with IV than with OLS, but the IV estimate still rejects constant returns to scale in favor of decreasing returns. However, we do not consider this result reliable because of our inability to find good instruments for output growth.

The partial R^2 statistic developed by Shea (1997) provides quantitative confirmation of this interpretation. This statistic measures the relevance of instruments for each estimated coefficient after removing the explanatory power used in instrumenting other regressors. The partial R^2 for β is 0.040, dramatically

lower than the partial R^2 of 0.515 for σ.[22]

      To pursue this issue one step further, we re-estimate the model with IV imposing constant returns to scale ($\eta=1$). Under this assumption, $\beta=1$, and we no longer need to instrument output growth. The results appear in the third column of table 2. The IV estimate of σ is only modestly affected by imposing constant returns. The elasticity estimate rises to 0.434 from 0.390, a change much smaller than one standard error. This result demonstrates that, even if the IV estimate of returns to scale is unreliable due to the lack of relevant instruments for output growth, this difficulty does not "contaminate" conclusions about σ, which is the primary focus of our study.

      The second column of table 3 presents IV estimates with two-digit industry dummies. This specification accounts for industry-level productivity shocks between the $\tau=1$ and $\tau=2$ periods (cf. equation (7)). The point estimate of σ hardly changes from the benchmark value (0.373 versus 0.390). As was the case for the OLS estimates with industry dummies, however, the standard error of σ rises dramatically, almost by a factor of three.[23]

      As a final test of the validity of the OLS estimates, we performed Hausman tests on the σ parameters. The Hausman statistics are asymptotically distributed $\chi^2(1)$ under the null hypothesis that the OLS estimates are consistent. For the benchmark model, the test statistic is 0.07 and for the constant returns to scale

---

[22] The partial R^2 statistic is preferable to the more common first-stage R^2 as discussed by Shea (1997).

[23] Because of collinearity, it was not useful to include industry dummies in the model as both regressors and instruments. In the second column of table 2, the instrument set for output and user cost growth is the same as for the other IV regressions; the industry dummies are instrumented by themselves.

model it is 0.92.[24] Both test statistics are far below the 90 percent critical value for the $\chi^2(1)$ distribution of 2.71. These tests support the validity of the OLS estimates of σ. Taken together, the unconstrained OLS and IV estimates strongly suggest that σ is approximately 0.40.

F. Split-Sample Estimates

Table 4 explores our results further by assessing the stability of structural parameter estimates in several sub-samples chosen to address issues that have arisen with empirical investment models. In each sub-sample, we expect σ to remain similar to its value in the full sample results. All estimates are with the benchmark model. The first panel presents results with the sample split by the ratio of cash flow to the capital stock. In investment regressions using annual data, Chirinko, Fazzari, and Meyer (1999) found that including cash flow had a significant effect on the estimated σ. We interpreted that finding in the context of the extensive literature on finance constraints and firms' investment spending. The approach here, however, emphasizes the *long-run* impact of the user cost on the capital stock. We therefore expect financial constraints to be less important. The first panel of table 3 presents results from data split according to the pre-sample median cash flow-capital ratio. If financial constraints were important at the horizon relevant for our estimation, we would expect the estimated σ to be significantly different across high and low cash flow firms that differ by their inadequate access to finance. There is little evidence of such an effect in our data. The OLS point estimate of σ is somewhat larger for the high cash flow firms than for low cash flow firms, but the difference is less than two standard errors.

---

[24] The Hausman test is not defined for the model that includes industry dummies because the standard error of the IV estimate is slightly smaller than the standard error of the OLS estimate.

Similar results hold for the IV regressions except that σ is relatively larger for the low cash flow firms. The formal test statistics (θ's) for the equality of the σ's from the two sub-samples have p-values greater than 0.35, easily sustaining the null hypothesis of equal σ's.[25]

Our second sort is by size, defined by the median average capital stock in the pre-sample period ($\tau=0$). The technologies utilized by firms may vary systematically by size, and the technology parameters estimated here may change accordingly. Moreover, size is frequently used to identify firms that may be finance constrained. External finance may be relatively costly for smaller firms because they are not able to bear the substantial fixed costs of obtaining external funding or they lack visibility in external capital markets. Relative to the results in table 2, the OLS point estimates of σ are higher for small firms and lower for large firms. With IV, the point estimates have the reverse pattern, and both are lower than the comparable estimate of 0.390 based on the full sample (table 3). None of these differences is statistically significant.

