ABSTRACT

We construct cosmic microwave background lensing mass maps using data from the 2014 and 2015 seasons of observations with the Atacama Cosmology Telescope (ACT). These maps cover 2100 square degrees of sky and overlap with a wide variety of optical surveys. The maps are signal dominated on large scales and have fidelity such that their correlation with the cosmic infrared background is clearly visible by eye. We also create lensing maps with thermal Sunyaev–Zel’dovich contamination removed using a novel cleaning procedure that only slightly degrades the lensing signal-to-noise ratio. The cross-spectrum between the cleaned lensing map and the BOSS CMASS galaxy sample is detected at 10σ significance, with an amplitude of $A = 1.02 \pm 0.10$ relative to the *Planck* best-fitting Lambda cold dark matter cosmological model with fiducial linear galaxy bias. Our measurement lays the foundation for lensing cross-correlation science with current ACT data and beyond.

Key words: gravitational lensing; weak – cosmic background radiation – large-scale structure of Universe – cosmology: observations.

1 INTRODUCTION

Along their paths to our telescopes, the photons of the cosmic microwave background (CMB) are deflected, or lensed, by the gravitational influence of the matter in our Universe. This leads to a remapping of the observed CMB anisotropies on the sky described by $T(\hat{\mathbf{n}}) = T^u(\hat{\mathbf{n}} + \mathbf{d})$, where T and T^u are the lensed and unlensed temperature fields and $\hat{\mathbf{n}}$ is the line of sight. (Analogous expressions hold for the remapping of polarization Q and U). The lensing deflection field $\mathbf{d}(\hat{\mathbf{n}})$ that describes the remapping depends on a weighted integral of the mass along the line of sight; although this integral extends to the last-scattering surface, most of the lensing signal arises between redshifts $z = 0.5$ and $z = 3$ (Zaldarriaga & Seljak 1999; Lewis & Challinor 2006). Since maps of the CMB lensing signal are sensitive to the total matter distribution, including dark matter, they contain a wealth of information about cosmology

and fundamental physics (e.g. Lesgourgues et al. 2006; Sherwin et al. 2011; Planck Collaboration VIII 2020).

In this paper, we present a CMB lensing map constructed from new observations from ACT, which will be useful for cross-correlation analyses.

Cross-correlation measurements can be used to break the degeneracy of galaxy bias (the factor relating the galaxy and matter density contrasts) and the amplitude of matter density fluctuations. This allows us to determine the amplitude of structure at different redshifts $\sigma_8(z)$ (e.g. Giannantonio et al. 2016; Doux et al. 2018; Giusarma et al. 2018; Peacock & Bilicki 2018) and hence probe physics such as dark energy, modified gravity, and neutrino mass. CMB lensing cross-correlations can also be used to constrain multiplicative biases in shear measurements (e.g. Vallinotto 2012; Das, Errard & Spergel 2013; Hand et al. 2015; Liu, Ortiz-Vazquez & Hill 2016; Schaan et al. 2017), measure cosmographic distance ratios (e.g. Hu, Holz & Vale 2007b; Das & Spergel 2009; Miyatake et al. 2017; Prat et al. 2019), calibrate the masses of galaxy groups and clusters (e.g. Baxter et al. 2015; Madhavacheril et al. 2015; Melin & Bartlett 2015; Planck

* E-mail: od261@cam.ac.uk

Collaboration XXIV 2015b; Baxter et al. 2018; Zubeldia & Challinor 2019; Raghunathan et al. 2019a; Raghunathan et al. 2019a,b), and probe astrophysics via the relation of dark to luminous matter (e.g. Bleem et al. 2012; Sherwin et al. 2012; Planck Collaboration XVIII 2014; Allison et al. 2015; van Engelen et al. 2015; Hurier, Singh & Hernández-Monteaudo 2017; Omori et al. 2017; Raghunathan, Bianchini & Reichardt 2018; Geach et al. 2019; Han et al. 2019). However, a key challenge in such analyses is that CMB lensing maps reconstructed from temperature anisotropies can be contaminated by foreground emission and scattering (Hirata et al. 2004; Smith, Zahn & Doré 2007; Das et al. 2011; van Engelen et al. 2014; Ferraro & Hill 2018), which can induce 10–20 per cent level biases in the measured cross-correlation signal (Baxter et al. 2019; Omori et al. 2019). For cross-correlations with low-redshift tracers, these foreground biases arise predominantly from the thermal Sunyaev–Zel’dovich (tSZ) residuals that lie in the map.

To solve this problem, in this paper we develop and implement a new cleaning method, building on Madhavacheril & Hill (2018) (hereafter MH18), in order to eliminate foregrounds from the tSZ effect in cross-correlations. The foreground removal in our method is achieved while preserving nearly all of the cross-correlation signal to noise.

We demonstrate the potential of our new foreground-cleaned CMB lensing maps, which overlap with a variety of optical surveys, by measuring a robust cross-correlation of these maps with Sloan Digital Sky Survey DR12 BOSS CMASS spectroscopic galaxies (Reid et al. 2016).

We also note that some analyses found a lower cross-correlation spectrum between CMB lensing and both low-redshift galaxies and weak lensing than expected from the *Planck* cosmology (e.g. Liu & Hill 2015; Pullen et al. 2016). Testing this possible discrepancy with our new lensing maps provides further motivation for our analysis.

Our paper is structured as follows. Section 2 explains the theoretical background for our cross-correlation measurement. In Section 3, we present our data and discuss the new lensing maps constructed from ACT data. In Section 4, we discuss the construction of tSZ-free lensing maps. In Section 5, we present the cross-correlation measurement with CMASS BOSS galaxies, followed by a discussion of systematic errors in Section 6. The conclusions follow in the final section of our paper. Two appendices explain the CMB map pre-processing and discuss, in more detail, the cleaning method used to remove the tSZ bias from the lensing maps.

2 THEORETICAL BACKGROUND

The CMB lensing convergence field κ , which is related to the lensing deflection via $\kappa = \frac{1}{2} \nabla \cdot \mathbf{d}$, is a direct measure of the projected matter field. In particular, the convergence can be shown to equal a weighted integral of the matter density perturbation along a line of sight with direction $\hat{\mathbf{n}}$

$$\kappa(\hat{\mathbf{n}}) = \int_0^{z_*} dz W^\kappa(z) \delta(\chi(z)\hat{\mathbf{n}}, z) \quad (1)$$

with z_* the redshift at the last scattering surface, δ the three-dimensional matter density contrast field at redshift z , $\chi(z)$ the comoving distance at redshift z , and the window response kernel W^κ for redshift z given by (e.g. Sherwin et al. 2012)

$$W^\kappa(z) = \frac{3}{2H(z)} \Omega_{m,0} H_0^2 (1+z) \chi(z) \frac{\chi_* - \chi(z)}{\chi_*}, \quad (2)$$

where $H(z)$ is the Hubble parameter as a function of redshift, H_0 its value today, $\chi_* = \chi(z_*)$, and $\Omega_{m,0}$ is the value of the matter density parameter today.

The 3D distribution of galaxies can provide an independent view of the matter distribution in combination with lensing, and one that can probe the time dependence of structure growth. (In contrast, κ is a projection of the matter field over a very wide range of redshifts and so cannot provide tomographic information.) The relevant cosmological field is the fractional number overdensity of galaxies in a direction $\hat{\mathbf{n}}$, given by another weighted integral along the line of sight

$$\delta_g(\hat{\mathbf{n}}) = \int_0^{z_*} dz W^g(z) \delta_g^{\text{3D}}(\chi(z)\hat{\mathbf{n}}, z), \quad (3)$$

where δ_g^{3D} is the three-dimensional galaxy distribution at redshift z and the window function $W^g(z)$ is $\frac{dn}{dz}(z)$, the redshift distribution of galaxies in a galaxy survey, normalized to unity.¹ In this work, we consider a spectroscopic galaxy survey with a redshift-binned sample such that the kernel W is only non-zero between z_i and z_f , with z_i , z_f the low and high redshifts defining the survey.

Since galaxies are biased tracers of the underlying matter distribution, the matter–galaxy power spectrum is

$$P_{\text{mg}}(k, z) = b_{\text{cross}}(k, z) P(k, z), \quad (4)$$

where $b_{\text{cross}}(k, z)$ is a general scale- and redshift-dependent clustering bias and $P(k, z)$ is the matter power spectrum (Blanton et al. 1999). In our cross-correlation analysis, we explicitly choose the scales and redshift-range included such that the scale- and redshift-dependence of the galaxy bias is not large and $b_{\text{cross}}(k, z) \approx b = \text{const}$. We will consider multipoles L in the range $100 < L < 1000$; this choice will be motivated in Section 5.

The cross-power spectrum of the two observables κ and g is directly related to the cosmological parameters of the underlying Lambda cold dark matter (Λ CDM) model. Using the flat-sky approximation valid for a small sky fraction f_{sky} and the Limber approximation (Limber 1953), the expression for the cross-spectrum in the linear Λ CDM model is (e.g. Omori & Holder 2015)

$$C_L^{\kappa g} = \int_0^{z_*} dz \frac{H(z)}{\chi^2(z)} W^\kappa(z) \frac{dn}{dz}(z) P_{\text{mg}} \left(k = \frac{L + \frac{1}{2}}{\chi(z)}, z \right). \quad (5)$$

3 LENSING MAPS FROM ACT DATA ALONE

We construct two CMB lensing maps. The first map, described in this section, uses ACT data alone. The second, described in the following section, also uses multifrequency data from *Planck* in order to clean foregrounds.

