ABSTRACT

We make detailed theoretical predictions for the assembly properties of the Local Group (LG) in the standard Λ cold dark matter cosmological model. We use three cosmological N -body dark matter simulations from the Constrained Local Universe Simulations project, which are designed to reproduce the main dynamical features of the matter distribution down to the scale of a few Mpc around the LG. Additionally, we use the results of an unconstrained simulation with a 60 times larger volume to calibrate the influence of cosmic variance. We characterize the mass aggregation history (MAH) for each halo by three characteristic times: the formation, assembly and last major merger times. A major merger is defined by a minimal mass ratio of 10: 1.

We find that the three LGs share a similar MAH with formation and last major merger epochs placed on average ≈ 10 – 12 Gyr ago. Between 12 and 17 per cent of the haloes in the mass range $5 \times 10^{11} < M_h < 5 \times 10^{12} h^{-1} M_\odot$ have a similar MAH. In a set of pairs of haloes within the same mass range, a fraction of 1–3 per cent share similar formation properties as both haloes in the simulated LG. An unsolved question posed by our results is the dynamical origin of the MAH of the LGs. The isolation criteria commonly used to define LG-like haloes in unconstrained simulations do not narrow down the halo population into a set with quiet MAHs, nor does a further constraint to reside in a low-density environment.

The quiet MAH of the LGs provides a favourable environment for the formation of disc galaxies like the Milky Way and M31. The timing for the beginning of the last major merger in the Milky Way dark matter halo matches with the gas-rich merger origin for the thick component in the galactic disc. Our results support the view that the specific large- and mid-scale environments around the LG play a critical role in shaping its MAH and hence its baryonic structure at present.

Key words: Galaxy: formation – galaxies: haloes – Local Group – cosmology: theory.

1 INTRODUCTION

Observations of the Milky Way (MW) and the galaxy M31 shape to a great extent our understanding of galaxy formation and evolution. In particular, three landmarks have been pivotal in the development of theoretical studies of structure formation: (i) the abundance of MW galaxy satellites that motivated one of the strongest points of tension with the now standard Λ cold dark matter (Λ CDM) paradigm of structure formation (Klypin et al. 1999; Moore et al. 1999); (ii) the

spatial distribution of the same satellites which triggered discussions on how unique the host dark matter halo of the MW is (Metz, Kroupa & Jerjen 2009) and (iii) the measurements of the tidal debris of disrupted merging galaxies around the MW and M31 galaxy, confirming the hierarchical nature of galaxy evolution, one of the fundamental characteristics of Λ CDM (McConnachie et al. 2009). However, inferring general conclusions on galaxy evolution based on observations of these two galaxies requires an assessment on how biased the properties of the MW and M31 are with respect to a given control population.

In the framework of Λ CDM, the study of the MW and M31 starts by modelling their individual host dark matter haloes, *assuming*

*E-mail: jforero@aip.de

that their simulated formation histories are ‘typical’, or at least compatible with the assembly of the real Local Group (LG; de Rossi et al. 2009; Boylan-Kolchin et al. 2010). The basic definition of a LG (in terms of the dark matter distribution) has two basic elements based on the state of the system *today*: (i) the estimated masses of the dark matter haloes corresponding to the MW and M31 (see, for instance, Watkins, Evans & An 2010, and references therein) and (ii) the isolation of these two haloes from other massive structures (Karachentsev et al. 2004). Two additional constraints could be the separation and the relative velocity of the two haloes (Ribas et al. 2005). However, the condition on the LG isolation admits a strict formulation, by requiring that the environment, in terms of the mass and position of the dominant galaxy clusters in the local Universe, be as close as possible to the one inferred from observations. Such an additional condition imposes restrictions on the possible outcomes of structure formation on scales of the order of ~ 5 Mpc. This is considered here as the meso-scale as opposed to the large ($\gtrsim 5$ Mpc) or the small ($\lesssim 1$ Mpc) scales.

The new feature in the analysis presented in this paper is the inclusion of such observational constraints around the LG environment in the initial conditions of the simulation. In a series of three simulations from such initial conditions, in a *Wilkinson Microwave Anisotropy Probe 5* (WMAP5) cosmology with a normalization $\sigma_8 = 0.817$ (Komatsu et al. 2009), we are able to define a sample of three LG dark matter halo pairs that form and evolve under specific conditions reflecting structure of the local Universe. In addition, we will take advantage of one of the largest cosmological simulations carried out to date, the Bolshoi simulation (Klypin, Trujillo-Gomez & Primack 2010), to explore a larger sample of haloes within the mass range of the LG, and calibrate possible cosmic variance effects.

We analyse the constrained simulations with the primary goal of quantifying the assembly histories of the LG haloes. This is driven by two different motivations. One is to find out whether the simulated LGs, that are selected by dynamical considerations pertaining to their redshift zero structure, have mass aggregation histories (MAHs) that lead to the formation of disc galaxies like the MW and M31. The other is to find out whether such a MAH is dictated by meso-scale environment of the LG or whether a random selection of objects similar to the LG is likely to have a similar MAH.

