Sophisticated techniques of archaeological survey, including airborne imaging spectroscopy, electromagnetic induction and ground-penetrating radar, are opening up new horizons in the non-invasive exploration of archaeological sites. One location where they have yielded spectacular results is Carnuntum in Austria, on the south bank of the Danube, capital of the key Roman province of Pannonia. Excavations in the late nineteenth and twentieth centuries revealed many of the major elements of this extensive complex, including the legionary fortress and the civilian town or municipium. Excavation, however, is no longer the only way of recovering

and recording the details of these buried structures. In 2011, a combination of non-invasive survey methods in the area to the south of the civilian town, where little was visible on the surface, led to the dramatic discovery of remains interpreted as a gladiatorial school, complete with individual cells for the gladiators and a circular training arena. The combination of techniques has led to the recording and visualisation of the buried remains in astonishing detail, and the impact of the discovery is made all the greater by the stunning reconstruction images that the project has generated.

Introduction

In September 2011 the discovery of a gladiatorial school (*ludus gladiatorius* or simply *ludus*) at Carnuntum was announced to the public by the Ludwig Boltzmann Institute for Archaeological Prospection and Virtual Archaeology (LBI ArchPro) and its international partner consortium (Neubauer & Seren 2012: 4). This unique discovery was enabled by systematically applying a multi-disciplinary approach based on remote sensing and high-resolution near-surface geophysical prospection (Neubauer 2011; Neubauer *et al.* 2012). The foundations of a large buried building complex, including a circular training arena, cell blocks, training and assembly halls, infrastructure, practice fields, a bath complex and an administrative wing were mapped in three dimensions in unprecedented detail. The completeness of preservation of this gladiatorial school at Carnuntum is considered unique in the entire former Roman Empire. This paper presents the first detailed description of the non-invasive techniques applied and provides a first archaeological interpretation of the newly discovered monuments.

The archaeological landscape of Carnuntum

Approximately 40km south-east of Vienna on the southern bank of the River Danube, the site of Roman Carnuntum (Figure 1) constitutes the largest archaeological landscape in Austria and has been investigated by archaeologists for more than a century (Doneus *et al.* 2001). Roman Carnuntum was located on slightly undulating fluvial gravel terraces that were covered at the end of the Weichselian glacial period by aeolian loess deposits with a variable but generally limited thickness (Saey *et al.* 2013). The Danube flows from west to east, cutting through the foothills of the Carpathian mountain ridge at the eastern limits of the site, and the local landscape characteristics are largely determined by the river. At present, the main soil type of the area is classified as a calcic chernozem (Neubauer *et al.* 2002). The central archaeological zone of Carnuntum covers an area of approximately 650ha between the modern villages of Petronell-Carnuntum and Bad Deutsch Altenburg.

As the capital of the Roman province of Pannonia, the *Colonia Septimia Aurelia Antoniniana Karnuntum* was an important town on the *limes* during the first four centuries AD. The buried remains consist, to the east, of a legionary fortress with associated auxiliary camps, and surrounded by an extensive civilian settlement, the *canabae legionis* (Doneus *et al.* 2013). The western part was dominated by the civilian town with an adjacent *vicus*, the autonomous *municipium Aelium Karnuntum* (hereafter Carnuntum) founded by the emperor Hadrian around AD 124. Systematic aerial photography revealed that numerous *villae* and *vici* were distributed across the hinterland to the south of Carnuntum. Only a few monuments dating to the Roman period survive as upstanding remains above ground, the most prominent being the 'Heathen's Gate', a *quadrifrons* originally 15m high, and an amphitheatre south of the civilian town. The ruins of the latter had been unearthed by excavations in the 1920s. At that time the site had been identified as a municipal amphitheatre (Figure 2).