3.1 CMB maps for lensing analysis

The lensing convergence maps used in this work are constructed from CMB temperature and polarization data taken by the polarization-sensitive receiver on the Atacama Cosmology Telescope (ACT), a 6-m CMB telescope operating in the Atacama desert in Chile (see e.g. Thornton et al. 2016; Aiola et al. 2020; Choi et al. 2020). The CMB field maps are obtained from observations made during seasons 2014–2015 in the 98 and 150 GHz frequency bands; these maps will be made public, along with our lensing maps, in the upcoming ACT

¹We do not include magnification bias, since its magnitude is negligible given the low redshift range of the galaxy catalogue used in this work.

data release 4 (DR4). We will consider data coming from two regions of the sky, one referred to as BN (from the 2015 season, covering ≈ 1633 sq. deg. of the sky overlapping the SDSS BOSS northern field, with effective co-added white noise level of approximately $\Delta_T = 21 \mu\text{K-arcmin}$ for temperature and $\Delta_P = \sqrt{2}\Delta_T$ for polarization), and the other referred to as D56 (seasons 2014–2015, covering ≈ 456 sq. deg. of the sky, with effective co-added white noise level of approximately $\Delta_T = 10 \mu\text{K-arcmin}$ for temperature and $\Delta_P = \sqrt{2}\Delta_T$ for polarization).² Given the proximity of the maps to the equator and their moderate extent in declination, the flat-sky approximation is sufficient at our accuracy for constructing lensing maps; a simple estimate of the inaccuracy of this approximation gives no detectable effect for D56 and only a 1 per cent multiplicative bias for BN. We do not use 2013 or 2016 observations in our analysis (even though the latter are part of DR4), because the 2013 observations cover too little sky area and the 2016 observations are still too shallow to contribute significant signal-to-noise to cross-correlation measurements.

We combine the per-season and per-frequency CMB maps presented in Choi et al. (2020) to provide the input maps for our lensing estimator. The details of this procedure are described in Appendix A, but we briefly summarize them here. We construct our CMB input maps by co-adding source-subtracted³ maps from the two frequencies and two seasons of the data and convolving the result to a common beam after masking. In addition, we inpaint (fill with an appropriately correlated Gaussian random field) a 6-arcmin-radius circular area around bright compact sources and SZ clusters using the maximum-likelihood method of Bucher & Louis (2012). This inpainting step serves to reduce foreground biases arising from bright sources and massive clusters. We note that the main difference from the map processing employed in Sherwin et al. (2017) is that the different frequencies and seasons are coadded with weights that are local in Fourier space rather than real space; this is more optimal for multifrequency data due to the strong frequency dependence of the beams.

The results of our map construction and preparation process are masked, beam-deconvolved dimensionless CMB fluctuation maps of temperature T as well as Q and U polarization in each of the two sky regions. The Q and U polarization maps are transformed into $E - B$ polarization maps using the pure $E - B$ decomposition method outlined in Louis et al. (2013). As a final step in the preparation of the maps for lensing reconstruction, we follow the nominal analysis methodology of Choi et al. (2020) to reduce the impact of ground contamination in the T , E , and B maps, filtering out all modes $\ell = (\ell_x, \ell_y)$ that have $|\ell_x| < 90$ and $|\ell_y| < 50$. We also remove all modes that are outside the range of scales $500 < \ell < 3000$ in order to restrict our lensing analysis to scales where the ACT map-maker transfer function is small⁴ and where contamination from foregrounds is small ($\ell < 3000$).

²Atmospheric noise contributes a $1/f$ component that is non-negligible and must be included when forecasting the signal-to-noise ratio in the lensing map.

³See Madhavacheril et al. (2020), Choi et al. (2020), and Aiola et al. (2020) for details.

⁴The map-maker transfer function is close to unity for $\ell > 500$ in D56, but the deviation from unity may be as large as 10 per cent in the BN analysis region between ℓ of 500 and 600 (Aiola et al. 2020; Choi et al. 2020). However, because of the fact that the lensing estimator only draws a small fraction of its statistical weight from multipoles $500 < \ell < 600$ (less than 2 per cent, see e.g. Schmittfull et al. 2013) we expect an effect on lensing cross-correlations that is much smaller than the statistical uncertainty and is thus negligible.

As well as processing data, we also produce $N = 511$ CMB simulations matching each of the CMB maps described above. These simulations are generated using the pipeline described in Choi et al. (2020) and include primary CMB, lensing, noise, and foregrounds. The foregrounds are Gaussian and spatially homogeneous and the noise is Gaussian but spatially inhomogeneous, as described in Choi et al. (2020). We use the simulations to test our lensing reconstructions, derive small transfer function corrections and construct covariance matrices, as described in the following sections of this paper. To reconstruct lensing convergence maps from simulations we use the same pipeline that we apply to the data. We describe this lensing reconstruction pipeline in the following section.

3.2 Lensing reconstruction and validation

Exploiting the mode couplings induced by lensing, we reconstruct the lensing convergence field from our CMB maps with a minimum variance quadratic estimator (Hu & Okamoto 2002)

$$\bar{\kappa}^{XY}(\mathbf{L}) = A^{XY}(\mathbf{L}) \int \frac{d^2\ell}{(2\pi)^2} X(\ell)Y(\mathbf{L} - \ell)f^{XY}(\ell, \mathbf{L}), \quad (6)$$

where $A^{XY}(\mathbf{L})$ is a normalization (derived from our fiducial cosmology) to ensure that the estimator is unbiased. $f^{XY}(\ell, \mathbf{L})$ is an optimal weighting function chosen to minimize the reconstruction noise of the estimator; it includes a Wiener filter for the CMB input fields X, Y . As in Sherwin et al. (2017) we will consider only the pairs $XY \in \{TT, TE, EE, EB\}$, as the TB combination has negligible signal to noise. Expressions for the weighting function f and the theory normalization A can be found in Hu & Okamoto (2002), although following Hanson et al. (2011) we replace the unlensed spectra with lensed spectra in the weighting functions to cancel higher order biases. A spurious signal on the largest scales of the reconstructed lensing map arises from non-lensing statistical anisotropy due to sky masks or inhomogeneous map noise; this spurious lensing ‘mean field’ must be subtracted from equation (6) (e.g. Namikawa, Hanson & Takahashi 2013). We calculate this mean field correction by generating 511 lensing reconstructions from simulations and averaging these reconstructions. We thus obtain the mean-field subtracted lensing convergence estimator

$$\hat{\kappa}^{XY}(\mathbf{L}) = \bar{\kappa}^{XY}(\mathbf{L}) - \langle \kappa_s^{XY}(\mathbf{L}) \rangle_s, \quad (7)$$

where $\kappa_s^{XY}(\mathbf{L})$ is the lensing reconstruction $\bar{\kappa}^{XY}$ for the simulation realization s and the angle average $\langle \rangle_s$ is over simulations.

We complete the lensing map by creating a minimum variance combination of the different types of quadratic estimators $XY \in \{TT, TE, EE, EB\}$,

$$\hat{\kappa}_L^{\text{MV}} = \sum_{XY} w^{XY}(\mathbf{L}) \hat{\kappa}^{XY}(\mathbf{L}), \quad (8)$$

where $w^{XY}(\mathbf{L})$ are minimum variance weights.

Finally, the particular form of the normalization $A^{XY}(\mathbf{L})$ used in equation (6) is valid for CMB maps with periodic boundaries. This is clearly an idealization; for example, using masked CMB maps introduces spurious gradients at the mask boundary (Hirata et al. 2008), changing the form of the correct lensing normalization (although this effect is reduced by apodization). We capture this and other non-idealities by introducing an extra multiplicative normalization function $r^{\text{MC}}(\mathbf{L})$.

To calculate this function, we cross-correlate our $N = 511$ reconstructed lensing simulations $\hat{\kappa}_s^{\text{MV}}$ with the true input lensing

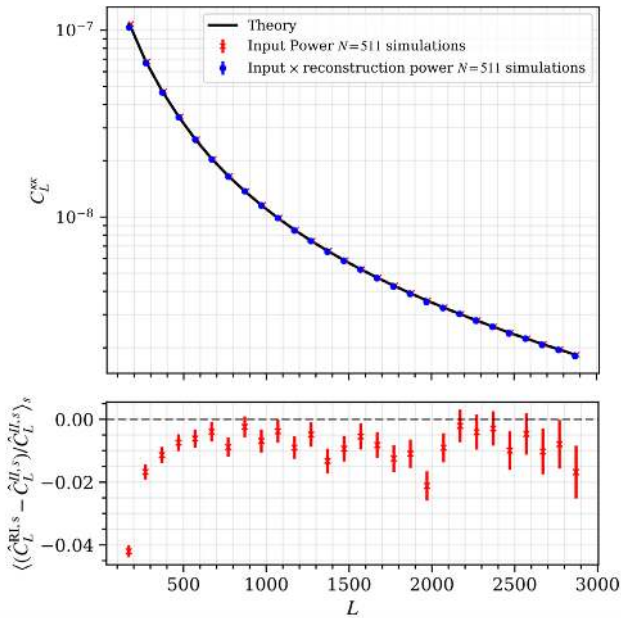

Figure 1. Verification of our lensing reconstruction pipeline for the tSZ free lensing maps (shown for the D56 patch). We plot the average cross-spectrum of the reconstructed lensing maps with the input lensing simulations (blue dots), the average power spectrum of the input lensing simulations (red crosses) and a binned lensing power theory curve in black. (The BN patch gives quantitatively similar results.) The bottom panel shows the fractional difference of the input-reconstruction cross-correlation with the input lensing power. The ACT only simulations give residuals of similar magnitude. From the good agreement of the input-reconstruction cross-correlation with the input lensing power, we can see that the true lensing signal in the simulations is recovered within percent-level accuracy; we absorb only a small correction into a simulation-based re-normalization.