Finally, we split the data at the median value of the Brainard-Tobin Q variable to address how sensitive our estimation strategy is to investment dynamics and shocks. Firms with high values of Q are presumably further from their long-run equilibrium capital stock for, among other reasons, favorable demand or productivity shocks. Therefore, if our estimation method did not adequately account for investment dynamics or shocks, we might expect a

---

[25] The null hypothesis that $\sigma' = \sigma''$ (where the ' and " refer to estimates based on the low and high sub-samples, respectively) is evaluated by θ in the following auxiliary equation based on equation (7): $\Delta k_f = -\sigma \Delta c_f - \theta \Delta c_f * I_f + \beta' \Delta y_f * I_f + \beta'' \Delta y_f * (1-I_f) - \gamma' * I_f - \gamma'' * (1-I_f) - \Delta w_f$, where I_f is an indicator variable equal to 1 for the low sub-sample and 0 for the high sub-sample and $\theta = \sigma' - \sigma''$ and is distributed asymptotic t under the null hypothesis that $\sigma' = \sigma''$. In the IV regressions, each individual instrument, z_f, appears twice in the instrument list as follows, $z_f * I_f$ and $z_f * (1-I_f)$.

difference in the estimated σ's across the high-Q and low-Q sub-samples. In table 4, the elasticities are virtually identical in the OLS results across the Q sub-samples. The low-Q firms have a modestly higher elasticity than the high-Q firms in the IV regression, but the difference is not statistically significant. This result provides additional support for the way our estimation method addresses problems with complicated investment dynamics, avoiding these difficult specification issues by focusing directly on the long-run growth of the capital stock.

G. Comparison to Other Approaches

Prior studies estimating σ (the substitution or user cost elasticity) can be set into three categories. Most previous research has been based on time-series data at the aggregate or industry levels. Prominent examples of this work are the exchanges between Hall and Jorgenson (1967, 1969, 1971) and Eisner and Nadiri (1968, 1970), Eisner (1969, 1970), and Coen (1969). Hall and Jorgenson's initial work was based on a Cobb-Douglas production function, and hence σ equals 1.00 by assumption. Eisner and Nadiri estimated σ freely, and reported that the responsiveness of capital to its user cost was 0.16. This gap has not been closed by subsequent research. Several important concerns, however, have been raised about elasticities estimated from aggregate data suggesting that such estimates may be biased downward due to problems with firm heterogeneity, simultaneity, measurement error, and capital market frictions.

These issues were difficult to address with aggregate data because of the limited amount of variation, and a more recent set of studies has exploited the substantial information in panel data. While some of these concerns can be addressed, these studies usually remove firm effects by differencing; thus, transitory time-series variation heavily influences the estimated elasticity. A recent example is Chirinko, Fazzari, and Meyer (1999), who find an elasticity of 0.25 for

a panel of firms. A similar elasticity is reported by Goolsbee (2000), who analyzes a panel of equipment assets. Cummins and Hassett (1992) and Cummins, Hassett, and Hubbard (1994, 1996) develop a novel approach, focusing on those years in which there are sizeable tax policy changes to mitigate concerns about endogeneity and measurement error. In these studies, cross-section variation is key and they report a substantial response of investment to the user cost. Nonetheless, based on some auxiliary assumptions, the implied capital elasticity for U.S. firm data in Cummins, Hassett, and Hubbard (1994) is somewhat lower than that obtained by Chirinko, Fazzari, and Meyer.[26] These studies use investment data, and the biases associated with investment models mentioned above may be important.

A third class of studies focuses on long-run relations between the capital stock and its determinants. To mitigate the distorting effects of complex dynamics, Caballero (1994) exploits the innovative idea that the elasticity can be estimated in a cointegrating equation that includes the capital/output ratio and the user cost. Because cointegration is an asymptotic property, this estimate can be biased downward in finite samples. Using aggregate quarterly data for equipment spending and the Stock-Watson (1993) correction to adjust the estimates for the effects of transitory variation, Caballero obtains a range of elasticity estimates, from 0.40 to 0.93, depending on the number of lags used in the correction. Also exploiting cointegration properties, Mairesse, Hall, and Mulkay (1999) and Harhoff and Ramb (2001) estimate error correction models (ECM) containing the long-run relation between the capital stock and its determinants and the percentage changes in these variables to capture short-run dynamics. Firm-level data and fixed effects are used in both studies. The parameters are imprecisely estimated, a

---

[26] See Chirinko, Fazzari, and Meyer (1999, section 5) for further details.

result that may be due to estimating both long-run and short-run parameters in the ECM with data that have substantial transitory time-series variation. Kiyotaki and West (1996) specify a model that includes deviations of the desired from the actual capital stock, and estimate desired capital in terms of a future projection from a two-step VAR procedure. With quarterly aggregate data for Japan, they find that the short-run and long-run user cost elasticities are 0.05 and 0.07, respectively. The authors attribute these very small responses to transitory variation in the user cost series as represented by a pronounced tendency for mean reversion. Caballero, Engel, and Haltiwanger (1995) estimate a model similar to Caballero (1994) with plant-level equipment spending. They obtain a range of elasticities across two-digit industries from 0.01 to 2.00, with an unweighted average of approximately unity. If we assume that the structures elasticity is one-third as large as that for equipment (per the results of Cummins and Hassett, 1992), then the overall elasticity is approximately 0.70.

The elasticity estimates of Caballero, Engel, and Haltiwanger and those presented in this paper are both based on a panel, but are not directly comparable for a variety of reasons, including the use of plant-level vs. firm-level data, the specification of the long-run determinants of the capital stock, and the manner in which the problem of capital stock dynamics is addressed. The Caballero, Engel, and Haltiwanger estimates are based on a cointegrating relation that emphasizes the time dimension of the panel, and deviations from long-run values are accounted for with the Stock-Watson correction. By contrast, our approach uses the time dimension of panel data to measure long-run variables in each interval, and then estimates the elasticity from the cross-section dimension of the panel. Given these differences, it is not surprising that we obtain different results.