In Section 2 we describe our simulations and the method to reconstruct the MAHs. In Section 3 we describe how we build the different control samples for our statistical analysis. In Section 4 we study the MAHs in the different samples and argue that the selection by different isolation criteria does not induce a strong bias in the statistics describing the MAHs. In Section 5 we discuss the possible origin of these findings and comment on the connection with observations of the MW and M31. In Section 6 we summarize our conclusions.

2 THE SIMULATIONS AND MASS AGGREGATION HISTORIES

In this paper we make use of four cosmological N -body dark matter simulations. Three of them are part of the Constrained Local Universe Simulations (CLUES) project,¹ whose aim is to perform N -body cosmological simulations that reproduce the local large-scale structure in the Universe as accurately as current observations allow. The fourth simulation is the Bolshoi simulation, which was

performed from unconstrained initial conditions and spans a volume ~ 60 times larger than each one of the CLUES simulations. In this section we will describe these simulations and the procedure we have used to construct the MAHs for the dark matter haloes.

2.1 The CLUES simulations

First we describe the procedure employed to generate the constrained initial conditions. The observational constraints are the peculiar velocities drawn from the Mark III (Willick et al. 1997), surface brightness fluctuation (Tonry et al. 2001) and the position and virial properties of nearby X-ray selected clusters of galaxies (Reiprich & Böhringer 2002). The Hoffman & Ribak (1991) algorithm is used to generate the initial conditions as constrained realizations of Gaussian random fields. These observational data sets impose constraints on the outcome of structure formation on scales larger than a few megaparsecs.

These constraints affect only the large- and meso-scales of the initial conditions of the simulations, leaving the small scales essentially random. In particular, the presence of a LG with two dark matter haloes roughly matching the masses, separation and relative velocities of the MW and M31 cannot be constrained. The strategy employed here is to construct an ensemble of 200 different realizations of the constrained initial conditions and simulate these with 256^3 particles on a box with side length $64 h^{-1}$ Mpc using the Tree-PM MPI N -body code GADGET2 (Springel 2005), and then scan these for appropriate LG-like objects within a search box centred on the actual position of the LG. Only three realizations are found to have such a LG object following the criteria detailed at the end of Section 3. It follows that the simulations analysed here obey two kinds of selection rules. By construction, these are constrained simulations whose large- and meso-scales are designed to mimic the local Universe. Then, post-factum, the simulations that have the appropriate LGs are selected for further analysis.

The selected simulations are then resimulated at high resolution of 1024^3 particles. The high-resolution extension of the low-resolution simulation is obtained by creating an unconstrained realization at the desired resolution, fast Fourier transforming it to k -space and substituting the unconstrained low k modes with the constrained ones. The resulting realization is made of unconstrained high k modes and constrained low k ones. The transitional scale happens around the length-scale corresponding to the Nyquist frequency of the 256^3 mesh, $\lambda_{\text{Ny}} = 2 \times 64/256 h^{-1} = 0.5 h^{-1}$ Mpc. This corresponds to a mass scale of $M_{\text{Ny}} \approx 1.2 \times 10^9 h^{-1} M_{\odot}$, below which the structure formation can be considered as emerging primarily from the unconstrained k modes.

The cosmological parameters in these high-resolution simulations are consistent with a WMAP5 cosmology with a density $\Omega_m = 0.28$, a cosmological constant $\Omega_{\Lambda} = 0.72$, a dimensionless Hubble parameter $h = 0.73$, a spectral index of primordial density perturbations $n = 0.96$ and a normalization $\sigma_8 = 0.817$ (Komatsu et al. 2009). With these characteristics, each particle has a mass $m_p = 1.89 \times 10^7 h^{-1} M_{\odot}$.

2.2 The Bolshoi simulation

We have used as well the Bolshoi simulation (Klypin et al. 2010) to verify that the constrained simulation did not bias the halo samples

¹ <http://www.clues-project.org/>

and their MAHs.² The simulation was done in a cubic volume of $250 h^{-1}$ Mpc on a side using 2048³ particles, leading to a particle mass of $m_p = 1.35 \times 10^8 h^{-1} M_\odot$, roughly 10 times lower than the resolution in the CLUES simulations.

We take from the Bolshoi simulation eight non-overlapping subvolumes. Each subvolume has a cubic size of $100 h^{-1}$ Mpc on a side, corresponding to a comoving volume comparable to the three CLUES simulations combined. The halo samples in the subvolumes will be used to calibrate the impact of cosmic variance on the different statistics we use to characterize the halo populations.

2.3 Halo identification and merger tree construction

In order to identify haloes we use a friends-of-friends (FOF) algorithm. We do not include any information of the substructure in each halo. All the analysis related to the MAH is done in terms of the host haloes. In particular, the mergers do not correspond to the fusion of an accreted subhalo with a central dominant host halo, but instead correspond to the moment of two haloes overlapping for the first time.