convergence field κ_s used to generate the simulations,⁵ obtaining the reconstruction-input cross-spectrum $\hat{C}_L^{\text{RI},s}$. We compare this cross-spectrum with the auto-spectrum of the input convergence field $\hat{C}_L^{\text{II},s}$. Taking the ratio of averages over the N sims $\langle \hat{C}_L^{\text{RI},s} \rangle_s / \langle \hat{C}_L^{\text{II},s} \rangle_s$, we obtain a one-dimensional binned function of $L = |L|$, where $L_{\min} = 20$, $L_{\max} = 3000$, and $\Delta L = 100$. We then interpolate this over a two-dimensional grid to get the final isotropic correction function $r^{\text{MC}}(L)$ that we apply to the lensing maps to obtain the MC corrected minimum variance lensing maps

$$\hat{\kappa}_L = r^{\text{MC}}(L) \hat{\kappa}_L^{\text{MV}}. \quad (9)$$

If our pipeline is estimating the lensing signal reliably, the Monte Carlo based normalization correction of equation (9) should only require a rescaling of order a few percent. To validate our pipeline, we therefore test whether our lensing map is nearly correctly reconstructed even in the absence of Monte Carlo renormalization.

In Fig. 1, we show a comparison between $\langle \hat{C}_L^{\text{RI},s} \rangle_s$ and $\langle \hat{C}_L^{\text{II},s} \rangle_s$ for the D56 patch without the Monte Carlo normalization (this figure uses foreground-cleaned ACT + *Planck* lensing maps that we will introduce in the next section, but the residuals for the ACT-only maps are similar). We recover the signal with only per cent-level deviations (which implies that $r^{\text{MC}}(L)$ is within a few percent of unity); this

⁵To mimic the processing of the reconstructions we mask κ_s with the square of the data-mask, as this enters twice in the quadratic lensing estimator used to reconstruct the lensing simulation.

gives confidence that our pipeline is functioning correctly. We obtain quantitatively similar results for the BN patch.

3.3 Visualization of the maps and their correlation with large-scale structure

An image of the ACTPol CMB lensing maps is shown in Fig. 2. The maps have been Wiener filtered to show the signal-dominated scales (roughly 1 degree or larger for BN and 0.5 deg or larger for D56) and have been converted to maps of the lensing potential using the appropriate filtering. We also overplot contours of Cosmic Infrared Background (CIB) emission obtained from the GNILC *Planck* component separated maps (Planck Collaboration XLVIII 2016); the CIB maps have the same filtering applied as the lensing ones. In the BN region, we mask the CIB map using the *Planck* PR2 Commander high-resolution map of thermal dust emission (Planck Collaboration X 2015a). The mask is made by thresholding the dust map such that it covers regions of the CIB map that have visibly low power due to dust contamination; we only use this mask for the visualization of Fig. 2. The CIB arises from similar redshifts as CMB lensing and hence is known to be highly correlated with lensing (Song et al. 2003; Holder et al. 2013; Planck Collaboration XVIII 2014). Indeed, even by eye a high correlation of our lensing maps and the CIB is visible. This illustrates the fact that our lensing maps are signal dominated over a range of large scales and are a faithful tracer of the mass distribution (for other highly signal-dominated CMB lensing maps, see also Wu et al. 2019).

4 FOREGROUND-MITIGATED LENSING MAPS WITH NEW CLEANING METHODS

CMB temperature maps contain secondary anisotropies not only from lensing, but also from tSZ, CIB (Cosmic Infrared Background), kSZ (kinetic Sunyaev-Zel'dovich), and other foreground contributions arising from a wide range of redshifts. The lensing estimator is sensitive to these extragalactic foregrounds (see Osborne, Hanson & Doré 2014; van Engelen et al. 2014; Ferraro & Hill 2018), which can be problematic: foreground contamination that has leaked through the lensing estimator can correlate with the galaxy distribution, giving spurious biases to cross-correlation measurements. It is important to mitigate these foregrounds in temperature, as many current- and next-generation lensing maps will still depend to a large extent on temperature data, rather than on polarization. Indeed, for our current data-set, the temperature (TT) lensing estimator still provides the dominant contribution (> 50 per cent) to our minimum variance lensing estimate of equation (8).

One of the primary goals of making a lensing map is to enable cross-correlation science. For low- z large-scale structure tracers, such as the CMASS galaxies used in later sections of this paper, the main contribution to the cross-correlation bias comes from the tSZ contamination of the temperature maps (van Engelen et al. 2014; Madhavacheril & Hill 2018; Baxter et al. 2019). The tSZ is most important because, while the tSZ and the CIB can both be significant contaminants, the CIB only weakly correlates with low- z galaxies (as only a small fraction of the CIB arises from low redshifts).

The observed, SZ contaminated temperature map, denoted $T_{\text{with-sz}}$, now includes an SZ contribution T_{tSZ} , so that $T_{\text{with-sz}} = T_{\text{cmb}} + T_{\text{tSZ}}$.⁶

⁶The observed temperature map clearly also has other contributions in addition to T_{cmb} and T_{tSZ} , but our focus here will be just on these two components.

Figure 2. Map of the reconstructed lensing potential in the D56 region (upper panel) and the BN region (lower panel) after Wiener filtering, shown in greyscale. (The lensing maps shown are the tSZ-cleaned maps combining *Planck* and ACT, although the ACT-only lensing maps appear similar.) Overlaid, we also show contours of an identically filtered but completely independent cosmic infrared background map (*Planck* GNILC 545 GHz). Since the correlation between CMB lensing and the cosmic infrared background (CIB) is very high and since our CMB lensing map has high signal-to-noise ratio on large scales, the correspondence between the lensing potential and the CIB can be seen clearly. Parts of the CIB map contaminated by Galactic dust have been masked in the BN CIB contours for this visualization, using a mask derived from the *Planck* PR2 Commander thermal dust emission map.

When inserting this CMB map into a quadratic lensing estimator $\hat{\kappa}(T_{\text{with-SZ}}, T_{\text{with-SZ}})$ and cross-correlating the resulting lensing map with a galaxy map g , the cross-correlation is now biased by a new bispectrum term of the form $\langle gT_{\text{tSZ}}T_{\text{tSZ}} \rangle$.

For typical cross-correlations, this effect can be significant, giving biases up to a 10–20 per cent level on large scales (Baxter et al. 2019; Omori et al. 2019). The shape of the bias on large scales is typically similar to that of the signal itself; the sign of the effect is generically negative on large and intermediate scales $L < 1000$ (with a positive bias only arising on very small scales), so that a cross-correlation with a tSZ-contaminated lensing map is biased low.⁷

Since low cross-correlations were found in several analyses (e.g. Pullen et al. 2016); it is interesting to consider if this type of contamination could have an impact on previously published cross-correlation measurements. However, we note that most of the analyses with low cross-correlations used *Planck* lensing maps. For *Planck*, such foreground biases are expected to be much less problematic (due to the lower experimental angular resolution).

⁷A physical explanation for this negative bias effect is the following. Consider a direction in which there is a long wavelength overdensity. Due to non-linear evolution and mode coupling, small-scale tSZ fluctuations are also enhanced in this direction, which increases the CMB temperature power at small scales, $l > 2000$. This excess small-scale power is similar in effect to an overall ‘shift’ of the primary CMB towards smaller scales. The lensing estimator interprets this locally as arising from demagnification due to a matter underdensity: cross-correlating this spurious underdensity lensing signal with the distribution of galaxies (which trace the overdensity) therefore results in a negative cross-correlation (van Engelen et al. 2014).

4.1 A new tSZ-free estimator

To account for the potential problem of tSZ contamination, we attempted to use the method of MH18 to remove foreground contamination. However, this method did not perform as well as expected. We therefore developed a new foreground-cleaned lensing estimator, extending and revising the MH18 method; we will explain the relevant details in the following paragraphs.