V. Summary and Conclusions

The substitution elasticity between capital and labor (equivalent to the elasticity of business capital to its user cost) has been the focus of much research attention over the past 40 years. Among other issues, this parameter is central in assessing the validity of alternative models of long-run growth and translating the effects of tax policy into real outcomes. Prior work has relied in almost all cases on time-series variation in investment data at the aggregate, industry, or firm level to estimate this elasticity. This paper offers a different approach. The estimation strategy developed here classifies the time periods into three intervals and then averages the firm-level panel data within each interval. The data are differenced across intervals, and production function parameters are estimated in a cross-section of time-averaged, differenced firm data. Our approach accounts for a variety of productivity shocks, omitted variables, and firm effects. This econometric model does not *solve* the estimation problems inherent with investment models -- difficult-to-specify dynamics, transitory time-series variation, and positively sloped supply schedules -- that may bias estimates of the substitution/user cost elasticity. Instead, our approach *avoids* these problems by exploiting panel data in an original way and estimating directly the first-order condition for capital.

We find that the elasticity can be consistently and precisely estimated by OLS, and is approximately 0.40. Relative to a comparable investment study (Chirinko, Fazzari, and Meyer, 1999), the results here suggest that investment models impart a discernible bias toward zero in estimates of the elasticity. To the central question of whether the Cobb-Douglas assumption is valid, our results offer a strikingly negative answer. This robust finding raises questions about the frequent use of the Cobb-Douglas production function in theoretical and empirical models and about the cost-effectiveness of various tax proposals for stimulating

capital formation.

      Apart from our immediate objective, the method developed here may prove useful in estimating other structural parameters from long-panel datasets. Our approach, which uses interval averages to estimate long-run desired values of regression variables, could be applied to other problems where short-run dynamics may obscure long-run structural relations. There are likely to be a number of applications in, for example, labor and industrial organization, where the availability of long-panels and interest in structural parameters may make this method feasible and informative.

Appendix A: Trending Variables

This appendix considers the effects of trending variables on the specification of the model. We begin with the following decomposition for variable $W_{f,\tau,t}$ into non-growth (ng) and growth (g) components, where W corresponds to any of the model variables, K, Y, or C (note that, unlike in the text, we explicitly include an index for the τ interval even when it is redundant),

$$(A\text{-}1) \quad W_{f,\tau,t} \equiv W^{ng}_{f,\tau,t} + W^{g}_{f,\tau,t},$$

$$(A\text{-}2) \quad W^{ng}_{f,\tau,t} \equiv \mu^{ng}_{f,\tau} + \nu^{ng}_{f,\tau,t},$$

$$\mu^{ng}_{f,\tau} = \sum_{t=1}^{T_\tau} W^{ng}_{f,\tau,t} / T_\tau,$$

$$\sum_{t=1}^{T_\tau} \nu^{ng}_{f,\tau,t} / T_\tau = 0,$$

$$(A\text{-}3) \quad W^{g}_{f,\tau,t} \equiv \mu^{ng}_{f,\tau} [(1+g_f)^t - 1].$$

In (A-2), the non-growth component equals the mean over the τ interval ($\mu^{ng}_{f,\tau}$) and a deviation from the mean value ($\nu^{ng}_{f,\tau,t}$) that averages to zero. These summations are over all T_τ time periods that are in the τ interval. In (A-3), the growth component is proportional to the mean, and increases at a firm–specific rate of g_f.

As in Section II, we measure the long-run value of W ($W^{*}_{f,t}$) as a time-average over a τ interval ($W_{f,\tau}$),

(A-4) $W^*_{f,t} = W_{f,\tau}$

$$= \sum_{t=1}^{T_\tau} W_{f,\tau,t} / T_\tau \,,$$

$$= \sum_{t=1}^{T_\tau} W^{ng}_{f,\tau,t} / T_\tau + \sum_{t=1}^{T_\tau} W^{g}_{f,\tau,t} / T_\tau,$$

$$= \mu^{ng}_{f,\tau} + \sum_{t=1}^{T_\tau} v^{ng}_{f,\tau,t} / T_\tau + \sum_{t=1}^{T_\tau} \mu^{ng}_{f,\tau} [(1+g_f)^t - 1] / T_\tau,$$

$$= \mu^{ng}_{f,\tau} + 0 + \mu^{ng}_{f,\tau} \sum_{t=1}^{T_\tau} [(1+g_f)^t - 1] / T_\tau,$$

$$= \mu^{ng}_{f,\tau} * H[g_f],$$

$$H[g_f] \equiv 1 + \sum_{t=1}^{T_\tau} [(1+g_f)^t - 1] / T_\tau,$$

Our estimator (7) uses the difference between the $\tau=2$ and $\tau=1$ intervals in the logarithms of $W_{f,\tau}$,

(A-5) $Ln\{W_{f,\tau=2}\} - Ln\{W_{f,\tau=1}\} = Ln\{\mu^{ng}_{f,\tau=2}\} + Ln\{H[g_f]\}$

$$- Ln\{\mu^{ng}_{f,\tau=1}\} - Ln\{H[g_f]\},$$

$$= Ln\{\mu^{ng}_{f,\tau=2} / \mu^{ng}_{f,\tau=1}\},$$

which is the percentage change in the non-growth component of $W_{f,\tau}$. Thus, the variables entering the regression are not distorted by firm-specific growth.