So far, only small parts of this extended archaeological site and its surrounding landscape have been investigated through archaeological excavations. These were mainly conducted

between the years 1877 and 1913. While Carnuntum was called ‘Pompeii at the gates of Vienna’ in the nineteenth century due to the exceptionally good state of preservation of its ruins, this situation has changed drastically in recent decades. Intensive farming involving deep ploughing for vineyards, coupled with infrastructure development, the construction of new housing estates in the nearby villages, and active looting by treasure hunters has caused a dramatic increase in the irreversible destruction of the archaeological deposits and cultural heritage.

For more than 15 years, this archaeological landscape has been the focus of a large-scale project of archaeological prospection (Neubauer *et al.* 2012). This was initiated by ZAMG Archeo Prospections® and the University of Vienna (Doneus *et al.* 2001; Eder-Hinterleitner *et al.* 2003; Doneus & Neubauer 2005) and continued in 2010 by LBI ArchPro. The main objective of this project is the non-invasive mapping of the Roman landscape (Figure 1) by applying and developing the latest remote sensing and geophysical near-surface prospection methods and technologies for the imaging of buried Roman structures at unprecedented resolution and scale.

The municipal amphitheatre

The western amphitheatre (Figure 2) south of the civilian town was erected outside the *municipium* (Figure 3) in the first half of the second century AD, and was modified many times during later phases, as shown by excavations conducted from 1923 to 1930 (Egger 1926; Miltner 1933). Measuring 126.5m by 111m, the civilian amphitheatre was larger than the corresponding military amphitheatre located next to the legionary fortress to the east. The main entrances of the municipal amphitheatre were located on the northern and southern sides of the building. They were divided by rows of columns or pillars into three passageways. A sanctuary of Nemesis (*Fortuna Karnuntina*) was integrated into the southern entrance area, identified by several inscriptions dedicated to this well-known goddess of the amphitheatre (Egger 1926: 124–28, fig. 44; Hornum 1993: 41, 164–66, nos. 18–20). Visitors could reach the seats by staircases and even stair towers, one of which has been preserved. From the evidence found, spectator seating has been reconstructed as having been up to 25m in height; from this it is estimated that the civilian amphitheatre could host approximately 13 000 spectators. Two small chambers, which have been interpreted as animal cages, were located along the walls on either side of the arena. Despite the early excavations, the surroundings of the amphitheatre remained mostly *terra incognita*. In 1941, during the Second World War, a small-scale excavation was carried out in a building west of the amphitheatre without any results (Kandler 2004: 46). First indications of significant structures located near the amphitheatre came from aerial photographs showing a main Roman road leading from the town towards it, with buildings and memorials along its eastern side, whereas to the west of the road no structures at all were visible.

Integrated archaeological prospection

Repeated aerial reconnaissance flights over Carnuntum in the 1990s showed vague soil and vegetation marks in a field immediately to the west of the amphitheatre, indicating for the

first time the buried remains of buildings. In 2000, the first magnetic survey was carried out to investigate the anomalies observed from the air, using a manually operated five-sensor PICODAS MEP750 Caesium magnetometer system with Picotesla sensitivity (Figure 4B). The magnetometer data, sampled with a spatial resolution of 12.5cm × 50.0cm, revealed traces of the foundation walls of a large trapezoidal building complex, as well as associated infrastructure, such as a main aqueduct belonging to the water supply system of the Roman town. In the same year, a ground-penetrating radar (GPR) survey was conducted using a Sensors & Software pulseEkko 1000 system with 900MHz antennae towed manually in a sledge with 5cm in-line and 50cm cross-line GPR trace spacing.

Magnetometer surveys result in 2D images (Figure 5) representing subtle anomalies in the intensity of the Earth's magnetic field, without direct information about the depth of the buried structures. In contrast, GPR surveys provide detailed 3D information about the approximate depth, shape and location of archaeological structures. The collected GPR data generated equidistant GPR depth-slices (Figure 6), which are 2D data images at certain depth levels displaying considerably more details of the large building complex. Animations of the depth-slices revealed concentric circular structures in the building's courtyard, providing first indications on the function of the large complex.