The FOF algorithm has a linking length of $b = 0.17$ times the mean interparticle separation. The mean overdensity of objects found with this linking length at redshift $z = 0$ is 680 (More et al. 2011). We identify the haloes for 80 snapshots more or less equally spaced over the 13 Gyr between redshifts $0 < z < 7$. All the objects with 20 or more particles are kept in the halo catalogue and considered in the merger tree construction. This corresponds to a minimum halo mass of $M_{\min} = 3.78 \times 10^8 h^{-1} M_\odot$. Within the CLUES simulations a MW-like dark matter halo of mass $\sim 1.0 \times 10^{12} h^{-1} M_\odot$ is resolved with $\sim 5 \times 10^4$ particles, in the Bolshoi simulation it is resolved with $\sim 7 \times 10^3$ particles. For the Bolshoi simulation, we have used snapshots spaced by roughly 400 Myr and followed the exact same procedure to build the halo catalogues and the merger trees.

Within the FOF analysis, all FOF groups with 20 or more particles are identified. The merger tree construction is based on the comparison of the particles in FOF groups in two consecutive snapshots. Starting at $z = 0$ for every FOF group in the catalogue, G_0 , we find all the FOF groups in the previous snapshots that share at least 13 particles with G_0 and label them as tentative progenitors. Then, for each tentative progenitor, we find all the descendants sharing at least 13 particles. Since the smallest FOF groups contain 20 particles, at least two-third of the particles must be identified in tentative progenitors or descendants. Only the tentative progenitors that have as a main descendant the group G_0 are labelled as confirmed progenitors at that level. We iterate this procedure for each confirmed progenitor, until the last available snapshot at high redshift. By construction, each halo in the tree can have only one descendant, but many progenitors.

The mergers of FOF groups correspond to the time where the FOF radii of two haloes overlap for the first time. The infall of the less massive halo into the host and the subsequent inspiral, disruption and fusion will be delayed with respect to the time of the FOF merger. Different theoretical approximations and methodologies can predict the infall-fusion time-scale only as an order-of-magnitude estimate (Hopkins et al. 2010b). The most used time-scale for this process is based on the Chandrasekhar dynamical

friction formula, but improved estimates based on numerical simulations (Boylan-Kolchin, Ma & Quataert 2008; Hopkins et al. 2010b) yield

$$t_{\text{infall}} = 0.56 \left(\frac{R_{\text{vir}}}{V_{\text{vir}}} \right) \frac{(M_{\text{vir}}/M_{\text{sat}})^{1.3}}{\ln(1 + M_{\text{vir}}/M_{\text{sat}})}, \quad (1)$$

where R_{vir} , V_{vir} and M_{vir} are the virial radius, velocity and mass of the host halo, M_{sat} the mass of the future satellite at the moment of infall at R_{vir} . A median initial circularity of the satellite orbit of 0.5 has been assumed. For mass ratios of $M_{\text{vir}}/M_{\text{sat}} = 10$,

$$t_{\text{infall}} = 4.85 \left(\frac{R_{\text{vir}}}{V_{\text{vir}}} \right). \quad (2)$$

2.4 Local Group selection

A LG in a constrained simulation consists of two main haloes within a certain mass range, within a distance range and obeying some isolation conditions.³ In addition, it should reside close to the relative position of the LG with respect to the Virgo cluster. Given the periodic boundary conditions of the simulations and the lack of treatment of the Zeldovich linear displacement in the reconstruction of the initial conditions, the large-scale structure of the simulations is displaced by a few megaparsecs among different realizations of the simulation. The most robust features of the constrained simulations are the Virgo cluster and the Local supercluster. Their positions in the initial conditions are known, at $z = 0$ their environment is searched for haloes in the corresponding mass range to determine their present positions. These are used to fix the ‘position’ of the simulation in relation to the actual universe. In Table 1, we summarize the masses of the MW and M31 haloes identified by the FOF halo finder in these three simulations.

Fig. 1 shows the large-scale structure of the three constrained realizations centred on the position of the LG in each box in a slice $25 h^{-1}$ Mpc thick. In the three CLUES simulations shown in Fig. 1, the projected position of the Virgo cluster is shown by a thick circle. The fourth panel in the same figure shows a cut of the same geometrical characteristics from the Bolshoi simulation, centred on one LG-like object.

2.5 Merger trees description

For each merger tree we define three different times to characterize the MAHs. Each time has direct connection with the expected properties of the baryonic component in the halo. The times, measured as look-back time in Gyr, are given below.

(i) Last major merger time (τ_M): defined as the time when the last FOF halo interaction with ratio 1:10 starts. This limit is considered to be the mass ratio below which the merger contribution to the bulges can be estimated to be < 5 – 10 per cent (Hopkins et al. 2010a). Strictly speaking, as we do not follow substructure in the simulation, this event corresponds to the time when the merger fell into the larger halo and for the first time became a subhalo. One can use equation (2) to estimate the infall time-scale of the satellite to the centre of the host.

(ii) Formation time (τ_F): marks the time when the main branch in the tree reached half of the halo mass at $z = 0$. This marks the

² Halo catalogues for these simulations are available at <http://www.multidark.org/MultiDark/>.

³ A quantitative description of these conditions is presented at the end of Section 3.