Appendix B: The Replacement Value of Capital

The capital stock is a key variable in this study, and this appendix provides details about how we overcome several significant problems in measuring the capital stock from accounting data. The obvious proxies for the capital stock in the Compustat data, book values of gross or net property, plant, and equipment, are not acceptable measures of the economic value of the capital stock for two reasons. First, they value assets at the historical cost prevailing when the assets were acquired and therefore contain a mix of historical price levels that cannot be easily adjusted for inflation. Second, accounting depreciation rules likely do not capture economic depreciation correctly. The iterative "perpetual inventory" algorithm described here addresses these problems.

The first step in our procedure is to choose a seed value for the iteration. We use the nominal book value of net property, plant, and equipment for firm f from its first observation in the data set ($NPLANT_{f,0}$). To convert this value to real terms we employ data on the share of different kinds of capital assets (indexed by j) in the firm's two-digit SIC industry i. Denote this share as $\alpha_{i,j}$. The amount of capital ($\alpha_{i,j} NPLANT_{f,0}$) should be deflated by the asset-specific price index $p_{j,0}$. Then the real seed value of the capital stock ($K_{f,0}$) is defined as:

(B-1) $$K_{f,0} = \sum_j \frac{\alpha_{i,j} NPLANT_{f,0}}{p_{j,0}}.$$

Starting from this seed value, the remainder of the capital stock for firm k is constructed iteratively from:

(B-2) $$K_{f,t+1} = K_{f,t}\sum_j \alpha_{i,j}(1-\delta_j) + KCHG_{f,t}\sum_j \frac{\alpha_{i,j}(1-\delta_j)}{p_{j,t}}.$$

The first term in equation (B-2) is the depreciated value of the period t capital stock that remains in period t+1. The depreciation rate δ_j for each asset j is determined by DRI from the "double declining balance" formula:

(B-3) $\qquad \delta_j = 1 - e^{-2/LIFE_j}$,

where $LIFE_j$ represents the estimated average service life for capital asset j. The second term in equation (B-2) represents the addition (or deletion) to the period t+1 capital stock accounted for by new investment, acquisitions, or divestitures in period t. The variable $KCHG_{f,t}$ (discussed in detail below) represents the nominal addition (or subtraction) of new capital goods for firm f in period t prices. The deflation method for $KCHG_{f,t}$ is the same as for the seed value in equation (B1). We assume that new capital is acquired at the beginning of period t and depreciates one full year before entering the period t+1 capital stock. (We also constructed capital stock series using a half year's depreciation for KCHG and found that it had only a trivial impact on the results.) If a firm adds to its capital stock in period t only through conventional capital spending, the $KCHG_{f,t}$ variable in equation (B-2) would equal the firm's investment ($I_{f,t}$), that we obtain from Compustat's capital expenditure data in the sources and uses of funds statement. In practice, acquisitions and divestitures can augment and deplete the capital stock independent of reported investment. Many panel studies delete firms with substantial acquisitions or divestitures. However, there are a large number of observations with acquisitions and divestitures in the Compustat data. Deleting these observations reduces the sample size and could induce a selection bias. We therefore develop a method to account for acquisitions and divestitures when constructing the capital stock data. (To the extent that acquisitions or divestitures create outliers in the data, these should be captured by our outlier detection algorithm described in Section III.)

The capital change variable ($KCHG_{f,t}$) in equation (B-2) is defined in a way that accounts for large acquisitions and divestitures. We appeal to the following accounting identities to derive a formula for $KCHG_{f,t,}$:

(B-4) $$\Delta GPLANT_{f,t} = I_{f,t} + ACQUIS_{f,t} - RETIRE_{f,t}$$

(B-5) $$\Delta NPLANT_{f,t} = I_{f,t} + ACQUIS_{f,t} - DEPR_{f,t}$$

$\Delta GPLANT_{f,t}$ = the change in gross plant and equipment from the end of year t-1 to the end of year t;

$\Delta NPLANT_{f,t}$ = the change in net plant and equipment from the end of year t-1 to the end of year t;

$ACQUIS_{f,t}$ = acquisitions in year t;

$RETIRE_{f,t}$ = retirements in year t,[27] and

$DEPR_{f,t}$ = accounting depreciation in year t.

In the event of an acquisition, $KCHG_{f,t}$ equals $I_{f,t} + ACQUIS_{f,t}$. Because Compustat does not have reliable figures for $ACQUIS_{f,t}$, we rearrange equation (B-4) to obtain:

(B-6) $$I_{f,t} + ACQUIS_{f,t} = \Delta GPLANT_{f,t} + RETIRE_{f,t} \text{ or}$$

$$KCHG_{f,t} = \Delta GPLANT_{f,t} + RETIRE_{f,t}$$

In the event of a divestiture, we want to decrease the capital stock by the *depreciated* value of the capital sold. In this case:

(B-7) $$KCHG_{f,t} = \Delta NPLANT_{f,t}$$

If there is no major acquisition or divestiture, then we retain the basic formula:

(B-8) $$KCHG_{f,t} = I_{f,t}$$

---

[27] Compustat defines retirements as "a deduction from a company's property, plant, and equipment account resulting from the retirement of obsolete or damaged goods and/or physical structures."