Figure 4. Geophysical measurement systems used in the detection of the gladiatorial school at Carnuntum: **A)** the MALÅ Imaging Radar Array (MIRA) with $16 \times 400\text{MHz}$ channels spaced at 8cm. Recent technological and methodological advances leading to greatly increased efficiency of archaeological prospection formed the background for a renewed integrated investigation of the area by a multinational team of archaeologists, geophysicists, soil scientists and IT experts from LBI ArchPro and its international partners. In spring 2011, the team started with a high-definition GPR survey of the structural remains, using a MALÅ Imaging Radar Array (MIRA) system in motorised configuration (Figure 4A). This MIRA system consists of $16 \times 400\text{MHz}$ channels with 8cm cross-line channel spacing and possibilities for 4cm or 8cm in-line GPR trace spacing tracked by a real-time kinematic GPS with centimetre accuracy, permitting operating speeds of 12–15km/h (Trinks *et al.* 2010).

The recorded GPR data were processed into depth-slice images (Figure 6) using special imaging software developed by LBI ArchPro in close collaboration with ZAMG Archeo Prospections®. Subsequently, the new GPR results have been complemented by magnetometer data acquired using a novel GPS-tracked motorised 10-sensor Foerster fluxgate gradiometer array (Figure 4D), extending the coverage (Figure 5) of the initial Caesium magnetometer survey area. In collaboration with the research group ORBit from Ghent University, high-resolution electromagnetic induction (EMI) data were acquired in autumn 2011 by successfully employing a novel four-coil DualEM-21S sensor towed by

Figure 5. Magnetogram of the western area around the municipal amphitheatre showing the remains of the gladiatorial school and its surroundings. The prominent winding linear feature indicates a ditch dug for the installation of an aqueduct. As the building complex clearly respects this ditch, it is assumed to predate the construction of the gladiatorial school. An extended refuse dump obvious in the magnetic and radar data at the southern corner of the building proves that the ditch in Roman times was a distinct depression separating the gladiatorial school from the surrounding area of the amphitheatre (graphics: Wolfgang Neubauer and Alois Hinterleitner).

Specimaisa EAGLET system covered the entire city of Carnuntum. Data were acquired in 105 spectral bands ranging from 400nm to 1000nm with a ground-sampling distance of 40cm. During the same AIS flight, high-resolution topographical data were obtained using a Riegl LMS-Q680 airborne laser scanner. Post-processing to georeference and radiometrically calibrate the flight strips was followed by the application of recently developed processing algorithms to extract all archaeologically relevant information (Atzberger *et al.* forthcoming; Doneus *et al.* forthcoming). The processed AIS imagery (Figure 8A) is clearly superior to conventional RGB aerial images (Figure 8B) and enables enhanced archaeological interpretation. The remote sensing and near-surface geophysical investigations were followed up by a field survey using a raster of 10m × 10m in October 2012. The plough soil assemblages were systematically collected over an area of 2.45ha. Preliminary assessment of the collected pottery reveals that the artefacts generally date to the second and third centuries AD. This coincides well with the chronology known from the municipal amphitheatre.

The integration of individual survey methods in combination with a detailed digital terrain model and georeferenced excavation map situates the newly discovered Roman remains and their topographic position in context with the amphitheatre, associated infrastructure and environmental setting. Furthermore, this integrated data set places the whole site within a rough temporal frame. Combining all of the data permitted an integrated

a quad bike and using differential GPS for data positioning and navigation (Figure 4C). The EMI data (Saey *et al.* 2013) provided information complementary to the GPR and magnetic data, because of its simultaneous measurement of the magnetic susceptibility and apparent electrical conductivity of overlapping soil volumes (Figure 7).