Table 1. Properties of the MW–M31 pairs. Column 1: parent simulation; column 2: halo name (either MW or M31); column 3: FOF mass; column 4: last major merger time; column 5: formation time; column 6: assembly time; and column 7: matter overdensity calculated with in a sphere of $5 h^{-1}$ Mpc. All times are look-back times.

Simulation	Halo name	FOF mass ($10^{12} h^{-1} M_{\odot}$)	τ_M (Gyr)	τ_F (Gyr)	τ_A (Gyr)	$\delta_5 + 1$
CLUES-1	M31	1.39	11.0	11.0	11.5	0.72
CLUES-1	MW	0.99	10.0	9.3	9.7	0.69
CLUES-2	M31	0.98	12.0	10.0	10.4	0.78
CLUES-2	MW	0.77	11.3	11.0	11.0	0.87
CLUES-3	M31	1.45	11.0	10.6	11.0	0.75
CLUES-3	MW	1.11	9.8	9.8	11.0	0.80
Average		1.15	10.9	10.3	10.8	0.76
Standard deviation		0.23	0.8	0.6	0.6	0.05

epoch when approximately half of the total baryonic content in the halo could be already in place in a virialized object.

(iii) Assembly time (τ_A): defined as the time when the mass in progenitors more massive than $M_f = 10^{10} h^{-1} M_{\odot}$ is half of the halo

mass at $z = 0$. This time is related to the epoch of stellar component assembly, as the total stellar mass depends on the integrated history of all progenitors (Neistein, van den Bosch & Dekel 2006; Li, Mo & Gao 2008). The exact value of τ_A is dependent on M_f , the specific

Figure 1. Halo distribution in the three CLUES and the Bolshoi (lower right) simulations. Only haloes more massive than $M_h > 2 \times 10^{10} h^{-1} M_{\odot}$ have been included. The radius of each circle corresponds to the radius defined by the FOF algorithm, which is calculated to be the radius of a sphere with an equivalent volume as the FOF group. The dashed circle marks a $5 h^{-1}$ Mpc environment centred in the most massive halo of the LG. The solid thick circle shows the projected position of the halo identified with the Virgo cluster. The cut is $25 h^{-1}$ Mpc thick and is centred at the LG position.

Figure 2. Mass assembly histories of LG haloes in the CLUES simulation as a function of redshift. The solid black line shows the median MAH for all haloes in the CLUES simulations within the mass range $5.0 \times 10^{11} < M_h < 5.0 \times 10^{12} h^{-1} M_{\odot}$, the dashed lines show the first and third quartiles. Also plotted as colour lines are the MAHs for the MW (dotted) and M31 haloes (continuous) in the three constrained simulations. The assembly history for the LG haloes is systematically located over the median values as sign of early assembly with respect to all haloes in the same mass range.

value selected in this work was chosen to allow the comparison of assembly times against the results of the Bolshoi simulation which has a lower mass resolution than the CLUES volumes.

In Table 1 we summarize the values of these three different times for the three pairs of MW–M31 haloes. In Fig. 2 we show the median MAH in the main branch as a function of redshift for haloes in the mass range $5.0 \times 10^{11} < M_h < 5.0 \times 10^{12} h^{-1} M_{\odot}$. Following Boylan-Kolchin et al. (2010), we fit the MAH by a function of the kind

$$M(z) = M_0(1+z)^{\beta} \exp[-\alpha(\sqrt{1+z}-1)], \quad (3)$$

with $\alpha = 4.5$ and $\beta = 2.24$. These values provide a good fit within 2.3 per cent for $z < 7$. In the same figure, we overplot the main branch growth for the six haloes in the three simulated LGs. The MAHs of these haloes are systematically located above the mean, an indicator of early matter assembly with respect to the haloes within the same mass range.

3 SELECTION OF LOCAL GROUPS AND CONTROL SAMPLES

Four different samples of haloes are constructed here, in a nested hierarchy in which the first sample contains the second which contains the third. The fourth sample is the one that includes the three LGs. These are to be used to study how the various criteria employed in constructing the samples affect the MAH of its members. The first three samples are constructed also from the Bolshoi simulation, and are used to look for possible biases in the constrained simulations.

The first sample we define consists of all haloes in the mass range $5 \times 10^{11} < M_h < 5 \times 10^{12} h^{-1} M_{\odot}$ (Watkins et al. 2010). We refer to this set as the *Individuals* halo sample.

The second is a sample of halo pairs. Two haloes, H_A and H_B , from the *Individuals* sample are considered a pair if and only if

halo H_B is the closest halo to H_A and vice versa. Furthermore, with respect to each halo in the pair, there cannot be any halo more massive than $5.0 \times 10^{12} h^{-1} M_{\odot}$ closer than its companion (Karachentsev et al. 2004). We do not apply any further dynamical restrictions. For instance, an element in this sample may be a pair of haloes that are infalling into a cluster and are coincidentally close to each other. We refer to this set as the *Pairs* sample.

The third is a sample of isolated pairs. We construct it by imposing additional conditions on each member of the previous sample. These conditions are defined to obtain a LG-like halo pair according to a series of requirements that follow the lines of Governato et al. (1997), Macciò, Governato & Horellou (2005) and Martínez-Vaquero, Yepes & Hoffman (2007). We will refer to this sample as the *Isolated Pairs* sample. The conditions are the following.

