ABSTRACT

We have obtained *Spitzer* IRS 5.5–35 μm spectroscopy of the debris disk around β Pictoris. In addition to the 10 μm silicate emission feature originally observed from the ground, we also detect the crystalline silicate emission bands at 28 and 33.5 μm . This is the first time that the silicate bands at wavelengths longer than 10 μm have ever been seen in the β Pictoris disk. The observed dust emission is well reproduced by a dust model consisting of fluffy cometary and crystalline olivine aggregates. We searched for line emission from molecular hydrogen and atomic [S I], Fe II, and Si II gas but detected none. We place a 3σ upper limit of $<17 M_{\oplus}$ on the $\text{H}_2 S(1)$ gas mass, assuming an excitation temperature of $T_{\text{ex}} = 100$ K. This suggests that there is less gas in this system than is required to form the envelope of Jupiter. We hypothesize that some of the atomic Na I gas observed in Keplerian rotation around β Pictoris may be produced by photon-stimulated desorption from circumstellar dust grains.

Subject headings: circumstellar matter — planetary systems: formation —
planetary systems: protoplanetary disks — stars: individual (β Pictoris)

1. INTRODUCTION

The A5 V star β Pictoris (HD 39060 = HR 2020) at a distance $d \approx 19.3$ pc possesses a spectacular edge-on debris disk imaged in scattered light and thermal emission that extends to radii >1400 AU (Smith & Terrile 1984; Holland et al. 1998; Golimowski et al. 2006). An age of ~ 12 Myr has been estimated for the central star based on the properties of late-type members of the β Pic moving group (Zuckerman et al. 2001). The dust in this system is believed to be replenished from a reservoir, such as collisions between parent bodies or sublimation of comets because the estimated lifetime for the dust under radiation pressure, Poynting-Robertson drag, and grain-grain collisions is a few orders of magnitude shorter than the age of the system (Backman & Paresce 1993). There may be evidence for the presence of large bodies in the β Pictoris disk that perturb dust grains and parent bodies and instigate collisional cascades between them. A 5° warp at radii <80 AU has been observed in scattered light using STIS on *HST* and may be generated by either a brown dwarf close to the star (at distances <3 AU) or a $0.17 M_{\text{Jup}}$ planet at larger distances from the star (50 AU; Heap et al. 2000). The β Pictoris disk may also possess infalling, sublimating, refractory bodies. Time-variable, high-velocity, nonperiodic, redshifted atomic absorption features have been observed toward β Pictoris at ultraviolet (UV) and visual wavelengths that vary on timescales as short as hours. The velocity of the atoms, typically $100\text{--}400$ km s^{-1} , is close to the free fall velocity at a few stellar radii, suggesting that the absorption is produced as stellar photons pass through the comae of

infalling bodies at distances <6 AU from the star (Vidal-Madjar et al. 1998).

The origin of the micron-sized dust grains required to account for the observed scattered light and thermal emission is currently not well constrained. The broad 9.7 μm silicate emission feature and the narrow 11.3 μm crystalline olivine emission feature observed toward β Pictoris appear grossly similar to those observed toward comets Halley, Bradford 1987s, and Levy 1990 XX (Knacke et al. 1993), suggesting that the grains may be cometary. Models of cometary grains, idealized as fluffy aggregates of interstellar silicate cores with carbonaceous organic refractory mantles (and additional ice mantles at distances larger than the snow line), in radiative equilibrium with the central star are able to reproduce the observed 10 μm silicate feature and the spectral energy distribution (SED) at IR through millimeter wavelengths (Li & Greenberg 1998). Spatially resolved studies of the silicate emission feature, obtained using COMICS on the Subaru Telescope, suggest that the shape of the 10 μm feature changes as a function of position in the disk, with large and crystalline grains concentrated at the center and small grains located in ringlike bands at 6.4, 16, and 29 AU from the central star (Okamoto et al. 2004). The rings of small grains may be explained by collisions between large orbiting bodies. High-resolution, mid-IR imaging of β Pictoris, obtained with TReCs on the Gemini South Telescope, has resolved a prominent clump on the southwest side of the disk at 52 AU from the central star, which may also indicate that a recent collision has occurred in the β Pictoris disk (Telesco et al. 2005).