In the meantime, LBI ArchPro partner Airborne Technologies conducted an airborne imaging spectroscopy (AIS) survey of Carnuntum. In contrast to the three spectral bands acquired by the earlier conventional aerial photography, AIS typically captures more than 100 small bands of electromagnetic radiant energy per pixel location. The resulting three-dimensional data cube stacks images for every spectral band acquired, forming a spectrally extended version of aerial photography. The dense sampling of the spectral domain allows very subtle soil and vegetation properties to be mapped (Verhoeven & Doneus 2011). On 5 June 2011 an AIS flight conducted with the

GIS-based analysis of the archaeological stratification near the amphitheatre in relation to the underlying geology, the hydrological setting and the geomorphology, notably palaeorelief and pedology. The detailed geophysical and archaeological interpretation of the integrated prospection data, as realised within the GIS, resulted in 2D interpretation maps and a 3D subsurface interpretation model (Figure 9) of the detected remains of the *ludus*. The outstandingly well-preserved architecture was presented through virtual excavation within an integrated 3D data volume produced by high-resolution, non-destructive prospection methods (Ch'ng *et al.* 2011), followed by the generation of a virtual reconstruction model (Figures 10–11 and online supplementary material).

The school of gladiators—archaeological interpretation

The main building complex of the newly detected monument at Carnuntum covers 2800m² located within a walled plot of about 11 000m² west of the municipal amphitheatre and outside the Roman civilian town (Figure 12). The rectangular area is oriented north–south with no adjacent buildings or enclosures detectable outside the enclosed area. At the southern end of the walled area, the main buildings are arranged around a central inner courtyard 1100m² in extent, resulting in a building area of 1700m² (Figure 9). The main architectural

Figure 10. Virtual reconstruction model of the school of gladiators at Carnuntum. View from the north into the courtyard with the training arena (graphics: Michael Klein).

complex had been erected at the highest local elevation, which is formed by a gravel outcrop marking a buried hill left by the meandering Weichselian Danube, as detected by integrating the electrical conductivity (EC) measurements. As this gravel outcrop largely coincides with the location of the building complex, we assume that the Romans selected

Figure 11. Virtual reconstruction model of the school of gladiators at Carnuntum. View from the south (graphics: Michael Klein).

this specific location because it provided a stable and erosion-free foundation. Most of the wall foundations had been dug into the gravel subsoil, except along the northern edge, where a clay overburden was identified by the EC measurements.

The interpretation of this complex as a school of gladiators, a so-called *ludus*, is based on a series of different arguments. First, there is the close topographical relationship to the civilian amphitheatre. Then there is the internal structure that presents specific arrangements which confirm the proposed interpretation.

A single and easily controlled entrance into the complex can be seen on its eastern side, facing the amphitheatre. The walking distance from the gateway to the northern main gate of the amphitheatre is approximately 80m. Access to the walled complex was clearly restricted and may only have been possible through this 2.4m-wide gate. A paved access path 28m long and 2.2m wide and enclosed by walls on both sides incorporates a driveway and a separate path. The walls are interpreted as the base of a portico or canopy. The access path ends at the front gate of the building, leading into the courtyard. No anomalies were discernible to either side, indicating that there were no other permanent structures outside the building complex. The geophysical data indicate that these were garden areas. That to the north is clearly larger and ends at a massive wall separating the buildings from the large enclosed area beyond. The access path ends at a formal entranceway defined by the narrow sides of two rectangular buildings. These two buildings can clearly be discerned in the prospection data to the right and left of the front gate and formed the frontage of the entire building complex. The southern building is in a better state of preservation than the northern building. We interpret this part of the complex as the administrative block and living quarters of the school's owner, the *lanista* (Bomgardner 2000: 33; Meijer 2007). The *lanista* was head of his *familia gladiatoria* with complete legal power over the life and death of the gladiators—unless they were Roman citizens.