The basic goal of our foreground-cleaning approach is to remove foreground contamination without assuming a model for the foregrounds’ statistical properties, relying instead on the fact that the foregrounds’ frequency dependence differs from that of the CMB. A simplistic frequency cleaning of the CMB maps, however, typically degrades the lensing signal to noise. MH18 uses the standard lensing convergence quadratic estimator written in real space in a form where a gradient and a non-gradient field can be distinguished (e.g. Lewis & Challinor 2006; Hu, DeDeo & Vale 2007a). Usually, for the temperature quadratic estimator $\hat{\kappa}(T_1, T_2)$, the two fields T_1, T_2 are chosen to be identical. However, one may, of course, use two different CMB temperature maps in the estimator; the two maps could be processed differently or even come from different surveys. In particular, since the spectral energy distribution (SED) of the tSZ effect is known to high accuracy (barring relativistic and multiple-scattering effects), CMB maps made from multifrequency data that explicitly null or deproject the tSZ can be made. Such maps generally have higher noise. In the procedure suggested by MH18, it is pointed out that even if only one of the two fields in the quadratic estimator is free from tSZ, then the resulting lensing map cross-correlation will still have zero tSZ contamination,

while the noise increase due to foreground cleaning will only be moderate (since only one noisy cleaned map is used, instead of two). One way of understanding this is to note that, since the cross-correlation bias arises from a foreground–foreground–galaxy bispectrum $\langle gT_{\text{tSZ}}T_{\text{tSZ}} \rangle$, nulling even one of the foreground fields sets the whole bispectrum $\langle gT_{\text{tSZ}}0 \rangle$ to zero, which gives an effectively bias-free cross-correlation measurement. We denote this foreground-cleaned MH18 estimator as $\hat{\kappa}(T_{\text{no-tSZ}}, T_{\text{with-tSZ}})$ (where the first map is the gradient field in the lensing estimator). Despite the use of a noisier tSZ-deprojected map in one field of the quadratic estimator, the loss in signal to noise in constructing this foreground-free lensing map was claimed in MH18 to be only ≈ 5 per cent.

However, when implementing the MH18 estimator, we found that the actual lensing map noise obtained in both simulations and in data was larger for $L < 800$ (by more than an order of magnitude at $L \approx 100$, see Fig. B1) than the noise forecast presented in MH18. The explanation for this result is the following: in MH18 a simplified formula for the noise forecast was used (namely assuming the noise is equal to the normalization, i.e. $N_L \propto L^2 A_L$); however, this is only valid if the weights in the estimator are minimum variance. As detailed in Appendix B, the MH18 estimator does not use minimum-variance weights, which explains why the true noise we find is larger than the simplified forecast results. We note that the MH18 forecast is however accurate for cluster scales, where the gradient approximation holds in the squeezed limit (Hu et al. 2007a; Raghunathan et al. 2019b).

To solve the problem of increased noise on large scales, we propose a new ‘symmetrized’ cleaned estimator, in which we coadd the $\hat{\kappa}(T_{\text{no-tSZ}}, T_{\text{with-tSZ}})$ MH18 estimator with a version where the two fields have been permuted, $\hat{\kappa}(T_{\text{with-tSZ}}, T_{\text{no-tSZ}})$. In particular, we define $\hat{\kappa}_{\text{symm, tSZ-free}}^{TT} = \sum w_\alpha(\mathbf{L})\hat{\kappa}_\alpha(\mathbf{L})$ with weights

$$w_\alpha(\mathbf{L}) = \frac{\sum_\beta N_{\alpha\beta}^{-1}(\mathbf{L})}{\sum_{\gamma,\beta} N_{\gamma\beta}^{-1}(\mathbf{L})}, \quad (10)$$

where $\alpha \in \{(T_{\text{no-tSZ}}, T_{\text{with-tSZ}}), (T_{\text{with-tSZ}}, T_{\text{no-tSZ}})\}$, and N^{-1} is the inverse 2×2 covariance matrix taking into account the cross-correlation between the two estimators.

The resulting $\hat{\kappa}_{\text{symm, tSZ-free}}^{TT}$ map retains the property that the resulting cross-correlation with large-scale structure is unbiased, but the lensing map now has significantly lower noise: in fact, we find that our method appears to effectively recover the original forecast results of MH18, primarily due to the cancellation of anticorrelated noise on large scales from each of the two terms in the new estimator. Details can be found in Appendix B.

4.2 Application to data

The above technique requires maps of the CMB in which the tSZ signal has been deprojected (i.e. nulled) using multifrequency data. Such maps were presented in Madhavacheril et al. (2020); these maps were constructed by combining *Planck* and ACT⁸ data using an internal linear combination (ILC) algorithm. We use the constrained ILC CMB map (with tSZ deprojection) and the standard ILC CMB map (with no deprojection)⁹ from that analysis as the two input maps for the symmetrized cleaned lensing estimator $\hat{\kappa}_{\text{symm, tSZ-free}}^{TT}$.

⁸Despite including *Planck* data, in these maps, the small-scales relevant for lensing are dominated by the ACT 148 and 97 GHz channels.

⁹We use version v1.1.1 of the maps for which bandpass corrections for the tSZ response may not be accurate at the few percent level at the map-level. However, since the tSZ bias is at most 20 per cent in power, tSZ-cleaned cross-

described above; we thus create new foreground-cleaned temperature lensing maps.^{10,11}

The maximum CMB multipole, $\ell_{\text{CMB}}^{\text{max}} = 3000$, typically used in CMB lensing analysis is motivated by the desire to reduce contamination from foregrounds such as the tSZ. Since the tSZ bias is nulled in this new estimator, it is plausible that this maximum multipole is unnecessarily conservative and can be increased, thus improving the signal-to-noise ratio of the estimator. Motivated by this possibility, we increase our maximum multipole for the tSZ-free TT estimator map somewhat, to $\ell_{\text{CMB}}^{\text{max}} = 3350$; we perform a null test (see next section) to test for problematic contamination from other foregrounds such as CIB or kSZ. (This type of contamination becomes large when we use a higher l_{max} , such as 3500 and 4000, causing null test failures; for this reason, we choose to only modestly increase $\ell_{\text{CMB}}^{\text{max}}$ to 3350.) Furthermore, since the ILC maps include information from *Planck* for $l < 500$, we also relax the minimum multipole cut from $\ell_{\text{CMB}}^{\text{min}} = 500$ to $\ell_{\text{CMB}}^{\text{min}} = 100$, providing additional gains in signal-to-noise ratio.

We then create a foreground-cleaned minimum variance lensing map as in equation (8). The coadding procedure is the same as for the ACT-only lensing map, except that temperature lensing is now obtained from the tSZ-free symmetric estimator $\hat{\kappa}_{\text{symm, tSZ-free}}^{TT}$. We successfully repeat the lensing validation described in Section 3 with our new foreground cleaned estimator; the results are shown in Fig. 1.

5 GALAXY CROSS-CORRELATION MEASUREMENT

In the previous sections, we have introduced two types of CMB lensing maps, which will be publicly available as part of the upcoming data release DR4 associated with Aiola et al. (2020) and Choi et al. (2020). As an example of their utility, we cross-correlate these lensing maps with galaxies from the BOSS survey’s CMASS galaxy catalogue.

5.1 The CMASS galaxy map

We use the CMASS galaxy catalogue (with redshifts $z \in [0.43, 0.7]$) provided by the DR12 release of the BOSS spectroscopic survey¹² to construct a galaxy overdensity map. Given a pixel \vec{x} , we estimate the galaxy overdensity as

$$\delta_g(\vec{x}) = \frac{\sum_{i \in \text{unmasked } \vec{x}} w_i}{\frac{1}{N} \sum_{i, \text{all unmasked}} w_i} - 1, \quad (11)$$

where N is the number of unmasked pixels (see below) and following Pullen et al. (2016) and Miyatake et al. (2017) each galaxy i inside

correlations are only affected at the 1 per cent level, an order of magnitude below the statistical sensitivity of this work.

¹⁰Before applying the lensing estimator to these ILC maps we also inpaint SZ clusters as described for the ACT only maps.

¹¹We note that on CMB small scales ($l_{\text{CMB}} \sim 3000$), our multifrequency cleaning for tSZ deprojection is primarily achieved through the combination of 90 and 150 GHz channels from ACT, as the *Planck* data lacks useful information for $l_{\text{CMB}} > 2200$. In the tSZ deprojected leg, the CMB noise is very high on these small scales, as there are just two useful frequencies, and so we effectively do not use them for lensing reconstruction. Indeed, the gradient cleaning estimator picks most of the information from $< T_{\text{low}} T_{\text{high}} >$, where $l_{\text{CMB,low}} \leq 2200$ and the $l_{\text{CMB,high}}$ can be up to some $l_{\text{CMB,max}}$, e.g. of 3000.

¹²<http://www.sdss3.org/surveys/boss.php>

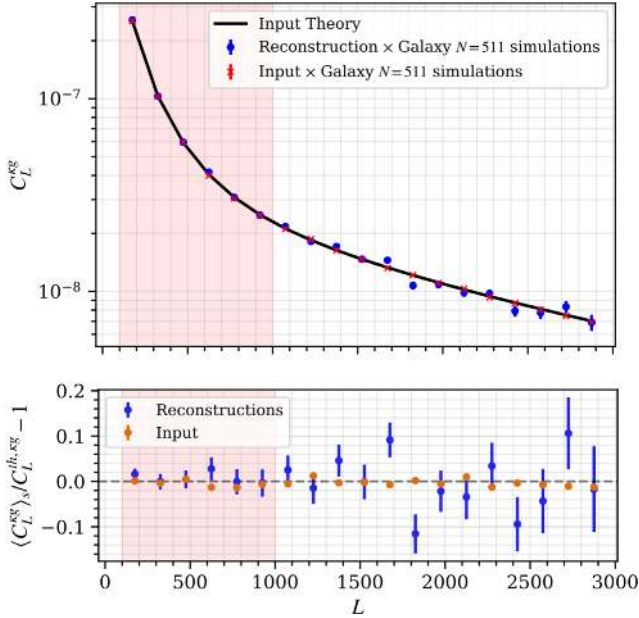

Figure 3. Lensing reconstruction test, as for Fig. 1, but now correlating with a simulated galaxy field instead of the input lensing convergence field. The shaded region shows the multipole range used for the cosmological analysis. The lower panel shows the fractional difference with respect to the theory curve. (The BN patch gives similar results.).

the pixel \vec{x} is weighted according to

$$w = (w_{\text{noz}} + w_{\text{cp}} - 1)w_{\text{see}}w_{\text{star}}, \quad (12)$$

where w_{noz} accounts for redshift failures, w_{cp} for fiber collisions, w_{star} for bright star contamination, and w_{see} for effects of seeing.