Spatially resolved visual spectroscopy of β Pictoris has revealed a disk of atomic gas in Keplerian rotation, observed via scattered emission from Fe I, Na I, Ca II, Ni I, Ni II, Ti I, Ti II, Cr I, and Cr II. The atomic gas possesses a northeast-southwest brightness asymmetry and an inner warp similar to that observed in the dust disk although the gas extends to larger heights than the dust (Brandeker et al. 2004). Estimates of the radiation pressure acting on Fe and Na atoms suggest that these species should be not be in Keplerian rotation but should be accelerated to terminal outflow velocities $\sim 100\text{--}1000$ km s^{-1} (Brandeker et al. 2004). Lagrange et al. (1998) showed that a ring of neutral hydrogen at

distance 0.5 AU could slow down the radial flow of gas. However, Fernandez et al. (2006) have recently proposed that the gas will not be radially accelerated if the carbon is overabundant; their model does not require a population of undetected atomic hydrogen. Since carbon does not experience strong radiation pressure ($F_{\text{rad}}/F_{\text{grav}} = \beta_{\text{carbon}} \approx 0$) and also has a large ionization fraction (~ 0.5), they suggest that Coulomb interactions between C II and other ions reduce the effective radiation pressure on the bulk gas. In this case, the ions and neutral atoms in the disk couple together into a fluid, with an effective radiation pressure coefficient, that is bound to the system and that brakes the gas if $\beta_{\text{eff}} < 0.5$. In particular, they suggest that if the carbon abundance is >10 times solar, then all the atomic gas will be retained. Measurements of the column density of the stable component of atomic carbon (with zero velocity relative to the star) via absorption from C I (3P) $\lambda 1613$ (Roberge et al. 2000) and absorption from C II $\lambda 1036$ and C II* $\lambda 1037$ superimposed on chromospheric O VI $\lambda 1038$, suggest that the bulk of the atomic gas is composed of carbon with a C/Fe abundance ratio that is 16 times the solar value and an ionization fraction of 0.5 (Roberge et al. 2006).

We report the results of a *Spitzer Space Telescope* IR Spectrograph (IRS) study of the dust and gas around β Pictoris, building on the model for the composition and spatial distribution of the grains by Li & Greenberg (1998) and placing 3σ upper limits on the line emission from H₂ $S(2)$, $S(1)$, $S(0)$, and [S I], Fe II, and Si II gas. Based on the similarity in the spatial distribution of the dust and gas observed in scattered light, we hypothesize that the dust and gas in this system are physically associated and that the observed gas is secondary; it has been produced from circumstellar material since the star formed. We quantitatively show that the observed Na I, seen in Keplerian rotation around the star, can be produced via photon-stimulated desorption in a time that is shorter than the residence time of the gas in the disk.

2. OBSERVATIONS

We obtained IRS (Houck et al. 2004) spectral mapping mode observations of β Pictoris using the Short-Low (SL; 5.2–14 μm ; $\lambda/\Delta\lambda \sim 90$), Short-High (SH; 9.9–19.6 μm ; $\lambda/\Delta\lambda \sim 600$), and Long-High (LH; 18.7–37.2 μm ; $\lambda/\Delta\lambda \sim 600$) modules on *Spitzer* (Werner et al. 2004). The SL2 slit has a size $3.6'' \times 57''$; the SL1 slit has a size $3.7'' \times 57''$; the SH slit has a size $4.7'' \times 11.3''$; the LH slit has a size $11.1'' \times 22.3''$. Both the low- and high-resolution observations were made with the spectrograph long slits aligned along the position angle of β Pictoris disk to within 5° .

The SL2 (AOR key: 8972288) and SL1 (AOR key: 8972544) spectra were obtained on 2004 November 16 by stepping the slit in seven and 11 $1.8''$ intervals perpendicular to the disk, respectively, with the center position centered on the disk. Each SL2 and SL1 map position was observed using nine and 14 cycles, respectively, of 6 s ramps. The SH (AOR key: 4879616) and LH (AOR key: 4876800) spectra were obtained on 2003 December 15 and 2004 March 4, respectively, by stepping the slit in three $2.4''$ and $4.8''$ intervals perpendicular to the disk, respectively, with the center position centered on the disk. Each SH and LH map position was observed using 25 and 24 cycles, respectively, of 30 and 14 s ramps. A high-accuracy peak-up, with the blue (13.3–18.7 μm) array, on the nearby star HD 38891 (located $12'$ north of β Pictoris), was used to center the disk in the SL2, SL1, and SH slits; a high-accuracy peak-up, with the red array (18.5–26 μm), on HD 38891 was used to center the disk in the LH slit.