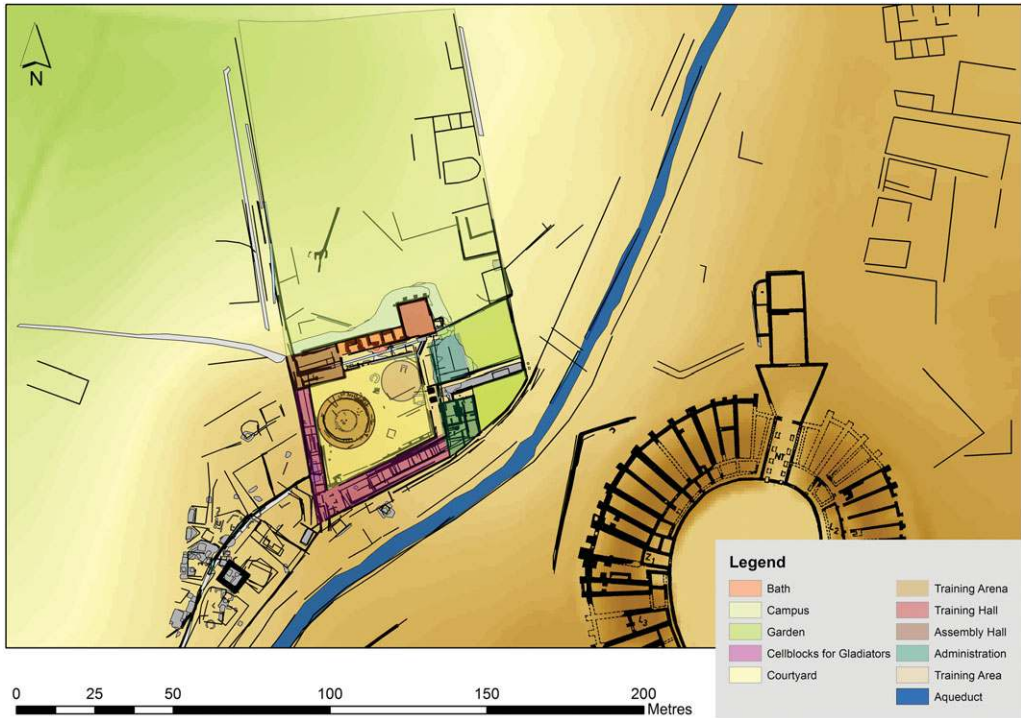

Figure 12. GIS-based archaeological interpretation map of the gladiatorial school at Carnuntum derived from the ground-penetrating radar and magnetic data combined with the topographic model derived from airborne laser scanning (graphics: Wolfgang Neubauer).

Passing through the front gate gave direct admission to the courtyard, via a structure like a triumphal arch clearly discernible as two $4.4\text{m} \times 3.8\text{m}$ -wide foundations. The most prominent feature inside the courtyard is a free-standing circular structure 19m in diameter, which could be interpreted as the training arena for the gladiators. This arena was surrounded by wooden spectator stands set on stone foundations that are clearly discernible in the GPR data. Evidence for a feature resembling a post-hole was recorded by the GPR measurements in the centre of the arena. This might be the foundation of the *palus*, a wooden pole used for exercising blows with the sword and body slams with the shield (Futrell 2006). The training arena and the foundation of the *palus* are the strongest arguments—beside the context and the various findings to be described below—for interpreting the complex as a gladiatorial school. The importance of this pole can also be deduced from the hierarchical system within the *familia gladiatoria*, which was based on a standard ranking system within each armament type, as many gladiatorial epitaphs and commemorative reliefs from across the Empire attest (Carter 2003: 89–93). The ranking was based on the abilities of the gladiators to use a specific type of weaponry in front of the *palus*: *primus palus*, *secundus palus*, etc. (Carter 2003: 93–95; Futrell 2006; Meijer 2007). The division of the gladiators by the use of *pali* facilitated training and instruction specific to the type of armament. The instructors or trainers (*doctores* or *magistri*) specialised, just as the gladiators did, in

a particular armament type. Exceptional gladiators were those who could fight with more than one type of equipment.