We now need an empirical test to determine whether a firm has undergone an acquisition or divestiture in a given year. There are two rules of thumb that aid us in this search. First, $\Delta\text{GPLANT}_{f,t}$ is normally less than $I_{f,t}$ because of retirements. Therefore, if $\Delta\text{GPLANT}_{f,t} > I_{f,t}$ by a substantial amount, it signals an acquisition with a high probability. Second, $\Delta\text{GPLANT}_{f,t}$ is normally greater than $\text{RETIRE}_{f,t}$ because retirements are the only way to reduce gross plant and equipment in the absence of a divestiture. Therefore, if $\Delta\text{GPLANT}_{f,t} < \text{RETIRE}_{f,t}$ by a substantial amount it signals a divestiture.

We define a "substantial" amount as a discrepancy of ten percent or more. The point of imposing the ten percent limit is to make acquisition and divestiture adjustments conservative. That is, we only deviate from the standard formula when there is clear evidence that this formula is misleading. In this case, if

(B-9) $$\frac{\Delta GPLANT_{f,t} - I_{f,t}}{GPLANT_{f,t-1}} > 0.1,$$

then we assume an acquisition and define $\text{KCHG}_{f,t}$ from equation (B-6). In contrast, if

(B-10) $$\frac{\Delta GPLANT_{f,t} + RETIRE_{f,t}}{GPLANT_{f,t-1}} < -0.1,$$

then we assume a divestiture and define $\text{KCHG}_{f,t}$ from equation (B-7). If neither rule holds, we simply define $\text{KCHG}_{f,t}$ as investment spending, as in equation (B-8).

Appendix C: Short-Run Frictions and Measurement Error

This appendix relaxes the assumption that the long-run values of capital and output appearing in the model of Section II can be measured without error as time-averages over a τ interval -- $\Sigma_t K_{f,\tau,t}/T_\tau \equiv K_{f,\tau} = K^*_{f,t}$ and $\Sigma_t Y_{f,\tau,t}/T_\tau \equiv Y_{f,\tau} = Y^*_{f,t}$ for $t=1,T_\tau$. (Note that, unlike in the text but as in Appendix A, we explicitly include an index for the τ interval even when it is redundant.) In particular, these equalities might be disrupted if short-run frictions affect long-run values. For example, a firm facing irreversibility constraints will exhibit a reluctance to invest that lowers its optimal capital stock. In this case, a negative, firm-specific measurement error drives a wedge between $K_{f,\tau}$ and $K^*_{f,t}$ and, through the production function, a wedge between $Y_{f,\tau}$ and $Y^*_{f,t}$. However, the same set of constraints create a "hangover effect," as a firm occasionally finds itself with capital that it would like to dispose of but can not due to irreversibility constraints. Thus, the long-run capital stock for a firm facing irreversibility frictions can be greater than or less than the long-run capital stock for a frictionless firm (Abel and Eberly, 1999). An additional friction is introduced by asymmetric adjustment costs implying that the average values of capital and output will differ in general from their long-run values.

These considerations introduce measurement error ($MEK_{f,\tau}$) that drives a wedge between $K_{f,\tau}$ and $K^*_{f,t}$ (a similar analysis applies to $Y_{f,\tau}$ and $Y^*_{f,t}$),

(C-1) $K_{f,\tau} = K^*_{f,t} + MEK_{f,\tau}$.

We assume that the measurement error between $K_{f,\tau}$ and $K^*_{f,t}$ increases with the size of the "true" long-run capital stock and that $MEK_{f,\tau} = M_{f,\tau} K^*_{f,t}$. Furthermore, $M_{f,\tau}$ consists of two components, m_f and $m_{f,\tau}$, representing measurement error that varies by firm and by firm and interval, respectively. Combined with (C-1), these

assumptions generate the following model of measurement error,

(C-2a) $\qquad K_{f,\tau} = K^*_{f,t} \, M_{f,\tau}$,

(C-2b) $\qquad M_{f,\tau} = 1 + m_f + m_{f,\tau}$,

To understand the impact of measurement error on our estimating equation, we analyze (C-2) in conjunction with the trending variables analyzed in Appendix A. We begin with $K^*_{f,t} = K_{f,\tau} / M_{f,\tau}$, and thus divide the right-side of (A-4) by $M_{f,\tau}$. Since $M_{f,\tau}$ is indexed by τ, it passes through the summation sign, and the version of (A-4) accounting for measurement error and trending variables is as follows,

(C-3) $\qquad K^*_{f,t} = \mu^{ng}_{f,\tau} * H[g_f] / M_{f,\tau}$,

where $\mu^{ng}_{f,\tau}$ is the mean of the non-growth component of $K_{f,\tau,t}$ and $H[g_f]$ is a function of the firm-specific growth rate. See Appendix A for details.