The raw data were processed into calibrated (flat-fielded, stray-light-corrected) two-dimensional spectra with version S11.0.2 of the SSC pipeline. We removed masked and rogue pixels from

the basic calibrated data by interpolating between their nearest neighbors, co-added the resulting images, and extracted one-dimensional spectra using the IRS team's SMART program (Higdon et al. 2004). Since separate nod observations of the sky were not made when β Pictoris was observed, we approximated the SL sky background as a constant at each wavelength and subtracted this value from each pixel in the spatial direction across the source. Since the SL slits are long enough to sample the PSF in the spatial direction, we fit one-dimensional Gaussians to the SL spectra in the spatial direction to determine the positions of the source in the slits. We extracted our low-resolution spectra by summing over a window whose width varied as a function of wavelength to account for the changing size of the point-spread function and was centered on the source position. Finally, we multiplied the resulting spectra with an α Lac relative spectral response function (RSRF), obtained by dividing an α Lac template spectrum with an observed α Lac SL spectrum (Jura et al. 2004). Since point sources fill the high-resolution slits, we extracted our high-resolution spectra (without background subtraction) by summing over all of the pixels in the SH and LH slits. The extracted high-resolution spectra were multiplied by a ξ Dra high-resolution RSRF.

We constructed a spectrum that is consistent with the LH slit, the largest slit we used to observe β Pictoris, centered on the disk. Since the source is extended in our IRS observations, we added multiple SL measurements together to construct an aperture equal to the LH aperture. Since our SH map was not large enough to cover the LH central slit position, we scaled our SH spectrum by a factor of 1.068 to match the SL and LH spectra, using the LL spectrum at 5.1939–9.9232 μm , the SH spectrum at 9.9461–19.3179 μm , and the LH spectrum at 19.2636 μm to 35.9892 μm . The final spectrum of β Pic (shown in Fig. 1) is that of a $11'' \times 22''$ region centered on the star and oriented along the disk.

The signal-to-noise ratio in our spectrum is very high. Over spans of many spectral resolution elements, the sensitivity of our spectrum is limited by flat-fielding errors to 1%–2% of the continuum flux density. Over smaller spans, ≤ 10 spectral resolution elements or so, the sensitivity is limited only by photon noise from the background and target, and is significantly better: 0.1%–0.5% of the continuum flux density in SH and LH, and 0.05%–0.2% in SL, consistent with the point-to-point scatter in the spectrum over such small spans, and (perforce) consistent with the *Spitzer*-IRS facility sensitivity tool, SPEC-PET. Thus, every spectral feature visible in our β Pic spectrum that is at least as wide as the spectral resolution is real, and the upper limits on weaker spectral lines are significantly smaller than 1% of the continuum. For simplicity we have calculated such upper limits directly from the point-to-point variation of the continuum-subtracted spectrum.

3. DUST PROPERTIES

Figure 1 plots the 5.2–36 μm IRS spectrum and the PHOENIX model stellar atmospheric spectrum with effective temperature $T_* = 8000$ K and surface gravity $\log g = 4.2$. Figure 1 clearly shows that the dust excess emission above the stellar atmospheric radiation is even seen at wavelengths as short as $\lambda \sim 5$ –8 μm , indicating that there may exist a population of hot dust (~ 400 –600 K) at a distance of <10 AU from the central star (see Fig. 1 of Li & Greenberg 1998).

Mostly prominent in Figure 1 are the broad 10 μm feature (which reveals the presence of both amorphous silicates and crystalline silicates in the β Pictoris disk) and the 28 and 33.5 μm crystalline olivine emission features (see the inset in Fig. 1a),

FIG. 1.—(a) *Spitzer* IRS SL, SH, and LH spectrum of β Pictoris (red line) with the PHOENIX atmospheric spectrum (black line) overlaid. The inserted panel illustrates the 5–36 μm stellar-subtracted *Spitzer* IRS dust excess emission. Also plotted are the *UBVR/IJHK* stellar photometry (magenta squares), the ground-based spectrometry of Knacke et al. (1993; labeled “K93”), and the IRS spectrum in the inner 3.6” [corresponding to ~ 35 AU; approximately the same beam size as that of Knacke et al. (1993)] disk (green line). (b) Comparison of the stellar-subtracted *Spitzer* IRS dust excess emission (red line) with the *IRAS* photometry (cyan open circles), the Big Mac/IRTF photometry (black filled circles), the IRTF *N*-band and *Q*-band photometry (green open stars), and the IRTF 2.6–13.5 μm spectrometry of Knacke et al. (1993; blue open squares). Numerous hydrogen absorption features can be seen between 5 and 13 μm ; their depths are consistent with that expected for a star with A5 V photosphere at spectral resolution of the IRS.

which closely resemble the Li & Greenberg (1998) model spectrum (see their Fig. 6c).¹⁰ This is the first time that the silicate bands at wavelengths longer than 10 μm have ever been detected in the β Pictoris disk.