The ground of the training arena consisted of gravel covered with sand, featuring a 6.7-m-diameter inner ring delimited by a wall. The function of the inner ring is not immediately clear, but it may have served as the foundation for a portable barrier during training shows involving wild beasts. The spectator stand has a width of 2.4m. Allowing 0.6m for each row of seats, up to four levels can be assumed. The larger foundations in the north-east of the training arena indicate a staircase to access the tiers. The arena had a convergent entrance in the north-west, providing access for the gladiators from a 45m² hall in the north-western corner of the courtyard. This hall had only a front door with a doorsill 0.4m wide and 1.9m long, indicating a massive door frame. No traces of a pavement are visible, and the hall most likely was furnished with wooden flooring. It could be interpreted as the room where the gladiators were equipped with their armament for training or special shows for investors.

The arena abuts the western wing of the building complex, where foundations indicate a special raised area for prominent spectators or high-ranking investors who were selecting gladiators for forthcoming spectacles. The purpose of this training area may have been to provide a private place for a limited audience to inspect new gladiators and their fighting techniques and specific skills. In the north-eastern corner of the courtyard, another circular anomaly discernible in the GPR data suggests an additional training area without spectator stands. The circular layout of the training arena is not one commonly documented in Roman amphitheatre architecture. In addition to the customary elliptical shape of amphitheatres, however, there are a few examples of circular buildings that were probably used for gladiatorial games, both in Italy and in the provinces (Golvin 1988: pl. 20, no. 3; Sommer 2009).

Accommodation for the gladiators was most likely located in the southern and perhaps partly in the western wing of the building complex. As indicated by the foundations, the southern wing had a portico facing the courtyard. The southern wing shows a central row of small cells 3–7m² in area arranged within an elongated cell block (total size 130m²), which could be accessed from the north and south as indicated by the respective corridors. This same design is also found at the barracks at the *ludus magnus*, the gladiatorial school close to the Flavian amphitheatre in Rome. The western wing shows larger paved rooms at the back of the raised viewing area with foundations indicating a staircase and additional cells or rooms in the southern third of this wing. The consistently strong magnetic signal from some of the cell-sized rooms indicates floors covered with small tiles. These rooms were the most elaborate within the western wing of the building, and were most likely reserved for the highest ranking gladiators or the instructors, many of whom probably were drawn from the ranks of senior and ex-gladiators (Carter 2003: 95).

The cell blocks in the western and southern wings are connected by a 90m² corner building with evidence of additional stairways. It was most probably used for instructors or supervisors, other staff and related infrastructure. The corner building was accessible from the courtyard through a door right in the corner of the barracks. The southern barracks of the school and the *lanista's* buildings were at least two storeys high, as indicated by the typical stairway corridors. Assuming a single gladiator inhabiting each of the smallest cells of 3m², and taking into account the two-storey character of the southern gladiator barrack block, an estimated total of 75 gladiators could have been housed within this wing of the *ludus*.

At a distance of 1.2m from the courtyard-facing front of the barracks, a row of rectangular foundations spaced 4m apart was detected. These may be the foundation blocks for memorials. Below the main entrance path in front of the triumphal arch, a 2.8m × 1.5m sunken cell accessible by a ramp or stairs with a height of less than 0.8m was located by the GPR measurements. This sunken cell, constructed without access to daylight and so low that standing was impossible, was probably used for disciplinary measures.

The northern wing of the building complex was accessible from the courtyard through a 1.3m-wide gate leading into a closed compound (570m²) of the school. A massive wall seals off the courtyard from the corridor that gives access to the northern part of the building. This corridor, 3.9m wide and 30m long, was most likely not roofed but had the function of a pathway connecting the three individual parts of the northern wing, which were accessible solely from this corridor.

The most prominent architectural element is a protruding rectangular building or hall with interior dimensions of 8.7m × 10.5m at the north-eastern corner of the complex. Animations of the GPR depth-slices indicate an internal structure of varying shape and irregular distance from the wall, which is caused by a sloping surface interpreted as a collapsed pavement. Collapse to that degree is only imaginable by assuming a corresponding hollow space underneath the pavement. From our experience, this clearly indicates the presence of a hypocaust system for under-floor heating. The large furnace, the 6.5m² *prae-furnium*, can be found on the eastern wall of the hall close to its south-eastern corner. On its northern side, the hall shows four protruding bench foundations supporting the main wall in the area where the EC measurements provided evidence for a clay overburden on the gravel. The necessity for these additional foundations on the softer ground also relates to the exceptional height of the hall. This conclusion is supported by the massive layers of debris found surrounding the hall, caused by the structural collapse of the walls. The entrance is discernible in the middle of the southern wall, connecting the heated hall with the open corridor. As temperatures in winter normally fall to −25°C in combination with strong easterly winds, we interpret this building either as a heated training room or an assembly hall.