(a) The distance between the centre of the haloes is smaller than $0.7 h^{-1} \text{Mpc}$ (Ribas et al. 2005).

(b) The relative radial velocity of the two haloes is negative.

(c) There must not be objects more massive than either of the LG haloes within a radius of $2 h^{-1} \text{Mpc}$ from each object (Tikhonov & Klypin 2009).

(d) There must not be a halo of mass $> 5.0 \times 10^{13} h^{-1} M_{\odot}$ within a radius of $5 h^{-1} \text{Mpc}$ with respect to each halo centre (Karachentsev et al. 2004).

The final fourth sample contains the three objects that fulfil the criteria of third sample, and are located at about $10 h^{-1} \text{Mpc}$ ‘south’ of the Virgo cluster in the supergalactic plane. This sample is referred to as LG.

We build these three samples both from the CLUES and Bolshoi simulations. A short summary description of each sample is contained in Table 2.

4 RESULTS

The backbone of our analysis is the study of the MAH of haloes in the mass range $(5.0 \times 10^{11} - 5.0 \times 10^{12}) h^{-1} M_{\odot}$. Our results must be described in the six-dimensional parameter space, spanned by the three characteristic times of the two haloes, dubbed as MW and M31. The distribution of τ_M , τ_F and τ_A of the three different samples is studied in Section 4.1, and the possible dependence of these distributions on the ambient density around the LGs and the mass ratio of the MW and M31 members of the LGs in Section 4.2.

4.1 Mass accretion history of the different samples

Fig. 3 presents distribution of τ_M , τ_F and τ_A for the *Individuals* and *Pairs* samples of both the CLUES and Bolshoi simulations. The distribution with respect to the MW and M31 is virtually indistinguishable, and the curves present both haloes. We calibrate the effect of cosmic variance with the $(100 h^{-1} \text{Mpc})^3$ volumes extracted from the Bolshoi simulation. The results are overplotted as thin magenta lines. The distribution of τ_M and τ_F are well within the scatter of the subvolumes, while the τ_A is somewhat out of the range.

We conclude that with respect to the MAH, the constrained simulations are essentially unbiased with respect to the unconstrained one. The interesting fact that emerges here is the haloes in the *Individuals* and *Pairs* samples share the same MAH, as expressed by the three times described here.

Fig. 4 presents the main results of the paper. It shows the distribution of the three times for the different sample of pairs of haloes. The left column is made of three grey-scale maps describing the

Table 2. Names and description of the four samples used to quantify the formation history of the LG haloes. The three first samples are constructed both from the CLUES and Bolshoi simulations. By definition, the LG sample can only be constructed from the CLUES simulations. The size refers to the total number of objects in the corresponding volume (individual haloes or pairs).

Name	Description	Size (CLUES)	Size (Bolshoi)
<i>Individuals</i>	All the distinct haloes in the mass range $5.0 \times 10^{11} - 5.0 \times 10^{12} h^{-1} M_{\odot}$	4278	88 756
<i>Pairs</i>	All the pairs of haloes constructed from the <i>Individuals</i> sample	1101	21 877
<i>Isolated Pairs</i>	Subset from the <i>Pairs</i> sample following some isolation criteria (see Section 3)	85	1785
LG	The three pairs of LG haloes from the constrained simulations	3	–

Figure 3. Fraction of haloes with merger histories described by a MAH with τ_M , τ_F and τ_A larger than a given value. The lines represent different samples. The sample of *Individuals* (dashed) and *Pairs* (thick continuous lines) from the CLUES simulations and the *Pairs* extracted from eight subvolumes in the Bolshoi simulation (thin continuous lines).

number of objects in the *Pairs* sample in the subspace of $(\tau_X^{M31}, \tau_X^{MW})$, where $X = M, F, A$. The shades represent the number of pairs around a given region of parameter space calculated from the *Pairs* samples in the Bolshoi simulation. The three different LG pairs are overplotted as stars.

The right column of Fig. 4 shows the integrated relative distribution of the haloes in the three different times of the *Pairs*, *Isolated Pairs* and LG samples. For the LGs, this is further separated for the MW and M31 haloes. The distribution of the *Isolated Pairs* of the Bolshoi subvolume is presented as well.

Two important comments can be made based on Fig. 4. First, we see that the times in the LGs sample are confined to a narrow range compared to the broad *Pairs* sample. The merger, formation and assembly times in this sample are confined within the range 9.5–12 Gyr. Secondly, from the integrated distribution, we infer that the *Pairs* and *Isolated Pairs* samples are virtually indistinguishable. This implies that the commonly used isolation criteria (Governato et al. 1997; Macciò et al. 2005; Martínez-Vaquero et al. 2007) do not automatically produce the narrow parameter space occupied by the LG pairs.