Our estimator replaces the logarithm of $K^*_{f,t}$ in (4) with the logarithm of the expression in (C-3), and differences the resulting equation between the $\tau=2$ and $\tau=1$ intervals,

(C-4) $\text{Ln}\{K_{f,\tau=2} / M_{f,\tau=2}\} - \text{Ln}\{K_{f,\tau=1} / M_{f,\tau=1}\}$

$\qquad = \text{Ln}\{\mu^{ng}_{f,\tau=2}\} + \text{Ln}\{H[g_f]\} - \text{Ln}\{\mu^{ng}_{f,\tau=1}\} - \text{Ln}\{H[g_f]\}$

$\qquad\quad + (m_f + m_{f,\tau=2}) - (m_f + m_{f,\tau=1})$,

$\qquad = \text{Ln}\{\mu^{ng}_{f,\tau=2} / \mu^{ng}_{f,\tau=1}\} - \Delta m_{f,\tau}$,

which is identical to (A-5) in Appendix A with the addition of $-\Delta m_{f,\tau}$. Note the

firm-specific component of the measurement error (m_f) cancels in the first difference.

The additional term, $-\Delta m_{f,\tau}$, can be incorporated straightforwardly into the econometric model. The error term in (7) is composed of a productivity shock, $-\Delta w_{f,\tau}$, that is firm-specific and interval-specific and, to reflect the effects of measurement error, it can be replaced by the composite error, $-(\Delta w_{f,\tau} + \Delta m_{f,\tau})$. Note that the two components both vary by firm and interval. We expect the impact of $\Delta m_{f,\tau}$ to be relatively small because firm and industry effects have already been removed.

In the event that there is some correlation between $\Delta m_{f,\tau}$ and the regressors induced by measurement error, the estimated σ will be attenuated, that is, closer to zero than the "true" σ. Since the measurement error considered in this Appendix does not affect the user cost variable directly, the effect on σ is indirect, and equals the product of the attenuation of the coefficient on output and a coefficient representing the correlation between "true" sales growth and "true" user cost growth (Garber and Klepper, 1980, equation (2.6)). The quantitative impact of this type of measurement error is assessed in Section IV.C (the Rao test). Furthermore, since this type of measurement error applies only to capital and output, it will not impact the estimate of σ in the regression in the third column of Table 2 ($\eta = 1$) with the growth rate of the capital-output ratio as the dependent variable. This estimate of σ and the Rao test both suggest that the type of measurement error considered in this Appendix is quantitatively unimportant.

Table 1 – Summary Statistics

1. Percentage Change Between Interval $\tau = 1$ and $\tau = 2$

Statistic	Capital	Output	User Cost
Mean	36.4	27.5	-6.9
Median	16.9	14.6	-11.8
Standard Deviation	81.9	66.2	18.7
Coefficient of Variation	2.3	2.4	2.7

2. Levels in Interval $\tau = 0$

Statistic	Capital	Output	User Cost
Mean	320.8	948.1	0.282
Median	33.1	161.7	0.291
Standard Deviation	848.7	2562.0	0.056
Coefficient of Variation	2.6	2.7	0.2

3. Levels in Interval $\tau = 1$

Statistic	Capital	Output	User Cost
Mean	434.2	1169.5	0.242
Median	50.7	211.9	0.246
Standard Deviation	1141.3	3180.5	0.046
Coefficient of Variation	2.6	2.7	0.2

4. Levels in Interval $\tau = 2$

Statistic	Capital	Output	User Cost
Mean	529.2	1404.2	0.219
Median	62.3	253.7	0.218
Standard Deviation	1410.1	4237.4	0.028
Coefficient of Variation	2.7	3.0	0.1

Note: The statistics are derived from a sample of 1,860 firms constructed from Compustat and DRI sources as described in section III of the text. The standard deviations represent cross-sectional differences arising from firm heterogeneity in percentage changes across the $\tau=1$ and $\tau=2$ intervals (panel 1) and from firm heterogeneity in levels within an interval (panels 2, 3, and 4). Level statistics for capital and output are in millions of 1987 dollars.

Table 2 – Ordinary Least Squares Estimates

	Unconstrained Regressions		Constrained Regressions		Unconstrained Regression with Low-Pass Filter
	Benchmark Model	Model with Two-Digit SIC Dummies	$\eta = 1$	$\sigma = 1$ and $\eta = 1$	
σ	0.367 (0.067)	0.440 (0.293)	0.372 (0.067)	1.0	0.352 (0.057)
η	1.135 (0.042)	1.152 (0.102)	1.0	1.0	1.368 (0.070)
β	0.925 (0.019)	0.926 (0.019)	1.0	1.0	0.825 (0.019)
γ	0.084 (0.014)	-0.055 (0.114)	0.063 (0.013)	0.020 (0.013)	0.100 (0.016)
R^2	0.564	0.593	0.560	0.540	0.494

Note: Estimates of equation (7) with firm-level panel data as described in sections II and III. Standard errors appear in parentheses. The parameters are σ (the capital-labor substitution or user cost elasticity), η (the returns to scale elasticity), β (the regression coefficient on output growth) and γ (the intercept). See section IV.B for the formula used to compute η and its standard error.