A second distinct part of the northern wing is formed by six paved rooms (100m² in area) arranged in a row. The eastern four rooms (78m² in area) seem to be internally connected, forming a functional unit accessible from outside through a door in the middle of the corridor. The second room to the east shows an apse on its southern side, whereas the following room has a bank basement indicating a pool in the north and shows supporting pillars for a heated floor. The apse and this basement are connected with the sewer system, discussed below. On the eastern side of the apse a circular depression for a fountain or well has been detected, providing a direct supply of fresh water for this wing. The massive pavement visible in the GPR data and the typical magnetic anomaly characterising these four rooms indicates they formed another heated part of the building. The apse and the basement seem to have supported water basins. We interpret this part of the building as a bath complex which could have been used by both the gladiators and, during the time when all gladiators were locked in their cells, by the *lanista's* family.

Both of the two adjacent rooms to the west are directly accessible through doors from the corridor, indicating a function distinct from the bath. Another 200m² building was detected

at the western end of the northern wing. Access to this area was possible through a door 1.4m wide at the western end of the corridor. The building shows internal walls forming two larger compartments partly paved at the north-eastern edge. Two adjacent rooms to the west are accessible from the north-western corner of the building complex and from outside the walled compound to the north. Accessible without entering the *ludus* proper, and therefore less isolated, these rooms were probably used as a storage facility.

The gladiators represented a substantial investment for their *lanista*, and they were well cared-for. A high-energy diet, daily massage and high quality medical care were provided alongside the severe discipline and training regime. The discovery and detailed mapping of the *ludus* at Carnuntum proves for the first time that gladiators could recover from the harsh and difficult training in a fully equipped Roman bath. Training carried on throughout the entire year. So far, only the rooms and facilities for medical treatment, a refectory, a kitchen and a latrine are missing from this reconstruction of daily gladiatorial life (Junkelmann 2008). The western part of the northern wing provides the necessary space and infrastructure, as well as the logical configuration, to suggest that these facilities were located within this part of the *ludus*.

The magnetic survey revealed an important aqueduct passing along the south-eastern front of the *ludus*, erected in an artificial channel adapted to cut across the original terrain. A primary water line branched off the aqueduct and conducted the water along a local ridge to ingress through the south-western front of the *ludus*. The water conduits supplying all four wings around the courtyard can be traced inside the building. The sewer system is clearly identifiable in the GPR results, with two drain lines along the western wall of the *campus* and another passing below the corridor of the northern wing. The second and wider sewer crosses the north-western corner building running directly beneath a rather wide wall, hinting at the position of the latrines. This conduit had a large waste and rainwater inlet draining the courtyard at the north-eastern corner. To the east of the main door into the southern barracks it is possible to discern another isolated foundation, which is connected by a linear anomaly to the fresh water line entering the western wing. It is most likely the footing for a fountain.

To the north-west and within a further walled compound an extended open *campus* adjoins the school.

In the immediate vicinity of the *ludus*, spatially segregated from other burial grounds at Carnuntum, we discovered what is probably the cemetery of the gladiators, immediately behind the building complex, with large burial monuments, stone sarcophagi and other, simpler graves. This area is still under investigation and more details will be presented in a future paper on the *ludus* at Carnuntum. That will include studies on parts of a gladiatorial helmet and other (non-military) weapons, discovered in 1901 in Aequinoctium-Fischamend, some 18km west of Carnuntum, which were found in an area used as a graveyard (Groller 1903: 40–48, figs. 18–19).