The galaxy mask used to mask pixels is created using ‘random catalogues’ provided by the BOSS collaboration; these catalogues contain a dense sampling of sky locations proportional to the survey conditions but not to any cosmological galaxy clustering signal. The random catalogues are mapped to a number density count map (created setting $w = 1$) and then smoothed with a Gaussian beam with a width corresponding to a standard deviation of 2 arcmin. To obtain the final mask, we then set to zero the regions of the smoothed randoms’ counts below a threshold of 10^{-3} . The above choices are made so as to preserve survey information without picking up fluctuations in the random sampling. Our baseline analysis accounts for the effect of this mask simply by applying an overall scaling factor which compensates for the loss in power due to zeroed regions, as described in the next section. In general, the mask can also cause coupling of Fourier modes of the map leading to a modification of the estimated power spectrum. Although these effects are expected to be small since our mask is smooth, we test the impact of the mask on our cross-correlation measurement.

We validate the treatment of the galaxy mask by applying it to mock Gaussian galaxy overdensity simulations which are correlated with the lensing signal according to a theoretical cross-spectrum with a fiducial bias $b = 2$. We verify that the cross-power spectrum measured from these simulations, with a multiplicative correction for the mask as described in the next section, reproduces the original input theory cross-correlation signal. As shown in Fig. 3, we recover C_L^{kg} to better than 5 per cent over the cosmological analysis range, with no indication of an overall bias.

5.2 Extracting power spectra and obtaining the covariance matrix

Having constructed CMB lensing and galaxy maps we measure their cross-power spectra. Binned cross-power spectrum measurements are obtained using the following estimator valid for statistically isotropic fields

$$\hat{C}_{L_b}^{kg} = \frac{1}{w^{kg}} \frac{1}{N_{\mathcal{A}}} \sum_{L \in \mathcal{A}} \kappa_L^{\text{obs}} g_L^{\text{obs}*}, \quad (13)$$

where \mathcal{A} is an annulus in the Fourier plane with average radius $L = |\mathbf{L}|$, $N_{\mathcal{A}}$ gives the number of modes in this annulus, and w^{kg} is a correction factor due to masking that depends on the masked fields taken in consideration. For a slowly varying window function this is given by

$$w^{kg} = \langle W_{\kappa}^2(\vec{x}) W_g(\vec{x}) \rangle, \quad (14)$$

where W_{κ} is the mask we apply to our CMB map before lensing reconstruction, W_g is the mask applied to our galaxy overdensity map, and the average is performed over pixels. Two powers of the CMB mask appear in the correction above because the lensing reconstruction is a quadratic estimator involving two powers of the CMB map.¹³

We obtain the covariance matrix for the cross-spectra from simulations as follows:

$$\hat{C}_{L_b, L'_b} = \langle (C_{L_b}^S - \langle C_{L_b}^S \rangle_S) (C_{L'_b}^S - \langle C_{L'_b}^S \rangle_S)^T \rangle_S \quad (15)$$

where the column power spectrum vector is $\hat{C}_{L_b}^S = (C_{L_b}^{kgS})^T$ and the average is over the simulations S .

To calculate this matrix, we cross-correlate the $N = 511$ lensing reconstruction simulations with the QPM mock catalogues of CMASS galaxies (White, Tinker & McBride 2014).¹⁴ The cosmological signals in these simulations and catalogues are uncorrelated. We expect this not to be problematic because the uncorrelated part of the cross-correlation error dominates over the sample variance contribution. We verify this by calculating Gaussian theory standard errors with and without the $(C_{L_b}^{kg})^2$ sample variance term that arises from the presence of correlated structures, finding sub-percent level agreement between the two calculations.

The inverse covariance matrix obtained from N simulations is calculated as in Hartlap, Simon & Schneider (2007):

$$\widehat{C}^{-1} = \beta \hat{C}^{-1}, \quad (16)$$

where $\beta = \frac{N-p-2}{N-1}$ with p the number of angular bins.

Finally, we note that some care is required when choosing the range of scales $L_{\text{min}} < L < L_{\text{max}}$ which we use in our analysis. Our theoretical model is expected to break down on smaller scales, since we are assuming a simple scale-independent linear galaxy bias, ignoring baryonic feedback on the matter power spectrum and also assuming that the non-linear matter power spectrum derived from HMCode (Mead et al. 2015), implemented in CAMB, is reliable. We therefore initially pick a range of scales based on the cross-correlation measurement; we set the requirement that the difference between a cross-spectrum obtained from linear theory and one obtained from

¹³To avoid confirmation bias we did not plot a y-axis scale or overplot a theory curve over our cross-spectrum measurement until all the null tests and systematics checks, described in Section 6, had been successfully passed.

¹⁴Although more realistic mocks are available, the QPM mocks are sufficiently accurate for our purposes, i.e. to calculate error bars and verify our cross-correlation signal at the 10 per cent level.

Figure 4. The cross-correlation between CMASS galaxies and CMB lensing convergence reconstructions from ACT. The cross-correlation measurements in the D56 and BN patches are coadded to obtain these results. The red points show results using an ACT-only lensing map, the blue points show results using a lensing map that has been tSZ cleaned. The multipole values for different versions of lensing maps are slightly offset for visualization purposes. See Fig. 5 for comparison with a theory curve fit to the cleaned measurement.

a non-linear power spectrum (HMCode), assuming a linear constant bias, should not be larger than the 1σ uncertainty for our cross-spectrum measurement. In this way, we obtain that the appropriate cut-off is approximately $L_{\max,kg} = 1000$.¹⁵

In addition to the small-scale cuts described above, we also wish to avoid systematic errors which enter on large, degree-angular scales. On the galaxy side, such systematic errors include depth and selection function variations over the survey footprint; on the CMB lensing side, the main large-scale limitation is the challenge in simulating and subtracting the mean-field term sufficiently accurately, since it grows rapidly towards very low L ($L < 50$). While many systematics are nulled in cross-correlation, they could induce additional variance, and to be safe we choose $L_{\min} = 100$ for our analysis; at this scale, the power spectrum of the mean field is still smaller than that of the signal.

For our measurements, we choose a binning of $\Delta L = 150$; with this binning, we find that the correlations between different bandpowers are not strong (< 13 per cent).

5.3 Galaxy cross-correlation: results

In Fig. 4, we show the new tSZ-free CMB lensing – galaxy cross-correlation measurement. We also show the same cross-correlation with the ACT-only lensing maps, which have not been cleaned of tSZ.

A small shift between the bandpowers can be seen. It appears to match the form expected from bias due to tSZ in the ACT-only maps, *i.e.* a deficit on large scales and an excess on small scales. However, the difference was not found to deviate from zero by a statistically significant amount, with a χ^2 probability to exceed (PTE) of 0.29 (for the cosmology range). Nevertheless, we note that the difference is a

¹⁵Even if this is beyond the non-linear scale given at redshift $z \sim 0.57$, the mid-redshift of the CMASS catalogue, the relatively large $1 - \sigma$ uncertainty in the cross-correlation at $L \sim 1000$ implies that we are insensitive to the difference between linear and non-linear theory at that scale. Furthermore, as shown in Fig. 5, including wave numbers beyond $L \sim 1000$ only very slightly affects a simple cosmological analysis.

good fit to a simplified foreground bias model (given by a 10 per cent deficit in the cross-correlation at $L < 800$); the χ^2 to this model is lower than for a fit to null by $\Delta\chi^2 = 2.2$.

Although the tSZ-free measurement contains no bias from tSZ, the measurement errors on large scales are similar, which highlights the power of this new technique in providing unbiased measurements that do not sacrifice significant signal-to-noise ratio.¹⁶

We adopt the tSZ-cleaned cross-correlation as our standard analysis. We fit the cross-correlation with a fiducial theory model; this model uses both fiducial *Planck* parameters as well as a fiducial linear bias of $b = 2$, motivated by previous BOSS analyses (Alam et al. 2017). The cross-correlation measurement as well as a fit of the amplitude of this fiducial model are shown in Fig. 5. It can be seen that, for both the restricted analysis multipole range and the full range, the amplitudes obtained are consistent with the fiducial value ($A = 1$). In particular, we obtain $A = 0.92 \pm 0.12$ for a fit to the restricted analysis range and $A = 1.02 \pm 0.10$ for the fit to the full range of scales. Both theory curves are a good fit to the measurements, with χ^2 PTEs of 0.25 and 0.28, respectively. Thus, we find good consistency in both cases with the *Planck*-cosmology derived theory template.

6 SYSTEMATICS AND VALIDATION OF THE CROSS-CORRELATION MEASUREMENT

We perform several tests for systematic errors to validate both our lensing maps and our cross-correlation measurement. Note that the relevant covariance matrices are obtained from Monte Carlo simulations of each test. These covariances are used to derive a chi-squared to null probability to exceed (PTE) for every test.