Table 3 – Instrumental Variables Estimates

|	Unconstrained Regressions		Constrained Regressions	
	Benchmark Model	Model with Two-Digit SIC Dummies	$\eta = 1$	$\sigma = 1$ and $\eta = 1$
σ	0.390 (0.108)	0.373 (0.286)	0.434 (0.093)	1.0
η	0.603 (0.074)	0.633 (0.120)	1.0	1.0
β	1.402 (0.110)	1.364 (0.118)	1.0	1.0
γ	-0.049 (0.034)	-0.324 (0.134)	0.059 (0.014)	0.020 (0.013)

Note: Estimates of equation (7) with firm-level panel data as described in section III. Standard errors appear in parentheses. The parameters are σ (the capital-labor substitution or user cost elasticity), η (the returns to scale elasticity), β (the regression coefficient on output growth), and γ (the intercept). The instrument list is defined in section IV.C. In the second column, the industry dummies are instrumented by themselves. See section IV.B for the formula used to compute η and its standard error.

Table 4 – Ordinary Least Squares And Instrumental Variable Estimates: Various Sample Splits

	Split by Cash Flow-Capital Ratio				Split by Capital Stock Size				Split by Tobin-Brainard Q			
	OLS		IV		OLS		IV		OLS		IV

Note: Estimates of equation (7) with firm-level panel data as described in sections II and III. Standard errors appear in parentheses. The parameters are σ (the capital-labor substitution or user cost elasticity), η (the returns to scale elasticity), β (the regression coefficient on output growth), and γ (the intercept). The instrument list is defined in section IV.E. See section IV.B for the formula used to compute η and its standard error. Sample splits are based on the median value of the classifying variable in the $\tau=0$ (1972-1977) interval. θ is the coefficient measuring the difference between the σ's for the contrasting classes, and is distributed asymptotic t under the null hypothesis of equality. See section IV.F for further details about this statistic.
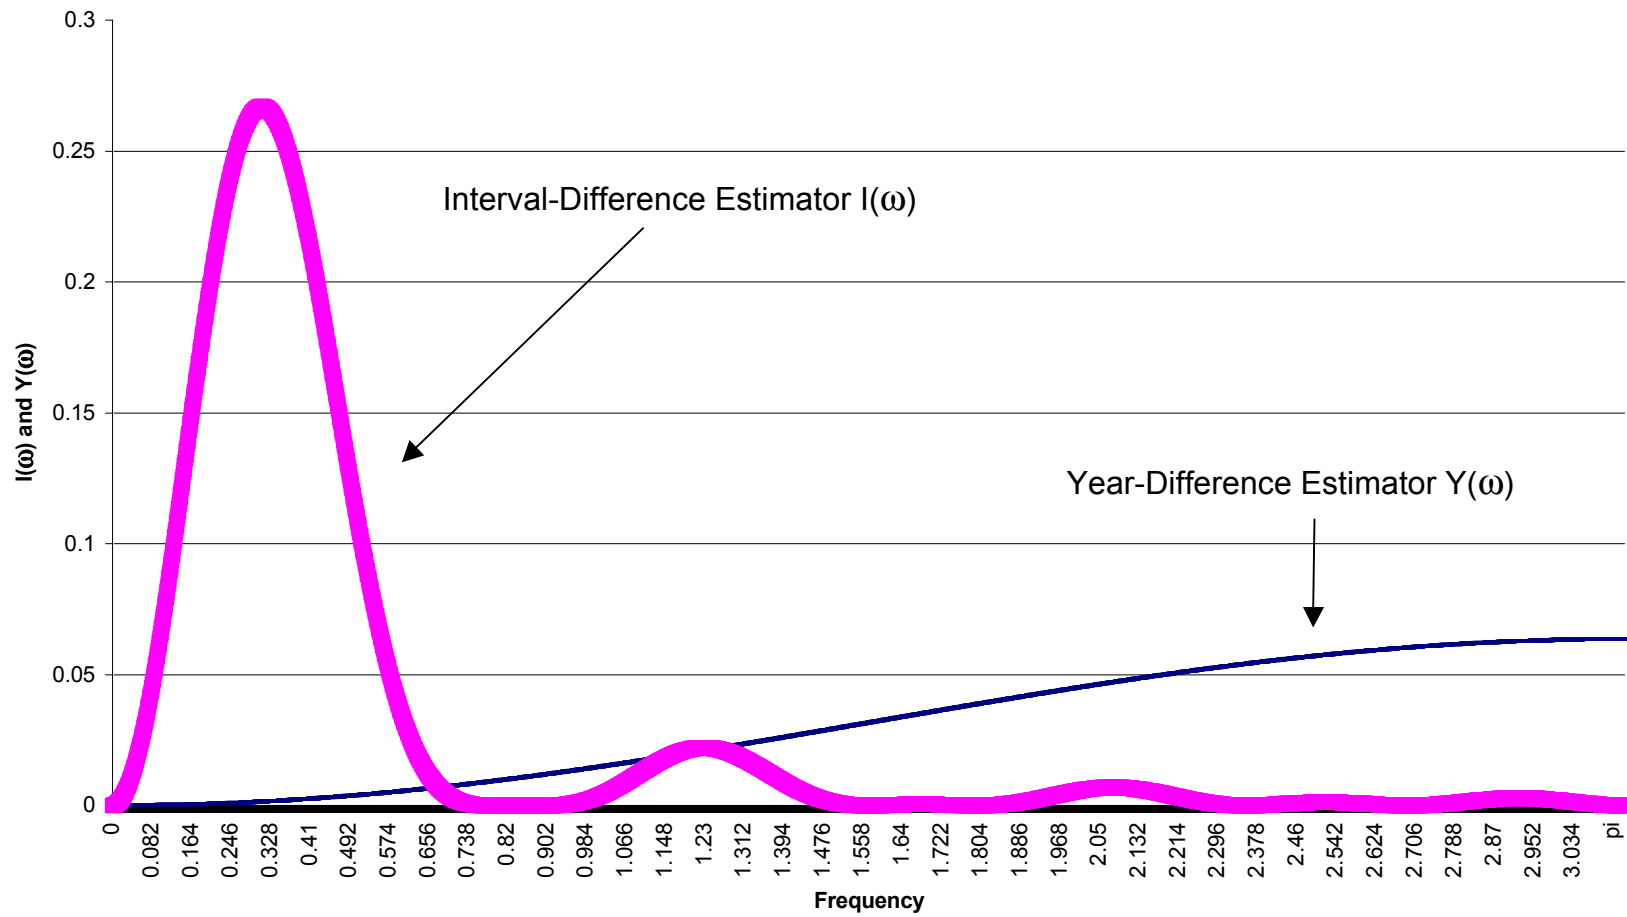