Conclusions

Given its state of preservation, dimensions and architecture, the newly discovered *ludus* at Carnuntum is considered to be unique. Although it is estimated that over 100 *ludi* must

have been built throughout the Roman period (Meijer 2007), most of them have been destroyed or covered over. The only known building directly comparable to the find made in Carnuntum is the partially excavated *ludus magnus* behind the Coliseum (*Amphitheatrum Flavium*) in Rome (Colini & Cozza 1962). Unlike the new discovery, the *ludus magnus* is only partly accessible today and fewer details have been preserved. The housing of gladiators in Pompeii can hardly be compared with the Carnuntum *ludus*. The so-called *caserma dei gladiatorum* at Pompeii seems to be the location for a small private *familia gladiatoria*, far away from the amphitheatre, whereas the gladiatorial training area in the so-called *Quadriporticus* is interpreted as an evacuation quarter after the Pompeii earthquake of AD 62 (Golvin 1988: 149–54; Jacobelli 2003: 65–68, figs. 54–55).

The unique archaeological discovery of a *ludus* exemplifies the tremendous amount of highly detailed information that can be gathered by employing the latest multidisciplinary, entirely non-invasive and hence archaeologically sustainable prospection approach, as promoted by LBI ArchPro. Both aerial photography and geophysical data show that the archaeological heritage has suffered severe damage. This case study exemplifies a long-term approach to the survey of Roman archaeological landscapes which was introduced at the Archaeological Prospection Conference in 2001 (Doneus *et al.* 2001; Doneus & Neubauer 2005). The discovery and public presentation of the *ludus* has convinced stakeholders of the benefits of this methodology to archaeological heritage, and new funds have been raised. As a result, the central area of the archaeological landscape of Carnuntum (Figure 1, highlighted) will be mapped over the course of the next three years in a large-scale prospection project directed by LBI ArchPro. Through combining aerial archaeology and modern remote sensing with ground-based high-resolution geophysical subsurface mapping and subsequent GIS-based archaeological interpretation and spatial analysis, the basis for sustainable cultural heritage management is established. The resulting archaeological maps and plans of individual buildings, streets and Roman infrastructure allow the virtual reconstruction of the city layout and the development of ancient land- and townscapes in two and three dimensions. These provide scholars, planning authorities and the public alike with detailed information about the ancient city of Carnuntum (Doneus *et al.* 2013). This non-invasive and sustainable approach to the archaeological survey of Roman city sites provides a model for modern, time- and cost-efficient archaeological research, covering not only the individual archaeological site but also its surrounding landscape, an approach in full compliance with the Valetta Convention (Council of Europe 1992).

Acknowledgements

The authors wish to express their thanks to the team at LBI ArchPro and its partners. The data acquisition was carried out by S. Seren, E. Bayirli, U. Fornwagner, Ch. Zingerle, N. Trochsler, A. Hinterleitner, E. Nau, T. Zitz, M. Kucera, G. Verhoeven, M. Doneus, T. Saey, V. Van Parys, W. Neubauer, Ch. Gugl and Airborne Technologies GmbH. Data processing was completed by A. Hinterleitner, M. Pregesbauer, G. Verhoeven and T. Saey. The GIS-based interpretation model was developed by W. Neubauer. The archaeological interpretation was accomplished by W. Neubauer, M. Scholz, F. Humer and Ch. Gugl. The initial virtual reconstruction was developed by W. Neubauer and M. Klein. The Ludwig Boltzmann Institute for Archaeological Prospection and Virtual Archaeology (<http://archpro.lbg.ac.at>) is based on an international cooperation of the Ludwig Boltzmann Gesellschaft, the University of Vienna, the Vienna University of Technology, ZAMG-the Austrian Central Institute for Meteorology and Geodynamics, the Province of Lower Austria, Airborne Technologies,

RGZM—the Roman-Germanic Central Museum Mainz, RAA—Swedish National Heritage Board, IBM VISTA—University of Birmingham and NIKU—Norwegian Institute for Cultural Heritage Research.