Our first null test relies on the fact that we expect the cosmological lensing signal from gravitational scalar perturbations to give rise to gradient-like deflections. Hence, this deflection field should be irrotational, with zero curl.¹⁷ In contrast, systematics that mimic lensing can have non-zero curl. Therefore, a detection of a curl signal can be a signature of unknown systematic errors present in our data. By using a quadratic estimator $\hat{\Omega}^{XY}(L)$ similar to that for the lensing potential but with different filters (Cooray, Kamionkowski & Caldwell 2005) (essentially the dot product in the potential estimator is replaced by a cross-product), it is possible to extract the curl signal and cross-correlate it with the BOSS galaxy field. As shown in Fig. 6, this cross-correlation signal is consistent with zero, with a PTE of 0.51 for the tSZ-cleaned lensing cross-correlation. We note that for the ACT-only cross-correlation, the PTE is only 0.05, although this may simply be due to a statistical fluctuation.

As a second test, we cross-correlate the galaxy map of one patch with the lensing convergence map of the other patch¹⁸ and check for consistency with zero. It is very difficult to imagine systematics that

¹⁶The fact that measurement uncertainties do not significantly increase in our method, although it removes foregrounds, is not just due to the inclusion of *Planck* data; indeed, a naive application of the standard quadratic estimator $T_{\text{no-tSZ}} \bar{V} T_{\text{no-tSZ}}$ to tSZ-deprojected ACT+*Planck* maps gives cross-correlation uncertainties that are ≈ 50 per cent larger. *Planck* enables better multifrequency cleaning, rather than adding much raw statistical weight to the ACT maps.

¹⁷The potential cosmological curl signal coming from tensor perturbations at linear order or from scalar perturbations at second order is well below current sensitivity.

¹⁸To perform this correlation, we extend with zero values the maps of the smaller patch, in this case D56, so that the two fields have the same size.

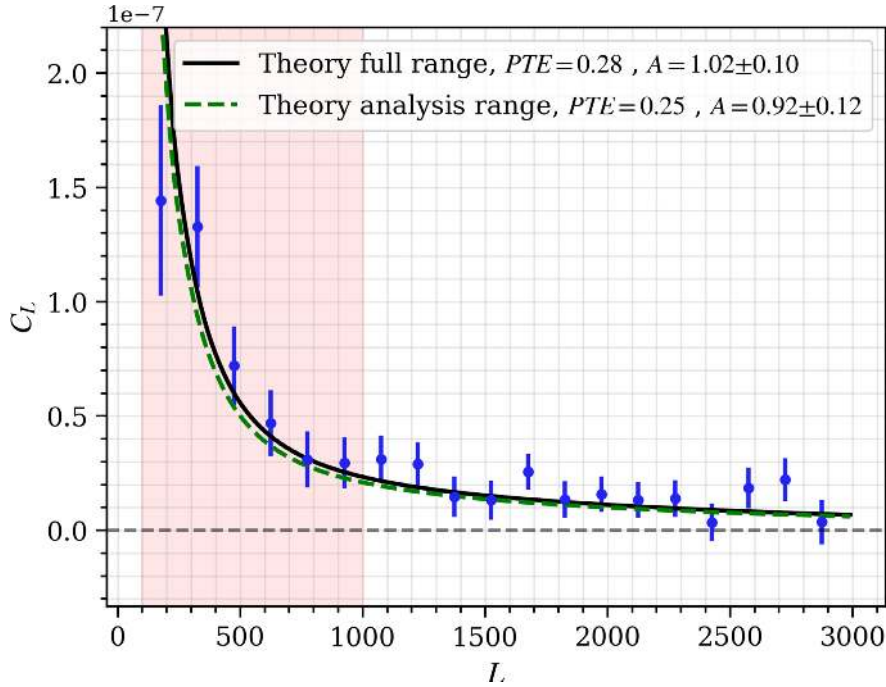

Figure 5. This plot shows our main CMB lensing–BOSS galaxy cross-correlation measurement with the ACT+*Planck* tSZ free lensing maps (blue points). A *Planck*-cosmology (and fiducial galaxy bias $b_{\text{fid}} = 2$) theory template, with a free amplitude fit to the data ($A = b/b_{\text{fid}}$), is also indicated with a dashed line. The green dashed theory curve is fit only over a restricted analysis range (shaded region for scales $100 < L < 1000$); the black solid curve is fit over the full L range shown in this plot. (The bandpowers are nearly independent, with the off-diagonal elements of the covariance matrix showing correlations of less than 13 per cent). We find good consistency in both cases with the *Planck*-cosmology derived theory template.

Figure 6. A curl null test: verification that the extracted curl-lensing – galaxy cross-correlation, which should be negligibly small in the absence of systematic errors, is consistent with the null hypothesis. The results shown are for a combination of both D56 and BN patches. The χ^2 probability-to-exceed (PTE) for this null test is also shown in the legend.

would correlate fields that are so far apart, and so this test primarily serves as a validation of our covariance matrix and uncertainty calculation. In Fig. 7, we see that the results of this null test are consistent with zero, with a PTE of 0.75 obtained for the tSZ-cleaned lensing map and 0.12 for the ACT-only map.

Thirdly, we wish to test for the presence of residual foreground-induced bias in the cross-correlation measurement, even though we expect to be insensitive to the dominant tSZ contamination when using our symmetric cleaned lensing estimator. To test for residual foreground biases from the CIB, kSZ (e.g. Ferraro & Hill

Figure 7. A null test verifying that cross-correlating the lensing map on one field with the galaxy map on the other field (and combining both spectra) gives a signal consistent with zero. Red points show ACT-only results, blue points show tSZ-deprojected lensing results. The fact that the PTEs in both cases are consistent with zero signal supports the conclusion that our uncertainty calculations are correct.

2018), or other sources (including those arising from incomplete tSZ cleaning), we make use of the fact that foreground contamination should become worse as the maximum CMB multipole $\ell_{\text{CMB,max}}$ used in the lensing reconstruction increases. If our foreground cleaning is working as expected and residual foregrounds are negligible, results with a high $\ell_{\text{CMB,max,high}}$ and a lower $\ell_{\text{CMB,max,low}}$ used in the reconstruction should be consistent. In Fig. 8, we show this foreground null test for the symmetric cleaned estimator; in particular, we plot the difference $C_L^{\text{low},g} - C_L^{\text{high},g}$ of the cross-correlation

Figure 8. An extragalactic foreground null-test for the cleaned maps. We show the difference between the cross-correlations of CMASS with the tSZ-deprojected lensing maps for the cases of $l_{\text{CMB,max}} = 3000$ and $l_{\text{CMB,max}} = 3350$, where $l_{\text{CMB,max}}$ is the maximum CMB multipole used in the lensing reconstruction. Since extragalactic foregrounds rise rapidly towards high l , a substantial foreground residual in the cross-correlation would cause a null test failure. However, our null test results shown here are consistent with zero contamination for both fields (blue: points for BN, orange: points for D56).

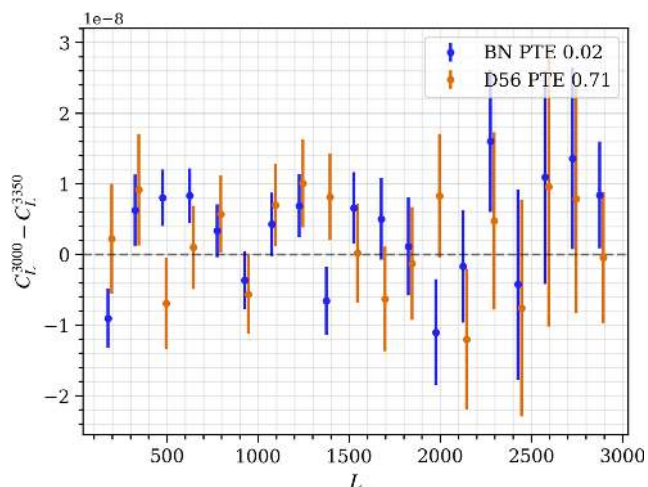

Figure 9. The same test as shown in Fig. 8, but applied to the ACT-only maps which have not been foreground cleaned (blue: points for BN, orange: points for D56). The PTE for BN shows a (mild) failure of the null test, as is expected if foreground residuals are important.

$C_L^{K_{\text{high}}^g}$ with a higher lensing reconstruction $l_{\text{CMB,max,high}} = 3350$ (the baseline used in this work) and the cross-correlation with a lower $l_{\text{CMB,max,high}} = 3000$, $C_L^{K_{\text{low}}^g}$. It can be seen that this difference is consistent with zero overall, with PTEs of 0.74 and 0.16 found for D56 and BN, respectively. The error bars are obtained from simulations and hence take into account the covariance between the two spectra. For comparison, in Fig. 9, we perform the same test for the ACT-only maps which are not free of tSZ; perhaps unsurprisingly, we find a (mild) null test failure (PTE of 0.02)

for the BN patch, although the D56 PTE of 0.71 still appears acceptable.¹⁹

Finally, to check for sensitivity to large-scale systematics, we vary the lowest multipole L_{min} of the first bandpower of the cross-correlation measurement; we find that the value of the first bandpower is stable. This was the only null test done after we unblinded.