Figure 1: The τ-Interval Definition
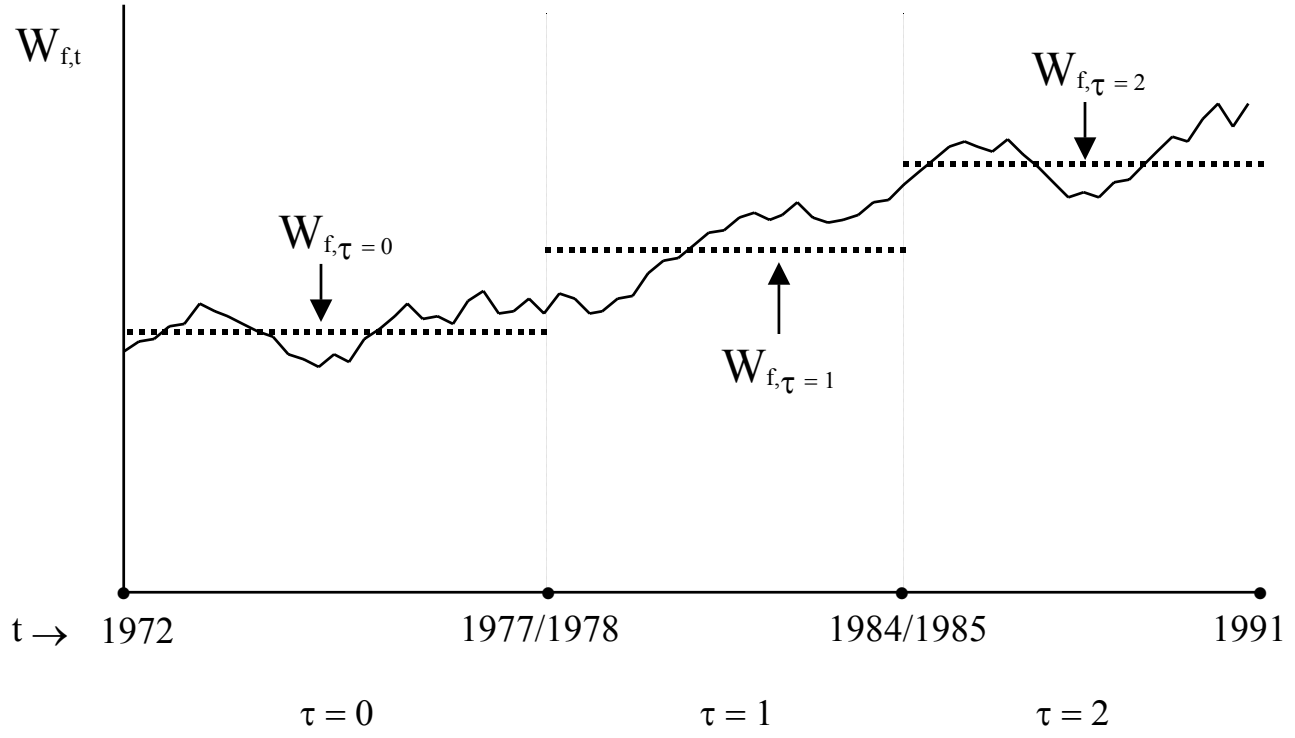

$$W_{f,\tau = 0} = \sum_{t = 1972}^{1977} W_{f,t} / 6$$

$$W_{f,\tau = 1} = \sum_{t = 1978}^{1984} W_{f,t} / 7$$

$$W_{f,\tau = 2} = \sum_{t = 1985}^{1991} W_{f,t} / 7$$

Figure 2
Normalized Spectra For The Year-Difference (Y(ω)) And Interval-DIfference (I(ω)) Estimators

See footnote 9 for details about construction of these spectra