4.2 The influence of the local matter density and the mass ratio

The *Pairs* and *Isolated Pairs* samples are selected based on isolation and dynamics. The similarity of the distribution of the different MAH times of the different samples motivates us to look for the possible dependence of these distributions on some other characteristics of the three LGs. In particular, the three LGs are found to share the two following properties: the mass ratio between the two haloes and the matter overdensity in a sphere of $5 h^{-1}$ Mpc radius,⁴

⁴ δ_5 has been calculated from the total mass in haloes more massive than $1 \times 10^{10} h^{-1} M_{\odot}$ contained within a sphere of radius $5 h^{-1}$ Mpc centred at the position of each halo.

noted as δ_5 . The values for the halo masses in the pairs and the local overdensities are listed in Table 1 together with the assembly, formation and last major merger times. A series of subsamples of the haloes sample is constructed by requiring that the masses and mass ratios between the pairs are bounded by the LG limits or the values δ_5 . These subsamplings do not bias the LG-like objects towards the region of parameter space defined by the LG sample.

5 DISCUSSION

Three basic facts emerge from the results presented in the previous section: (i) the three LGs share a common formation history, (ii) this formation history is quiet out to at $\approx(10-12)$ Gyr and (iii) none of the selection rules applied here to the pairs of haloes has defined a sample of objects with MAH similar to that of the three LGs. In what follows, we discuss the possible origin and the predictable consequences of these facts.

5.1 On the common formation history

Naively, one might hypothesize that the fact that all three CLUES LGs have a common MAH, as defined here, is consistent with being drawn at random from the sample of pairs, i.e. the range of properties spanned by three random halo pairs can be naturally expected to be narrow. This is the null hypothesis we test now.

What is the probability that three randomly selected pairs have MAHs within the range of properties found for the LG? We compute this probability based on the fraction of haloes in the pair samples that share the LG formation properties.

We define first the minimal subspace that contains the three simulated LGs by providing lower bounds on the different times describing the MAHs. Table 3 lists the minimal last major merger, formation and assembly look-back times, where two options are taken to estimate the minima. The first defines the ‘two sigma’

Figure 4. Left column: joint distributions of three different times (last major merger, formation and assembly) describing the MAHs. Each point in the plane represents a pair MW–M31 with histories described by the time values at that point. Levels in shading coding indicate the number of halo pairs in the Bolshoi simulations in that parameter range. Dark regions represent a high number of pairs. An absolute scaling for this shading can be obtained from the plots presented in the right column. The stars mark the location of the three LG pairs, each one coming from one of the constrained simulations. Right column: integrated probability of these three different MAH times. The continuous black lines represent the results for the *Pairs* sample in the CLUES simulations. The *Isolated Pairs* sample from CLUES is represented by the thick dashed lines. The results from the *Isolated Pairs* samples in eight subvolumes of the Bolshoi simulation are represented by the thin continuous grey lines. The thick continuous lines represent the results for the LG sample. The distributions from the *Pairs* and *Isolated Pairs* control samples are basically indistinguishable. In other words, detailed selection criteria for halo pairs, based on isolation only, do not narrow down significantly the range of dark matter halo assembly properties.

bound, namely the average value minus twice the standard deviation of each time of the six haloes of the three LGs, the second takes the minimum value for each time.

The table provides the fraction of haloes in the *Individuals* sample satisfying each one of the conditions $\tau_X \geq \tau_X^{\text{bound}}$ independently and all of them simultaneously, where $X = M, F$ and A , and the

superscript ‘bound’ denotes the minimal bound of such time. We find that the fraction of *Individuals* in the quiet MAH subspace is $f_i = 0.17(0.12)$ both in CLUES and Bolshoi for the first (second) minima option. If we consider now the haloes either in the *Pairs* or *Isolated Pairs* samples, only a fraction of $f_p = 0.03(0.01)$ pairs are composed of haloes that are both within the LG parameter space.

Table 3. Fraction of haloes/pairs of the different samples with times τ_M , τ_F and τ_A located in the parameter space defined by the minima characteristic times of the LG haloes in the constrained simulations. These minima from the LGs are defined for each τ_X in two different ways: (1) as the mean value minus two times the standard deviation (see Table 1) and (2) as the minimum value of all realizations. These minima times are denoted τ'_X and τ''_X respectively and are presented in the first rows. In the following rows, the first column describes the name and origin of the sample. The three following columns indicate the fraction of the total population with a τ_X larger than the calculated τ'_X or τ''_X (in parenthesis). In the case of pairs samples, we require the times for both haloes to be above the threshold. The last column refers to the three different τ_X being *simultaneously* larger than the corresponding τ'_X (τ''_X).