Our suite of null tests does not show evidence for foreground or systematic contamination to our measurement, as long as we use the symmetric cleaned lensing estimator. In particular, for the combined BN+D56 cleaned measurement we find a PTE of 0.28 for the foreground residual test, showing no evidence for foreground contamination in the cross-correlation.

7 DISCUSSION

In this paper, we present maps of CMB lensing convergence derived from ACT observations made in 2014–15. The lensing maps are constructed in two different ways: first, by applying the standard quadratic lensing estimator to only ACTPol CMB data; secondly, by implementing a new ‘symmetric’ foreground-cleaned lensing estimator, which makes use of component separated ACTPol+Planck CMB maps to return lensing maps that are free of tSZ-bias in cross-correlation.

We report combined cross-correlation measurements of our CMB lensing maps with BOSS CMASS galaxies at $\approx 10\sigma$ significance. We find that the use of our new tSZ-free estimator does not significantly increase the size of measurement uncertainties.

We will release these lensing maps to enable other cross-correlation analyses with large-scale-structure. However, several caveats should be kept in mind when making use of these maps. Only the bispectrum $\langle gT_{\text{tSZ}}T_{\text{tSZ}} \rangle$ tSZ contamination is nulled in our procedure, where T_{tSZ} is the tSZ signal and g is the large-scale structure field (e.g. galaxy overdensity or galaxy shear); this is the dominant source of contamination for near-term cross-correlations with $z < 1$ structure. Users of these maps should be aware that high-redshift cross-correlations can be contaminated with the CIB field T_{CIB} , both through $\langle gT_{\text{CIB}}T_{\text{CIB}} \rangle$ as well as through its correlation with the tSZ $\langle gT_{\text{tSZ}}T_{\text{CIB}} \rangle$. For cross-correlations where CIB contamination is more of a concern than tSZ contamination (e.g. for cross-correlations with the CIB itself), our pipeline allows the application of the analogue of our symmetric cleaned estimator on CIB-deprojected maps from Madhavacheril et al. (2020). Such analyses should be validated on realistic simulations (e.g. Sehgal et al. 2010; Stein et al. 2020) to verify that the tSZ contamination is sub-dominant. Looking beyond the 2014 and 2015 data used in this work, high-resolution 230 GHz data collected with the Advanced ACTPol instrument from 2016 and onward should allow for simultaneous deprojection of both the tSZ and CIB contamination for use in symmetric cleaned estimators that are robust at all redshifts. The contamination from the kSZ will, however, remain, since the kSZ has the same blackbody frequency spectrum as the primary CMB, although the contamination is much lower in amplitude (Das et al. 2011; Ferraro & Hill 2018). Alternatives to our method include shear-only reconstruction (Schaan & Ferraro 2019) (which requires the inclusion of smaller scales in the CMB map to achieve similar signal-to-noise ratio) and source hardening (Osborne et al.

¹⁹The fact that only one patch shows a null test failure does not have a clear explanation, although it may reflect the fact that our measurement errors are still fairly large compared to the foreground biases (and so fluctuations can be expected).

2014) (primarily targeted at reducing contamination from point sources and clusters). The optimal combination of all of these methods that minimizes bias (both from foregrounds and higher order effects) and maximizes signal-to-noise ratio remains an open problem.

We also caution users that the autospectrum of the lensing potential presents a much broader set of analysis challenges, both for mitigation of foregrounds (where the CIB contamination is expected to be larger van Engelen et al. 2014) and for characterization and subtraction of reconstruction noise bias. The latter requires an extensive set of simulations (e.g. Story et al. 2015; Sherwin et al. 2017) and methods robust to mismatch of simulations and the observed sky (e.g. Namikawa et al. 2013). The CMB lensing autospectrum from ACT data from 2014 and 2015 will appear in a separate work. In addition, care should be taken when attempting to interpret the signal from stacking massive clusters on our released CMB lensing maps; first, because inpainting and masking steps can introduce complications, and secondly, because higher order effects can bias the standard quadratic estimator near the most massive clusters (Hu et al. 2007a).

This work lays the foundation for upcoming, higher precision ACTPol and Advanced ACT cross-correlations with galaxy and lensing surveys. For upcoming cross-correlation analyses with ACT and other experiments, powerful methods to obtain foreground free measurements are necessary; our work represents one promising solution to this problem.

ACKNOWLEDGEMENTS

We thank Shirley Ho, Alex Krolewski, Will Percival and Anthony Pullen for useful discussions regarding the BOSS survey. Some of the results in this paper have been derived using the healpy (Zonca et al. 2019) and HEALPIX (Górski et al. 2005) package. This research made use of Astropy,²⁰ a community-developed core Python package for Astronomy (Astropy Collaboration 2013; Price-Whelan et al. 2018). We also acknowledge use of the matplotlib (Hunter 2007) package and the Python Image Library for producing plots in this paper, and use of the Boltzmann code CAMB (Lewis, Challinor & Lasenby 2000) for calculating theory spectra.

APPENDIX A: CMB MAP PRE-PROCESSING FOR LENSING RECONSTRUCTION

In this appendix, we describe in more detail the pre-processing of the ACT CMB maps which are used in the lensing reconstruction process.

The ACT raw maps are made available as four map splits $D_{A,f,j}$, $j \in \{1, 2, 3, 4\}$ with the same signal but independent instrumental noise contributions through the time-interleaved splitting scheme described in Aiola et al. (2020) and Choi et al. (2020), for each frequency f and instrumental array A . For the D56 region, data are from seasons 2014 and 2015 and observations of the sky are made from the following combinations of array-frequency (A, f) : (PA1-2014, 150), (PA2-2014, 150), (PA1-2015, 150), (PA2-2015, 150), (PA3-2015, 150), (PA3-2015,98), where only the dichroic PA3 array includes observations at both 98 and 150 GHz. For the BN region, the data are from season 2015 only, for the combinations (A, f) : (PA1-2015, 150), (PA2-2015, 150), (PA3-2015, 150), and (PA3-2015,98). Here, (PA3-2015,150), for example, corresponds to a map made using measurements from the 150-GHz channel of the PA3 detector array collected during the 2015 observing season.

The temperature maps that enter the ACT + *Planck* tSZ-free lensing maps are pre-processed and coadded (with appropriate tSZ deprojection) as described in Madhavacheril et al. (2020). All other maps (i.e. temperature maps for the ACT-only lensing maps and the polarization maps) are pre-processed and co-added as follows:

(i) To reduce noise and bias from radio sources and to make subsequent Fourier transforms well-behaved, we use source subtracted maps (see Aiola et al. 2020; Choi et al. 2020). Some residuals are left in these at the locations of bright compact sources; these are in-painted within each split using the catalogue and maximum-likelihood method described in Madhavacheril et al. (2020), i.e. we fill holes around compact sources with a constrained Gaussian realization. These holes of 6 arcmin radius are inpainted jointly for T, Q, and U. The algorithm used follows the brute-force approach presented in Bucher & Louis (2012). We then use these splits to obtain a co-added map $D_{A,f}$ using maps of the inverse white-noise variance in each pixel as well as two sub-splits $D_{A,f,1} = \sum_{j=1,2} D_{A,f,j}$ and $D_{A,f,2} = \sum_{j=3,4} D_{A,f,j}$ with independent noise. We use these two sub-splits to obtain an estimate of the 2d Fourier space noise power spectrum $N_{A,f}(\ell)$, by taking the difference between the mean autospectrum of each sub-split and the mean cross-spectrum between the sub-splits, and subsequently smoothing it.

(ii) We apply an apodized mask to each map which restricts our analysis to the well-crosslinked region used for power spectrum measurements in Choi et al. (2020) and Aiola et al. (2020). To account for pixelization effects, we deconvolve the pixel window function from each map in 2D Fourier space.

(iii) We next combine the various maps $D_{A,f}$ into a single CMB map M on which the lensing reconstruction is performed, for each of T , Q , and U . Unlike in previous work where a real-space coaddition was used (Sherwin et al. 2017), we now co-add the maps in 2D Fourier space (since this is more optimal for multifrequency data with different beams) as follows: $M(\ell) = B_{A_c, f_c}(\ell) \sum_{(A, f)} w_{A, f}(\ell) D_{A, f}(\ell) B_{A, f}^{-1}(\ell)$, where

$$w_{A, f} = \frac{N_{A, f}^{-1}(\ell) B_{A, f}^2(\ell)}{\sum_{(A, f)} N_{A, f}^{-1}(\ell) B_{A, f}^2(\ell)} \quad (\text{A1})$$

are normalized inverse variance weights. We note that here a deconvolution of the harmonic space beam $B_{A, f}(\ell)$ is performed for

each array, and finally a convolution to a common map beam $B_{A_c, f_c}(l)$ is reapplied; the choice of this beam does not matter since it is deconvolved later. This weighting scheme ignores correlations of the noise between arrays. Only the dichroic arrays (PA3, 150 GHz) and (PA3, 98 GHz) have substantial (≈ 40 per cent) noise correlations on the scales considered in this work. While this choice of weighting is sub-optimal, on scales where the (98–150) GHz correlation is important, our measurements are dominated by the CMB signal in the 98-GHz frequency and thus neglecting these correlations will not substantially increase the lensing reconstruction noise.