Sample	$\tau_M \geq \tau'_M$ (τ''_M)	$\tau_F \geq \tau'_F$ (τ''_F)	$\tau_A \geq \tau'_A$ (τ''_A)	$\tau_{M,F,A} \geq \tau'_{M,F,A}$ ($\tau''_{M,F,A}$)
‘Two sigma’ bound	τ'_M (Gyr) 9.3	τ'_F (Gyr) 9.0	τ'_A (Gyr) 9.6	
‘Minima’ bound	τ''_M (Gyr) 9.8	τ''_F (Gyr) 9.3	τ''_A (Gyr) 9.7	
CLUES <i>Individuals</i>	0.24 (0.18)	0.29 (0.24)	0.85 (0.85)	0.17 (0.12)
CLUES <i>Pairs</i>	0.06 (0.03)	0.09 (0.06)	0.74 (0.74)	0.03 (0.01)
CLUES <i>Isolated Pairs</i>	0.06 (0.03)	0.08 (0.05)	0.70 (0.70)	0.05 (0.03)
Bolshoi <i>Individuals</i>	0.23 (0.19)	0.23 (0.23)	0.87 (0.87)	0.17 (0.12)
Bolshoi <i>Pairs</i>	0.05 (0.04)	0.10 (0.05)	0.76 (0.76)	0.03 (0.02)
Bolshoi <i>Isolated Pairs</i>	0.05 (0.03)	0.10 (0.06)	0.73 (0.73)	0.03 (0.01)

To a good approximation, the pair fraction can be calculated as the individual fraction squared, $f_p \approx f_i \times f_i$. This is the expected result under the assumption that the assembly of the MW and M31 is independent.

The probability of randomly selecting three random halo pairs and having them within the range of parameters defined by the LG can be calculated as $p_{LG} = f_p^3 \approx 2.7 \times 10^{-5} (1.0 \times 10^{-6})$. This small probability is a consequence of having found three halo pairs within a set of properties shared by 0.17(0.12) of the total population of haloes. If we consider pairs with a range of desired properties within shared by, say, 0.68 of the haloes in the total population (the fraction within one standard deviation around the mean), the probability of finding three pairs inside that range would be $p_{1\sigma} (0.68 \times 0.68)^3 \approx 0.1$.

Comparing the results of the probabilities p_{LG} and $p_{1\sigma}$, the null hypothesis can be safely rejected. It is highly unlikely that the three randomly selected pairs show a narrow range of properties as in the case of the LG sample.

Both the *ab initio* and post-factum constraints imposed on the LG yield a LG sample with very similar MAHs. In the CLUES simulations, only the large- and mid-scales are effectively constrained by the data leaving the galactic and smaller scales effectively random. It follows that the MAH of objects similar to the LG is strongly affected by their environment. To what extent this is valid for dark matter haloes in general remains an open question.

5.2 On the quietness of the formation history

We established in the previous sections that the MAHs are quiet out to $\approx(10-12)$ Gyr, and that none of the selection rules applied here to the pairs of haloes has defined a sample of objects with MAH similar to that of the three LGs.

The last point is consistent with the results of previous studies that have approached the same question of estimating a possible bias of the LG with respect to a general halo population (de Rossi et al. 2009; Boylan-Kolchin et al. 2010). These studies apply isolation criteria on scales of $1 h^{-1}$ Mpc over haloes in the mass range we study here, and find as well that no significant bias is intro-

duced in the isolated halo population with respect to the parent halo population.

The parameter subspace defined by the three LGs cannot be explained either in terms of the isolation criteria listed at the end of Section 3 or by adding constraints on the values of the local overdensity on $5 h^{-1}$ Mpc scales. The properties of the dynamical environment, common to all the CLUES simulations and provide the quiet formation history for a LG, remain to be found. Ideally, that result should be expressed in a suitable form to search for LG pairs in an unconstrained simulation.

Is the observed LG biased in the same manner? We cannot provide the answer to that question with the simulations we present in this paper. None the less, the theoretical predictions we show here for the dark matter assembly in the LG seem to be in agreement with the disc-dominated morphology of MW and M31.

5.3 The connection with the observed Local Group

The most distinct feature of the MW and M31 is that both galaxies have a disc-dominated morphology. It is often mentioned that abundant mergers, which are presumed to destroy the disc and be source of morphological change, are expected on all mass scales in the hierarchical picture of galaxy formation of Λ CDM generating a possible contradiction with the abundance of disc galaxies in the local Universe and, in particular, with the fact that the MW and M31 are disc galaxies (Toth & Ostriker 1992; Quinn, Hernquist & Fullagar 1993; Kazantzidis et al. 2008).

Our results provide new theoretical evidence that the MW and M31 could be expected to be disc-dominated galaxies in Λ CDM. From the results presented here, we have found that the last merger started on average 11 Gyr ago. At these redshifts, the mass of the MW host halo is $1-4 \times 10^{11} h^{-1} M_\odot$, its virial velocity is $\approx 200 \text{ km s}^{-1}$ and its virial radius $\approx 0.1 h^{-1}$ Mpc. Using these quantities and equation (2), we estimate the final infall time for the satellite to be ≈ 3.5 Gyr, reaching the centre ≈ 7.5 Gyr ago. This quiet history should favour the survival of a disc formed in the halo (Guedes et al. 2011). Although, detailed estimations on these matters might have to include the inflow of gas into the disc (Scannapieco et al. 2009).

A distinct and well-characterized feature of the MW is the thick disc. This disc component of the MW has been known for more than 25 years (Gilmore & Reid 1983). The thick disc contains a population of stars with different kinematics, spatial distribution, ages and chemical enrichment compared to the thin galactic disc. Although M31 seems to have a similar component (Collins et al. 2011), the observational and theoretical work on the MW's thick disc has a long history, and its origin can therefore be discussed in greater detail. One of the possible formation scenarios for the MW thick disc is an *in situ* formation during/after a gas-rich merger (Sales et al. 2009). The analysis of the orbital eccentricity of stars based on Radial Velocity Experiment Survey (RAVE) and Sloan Digital Sky Survey data supports the gas-rich merger mechanism (Dierickx et al. 2010; Wilson et al. 2011). In our results, the last merger reaches the centre ≈ 7.5 Gyr ago, close to the look-back time of 8 Gyr as required by the *in situ* formation scenario.

6 CONCLUSIONS

We use constrained simulations of the local Universe to study the dark matter MAH of the LG. Two basic questions motivate this study. (1) To what extent the simulated LGs can account for the observed structure of the MW and M31 galaxies? Namely, if the disc-dominated morphology implies that the MW and M31 haloes had a quiet MAH over the last ≈ 11 Gyr, can simulations recover this recent quiet history? (2) Does this quiet MAH arise from the intrinsic properties of the DM haloes, or is it induced by environment within which the LG is embedded? Is the implied MAH of the LG triggered by the large- and meso-scales, or is it induced by the small, i.e. galactic and subgalactic, scales?

The methodology adopted here is to use constrained simulations of the local Universe, designed to reproduce the large- and meso-scales of the LG environment, and search for haloes that resemble the actual LG. The identification of a pair of haloes as a LG-like object is based on a set of isolation and dynamical criteria, all formulated by their redshift zero structure, in complete ignorance of their formation history. A LG-like object that is found close to the actual position of the observed LG with respect to the large-scale structure environment is defined here as a LG. By construction, a constrained simulation can have only one LG or none at all. Indeed, out of a suit of 200 constrained simulations only three harbour a LG. Controlled samples of individual haloes and pairs have been constructed as reference samples. The analysis has been extended to the unconstrained Bolshoi simulation that is used here for an unbiased reference (Klypin et al. 2010).

The construction of the identification of the three LGs is done independently of the MAH of the haloes. Yet, the MW's and M31's haloes of the three LGs all have a common quiet MAH, defined as having the last major merger, formation and assembly look-back time extending over $\approx (10-12)$ Gyr. This quiet formation history of the simulated LGs can help to explain the disc-dominated morphology of the MW and M31, adding evidence to the internal instability origin of the spheroidal component of the MW (Shen et al. 2010). Based on measurements of the eccentricity of orbits in the MW, it has been recently claimed (Sales et al. 2009; Dierickx et al. 2010; Wilson et al. 2011) that a rich merger taking place 10.5–8 Gyr ago is a favoured mechanism to explain the thick disc in the MW (Brook et al. 2004). Our finding of a quiet MAH of the LG provides a suitable platform for such a process to take place.

The LG haloes are assumed here to be selected from FOF haloes in the mass range $5 \times 10^{11} < M_h < 5 \times 10^{12} h^{-1} M_\odot$ at $z = 0$. Between 12 and 17 per cent of these haloes are found to have a quiet

MAH, depending on the detailed definition of the quiet parameter space. From this point of view, the MW and M31 haloes are not rare. However, how likely is a pair of haloes to have such a quiet history, shared by both haloes? Making the naive null assumption that the MAH of a halo is an intrinsic property of a halo independent of its environment, the fraction of pairs should be the product of the fractions for a single halo. Indeed, the *Pairs* sample drawn out of the Bolshoi simulation confirms this assertion, finding that between 1 and 3 per cent of the pairs have as quiet an MAH as the LG systems do. The probability of selecting three pairs randomly and finding them with a quiet MAH is on the order of $\sim 10^{-5}$.

Next, we look for what dynamical or environmental property determines the MAH of a LG-like object. We find here that the mere pairing of the MW-like haloes does not affect the MAH fiducial times. Imposing the isolation and dynamical constraints that define the *Isolated Pairs* sample does not affect it either. This leaves us with an open question as to what determines the MAH of halo pairs similar to the LG. The one hint that we have is that all of the three LGs reside in the same large- and meso-scale environment. We speculate that the cosmic web plays a major role in shaping the MAH of LG-like objects, although it is not yet clear what mechanism is responsible. A larger sample of constrained LGs is needed to confirm and further explore the reasons behind this result.

ACKNOWLEDGMENTS

We acknowledge stimulating discussions with Cecilia Scannapieco and Noam I. Libeskind. YH has been partially supported by the ISF (13/08) and the Johann Wempe Award by the AIP. We acknowledge the use of the CLUES data storage system EREBOS at AIP. GY would like to thank the MICINN (Spain) for financial support under project numbers FPA 2009-08958, AYA 2009-13875-C03 and the SyeC Consolider project CSD 2007-0050. The simulations were performed at the Leibniz Rechenzentrum Munich (LRZ) and at Barcelona Supercomputing Center (BSC). We thank DEISA for giving us access to computing resources in these through the DECI projects SIMU-LU and SIMUGAL-LU.