This procedure, performed separately for each of intensity T and the Q and U polarization stokes components, results in coadded CMB maps M_X with $X \in \{T, Q, U\}$. We repeat the same operations above on the sub-splits $D_{A, f, i}$, $i \in \{1, 2\}$ to obtain the corresponding maps $M_{X, i}$, $X \in \{T, Q, U\}$ from which we obtain an estimate of the experimental noise 2D power N_X , $X \in \{T, Q, U\}$ in the same way as described previously. These noise estimates of the co-added maps are used for optimal weighting in the lensing reconstruction.

(iv) While the previously described inpainting procedure removes a large amount of radio source contamination, bright galaxy clusters show up in these maps as decrements due to the tSZ effect. These add both noise and bias to the lensing estimation, and so we next in-paint a catalogue of SZ clusters that have been internally detected. For this catalogue, we use confirmed cluster locations inferred from co-add maps that include data up to the 2018 season. From this catalogue, we select and inpaint all the clusters with a signal-to-noise ratio greater than 5. The inpainting is performed (only in temperature) within circular holes of 5-arcmin radii using the same method as for the compact sources. A small number of clusters near the edge of the mask that caused problems due to the discontinuous boundary were not inpainted. This is expected to have a negligible impact on our analysis as the number of such clusters is very small, with no particularly bright ones among them. After inpainting, we deconvolve by the common map beam chosen above.

The CMB temperature and polarization maps that result from these steps are used (following filtering and $E - B$ decomposition) as inputs to our lensing reconstruction pipeline, described in detail in Section 3.

APPENDIX B: NOISE PROPERTIES OF THE SYMMETRIC FOREGROUND-CLEANED ESTIMATOR

The goal of this appendix is to illustrate the noise properties of the different lensing estimators used in this work, with particular emphasis on the noise of the new symmetric cleaned estimator that is free of tSZ contamination.

Indeed as explained in the main text, if left untreated, the tSZ induced contamination can bias the results of a low- z galaxy – CMB lensing cross-correlation measurement, by 10 per cent. In combination with cleaned multifrequency data, the lensing estimator we propose below can mitigate these biases, leading to a more robust cross-correlation analysis.

The estimated lensing convergence map in real space from a fixed polarization combination XY for CMB maps is (e.g. Hu et al. 2007a)

$$\hat{\kappa}^{XY}(\hat{\mathbf{n}}) = \int \frac{d^2L}{(2\pi)^2} e^{iL \cdot \hat{\mathbf{n}}} \hat{\kappa}^{XY}(L) \quad (\text{B1})$$

with

$$\hat{\kappa}^{XY}(L) = -A_L^{XY} \int d^2\hat{\mathbf{n}} e^{-i\hat{\mathbf{n}} \cdot L} \text{Re}[\nabla \cdot [\vec{G}^{XY}(\hat{\mathbf{n}}) L^{Y*}(\hat{\mathbf{n}})]], \quad (\text{B2})$$

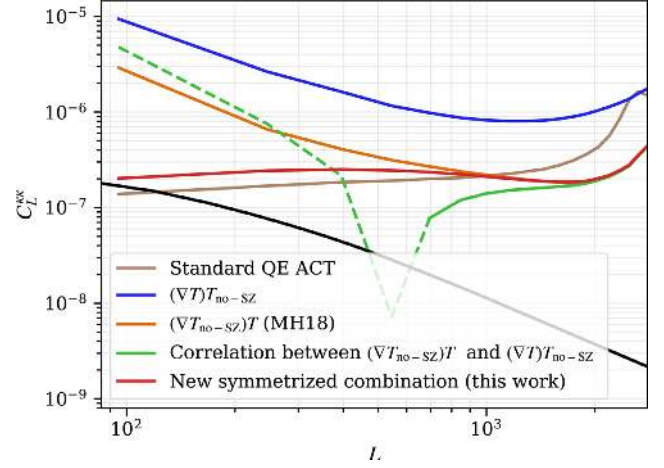

Figure B1. The noise power per mode for the temperature-only estimator for different cases in the D56 region. This plot shows how the symmetric cleaned estimator presented in this work lowers the noise compared to the asymmetric estimator. The green curve shows the cross-noise between the two different asymmetric estimators, with negative values in dashed. The anticorrelation of the noise on large scales between the two different asymmetric estimators leads to a cancellation in the optimal co-add of these that results in the red noise curve for our new symmetric cleaned estimator, which recovers the forecast performance in MH18.

where $XY \in \{T_i T_j, T_i E_j, E_i E_j, E_i B_j\} + i \leftrightarrow j$ with the indices characterizing maps with different data content (e.g. from different experiments or with different component separation techniques), A_L^{XY} is a normalization to ensure that we recover an unbiased estimate of the convergence field, and $\vec{G}^{XY}(\hat{\mathbf{n}})$ and $L^{Y*}(\hat{\mathbf{n}})$ are filtered versions of CMB maps. The details of these filtered maps can be found in Hu et al. (2007a).

The normalization is

$$A_L^{XY} = \frac{L^2}{2} \left[\int \frac{d^2\ell}{(2\pi)^2} (\mathbf{L} \cdot \ell) W_i^{XY} W_{|L-\ell}^Y f_{XY}(\ell, \mathbf{L} - \ell) \right]^{-1}, \quad (\text{B3})$$

where W_i^{XY} , W^X , $f_{XY}(\ell, \mathbf{L} - \ell)$ can be found again in Hu et al. (2007a). The lensing convergence estimator expands to

$$\hat{\kappa}^{XY}(L) = A_L^{XY} \int \frac{d^2\ell}{(2\pi)^2} (\mathbf{L} \cdot \ell) W_i^{XY} X(\ell) W_{|L-\ell}^Y Y(L - \ell). \quad (\text{B4})$$

The covariance of this estimator, $N^{XY, WZ}(L)$ is

$$\begin{aligned} & \langle \hat{\kappa}^{XY}(L) \hat{\kappa}^{WZ}(L') \rangle_{CMB} - \langle \hat{\kappa}^{XY}(L) \rangle_{CMB} \langle \hat{\kappa}^{WZ}(L') \rangle_{CMB} \\ &= (2\pi)^2 \delta_D^{(2)}(L - L') A_L^{XY} A_{L'}^{WZ*} \int \frac{d^2\ell}{(2\pi)^2} (\mathbf{L} \cdot \ell) W_i^{XY} W_{|L-\ell}^Y \\ & \quad \times [(\mathbf{L} \cdot \ell) W_i^{WZ} W_{|L-\ell}^Z C_i^{\bar{X}\bar{W}} C_{|L-\ell}^{\bar{Y}\bar{Z}} \\ & \quad + (\mathbf{L} \cdot (\mathbf{L} - \ell)) W_{|L-\ell}^{WZ} W_i^Z C_i^{\bar{X}\bar{Z}} C_{|L-\ell}^{\bar{Y}\bar{W}}]. \end{aligned} \quad (\text{B5})$$

When the maps involved are identical ($X = Y$, e.g. for TT and EE estimators where both fields have the same data), the minimum-variance filters have a simple form as shown in Hu et al. (2007a) and the estimator can be written in a separable manner (i.e. can be written using sums of products of a function of ℓ_1 times a function of ℓ_2) that allows for fast evaluation with FFTs. Moreover, the estimator variance ($X = Y = W = Z$ above) has a simple relation to the normalization $N_L \propto A_L L^2$. This no longer holds when $X \neq Y$. In particular, for our case of interest where we mix maps with different component separation techniques, $X = T_{\text{no-fg}}$ and $Y = T_{\text{with-fg}}$, the minimum variance estimator does not have a simple

Figure B2. The noise power per mode in our maps for different patches for the minimum variance (temperature + polarization) co-add of the CMB lensing maps from this work. Solid coloured lines represent D56, dashed lines represent BN and dashed and dotted represent *Planck* 2018. The theory expectation for the signal is shown in black. Our maps are signal dominated for $L < 100$ in BN and $L < 200$ in D56.

separable form. MH18 used an approximation to the minimum-variance estimator that consisted of the two different maps being independently Wiener filtered. When the weights in the estimator are not minimum-variance, the relation (assumed in the forecast of that paper) that $N_L \propto A_L L^2$ no longer holds. The true performance is the orange curve in Fig. B1. However, a simple heuristic extension of the MH18 estimator recovers performance close to what was forecast there: the two asymmetric estimators $\hat{\kappa}(T_{\text{no-fg}}, T_{\text{with-fg}})$, $\hat{\kappa}(T_{\text{with-fg}}, T_{\text{no-fg}})$ combined in a minimum variance combination $\hat{\kappa}_{\text{sym,fgfree}}^{TT} = \sum w_\alpha(\mathbf{L}) \hat{\kappa}_\alpha(\mathbf{L})$ with weights given by equation (10), where $\alpha \in \{(T_{\text{no-fg}} T_{\text{with-fg}}), (T_{\text{with-fg}} T_{\text{no-fg}})\}$, and N^{-1} the inverse of the 2×2 covariance matrix taking into account the cross-correlation between the two estimators.

In Fig. B1, we show the noise curves for this TT symmetric cleaned estimator, as well as the asymmetric estimators. In Fig. B2, we show lensing minimum variance noise curves, which include polarization lensing measurements. These are shown for three different cases that differ in how the TT estimator is calculated (a) using the tSZ-free symmetric cleaned estimator with both *Planck* and ACT data combined with ILC (our baseline, in purple) (b) using only ACT data with the $1/N$ co-adding scheme, and no deprojection of foregrounds (red) and (c) using the tSZ-free symmetric cleaned estimator with only ACT data combined with ILC (blue).