For comparison, we also show in Figure 1 the *IRAS* broadband photometry of Gillett (1986), the photometry of Telesco & Knacke (1991) at 8.8, 10.3, 11.7, and 12.5 μm obtained using the Big Mac spectral filters at the NASA Infrared Telescope Facility (IRTF), the IRTF *N*-band (10.1 μm) and *Q*-band (20 μm) photometry of Backman et al. (1992), the IRTF 2.6–13.5 μm intermediate-resolution ($\lambda/\Delta\lambda \approx 50$) spectrometry of Knacke et al. (1993), and the Kuiper Airborne Observatory (KAO) 47 and 95 μm photometry of Harvey et al. (1996). While the photometry of Telesco & Knacke (1991) and the IRTF *N*-band photometry of Backman et al. (1992) agree with the spectrometry of Knacke et al. (1993) very well, they are below the IRS spectrum by a factor of ~ 1.94 (see Figs. 1b and 2b). This difference is

¹⁰ Crystalline pyroxene $\text{Mg}_x\text{Fe}_{(1-x)}\text{SiO}_3$ grains also have a rich set of features in the mid-IR. But their peak wavelengths and relative feature strengths are inconsistent with the IRS spectrum (e.g., see Chihara et al. 2001). Olivine $\text{Mg}_{2-x}\text{Fe}_{2(1-x)}\text{SiO}_4$ is a mixture of forsterite Mg_2SiO_4 and fayalite Fe_2SiO_4 with a mixing proportion x . In this work, as well as in Li & Greenberg (1998), we adopt the refractive indices of $\text{Mg}_{1.8}\text{Fe}_{0.2}\text{SiO}_4$ (Mukai & Koike 1990). Although in principle it is possible to infer the Mg/Fe ratio from the locations and strengths of the IR features (e.g., see Koike et al. 1993, 2003; Fabian et al. 2001), neither the IRS spectrum reported here reveals a large number of crystalline silicate features nor does it cover a sufficiently broad wavelength range for constraining the exact crystal composition. As shown in Fig. 2, the dust model consisting of crystalline $\text{Mg}_{1.8}\text{Fe}_{0.2}\text{SiO}_4$ olivine reproduces the IR features reasonably well.

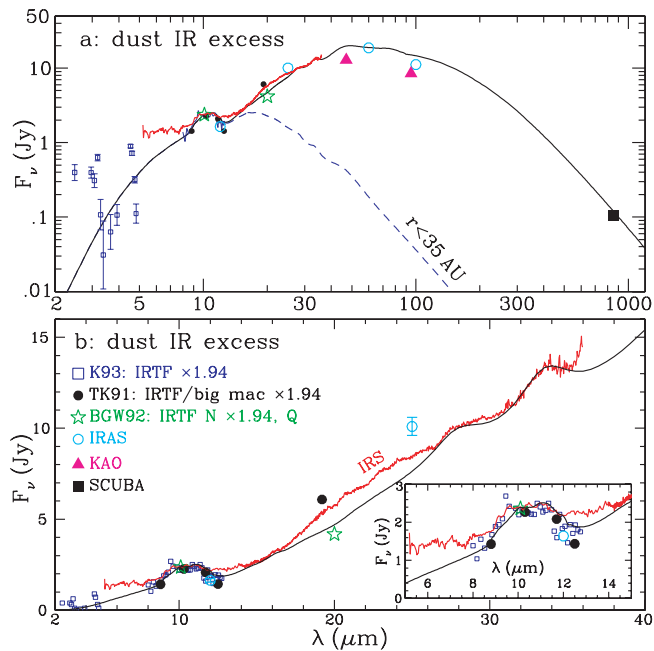

FIG. 2.—Comparison of the model (black line) to (a) the observed dust IR emission SED and (b) the *Spitzer* IRS spectrum (red line). Also plotted is the model-predicted emission in the inner 35 AU disk. Blue open squares: the IRTF 2.6–13.5 μm spectrometry of Knacke et al. (1993) increased by a factor of 1.94. Black filled circles: The Big Mac/IRTF photometry of Telesco & Knacke (1991) increased by a factor of 1.94. Green open stars: The IRTF *N*-band and *Q*-band photometry of Backman et al. (1992), with the *N* band increased by a factor of 1.94. Cyan open circles: The *IRAS* photometry of Gillett (1986). Magenta filled triangles: The KAO photometry of Harvey et al. (1996). Black filled squares: The 850 μm SCUBA photometry of Holland et al. (1998). With this increase (of a factor of 1.94), all observational data agree with each other very well. The inserted panel in (b) illustrates the model fit to the 10 μm silicate features.

much larger than the calibration uncertainty of IRS and is attributed to the fact that the *Spitzer* apertures (3.6” \times 57” for SL, 4.7” \times 11.3” for SH, 11.1” \times 22.3” for LH) are much larger than the apertures of ground-based observations (e.g., the 3.7” diameter of Knacke et al. [1993], the 3.9” \times 4.2” of Telesco & Knacke [1991], and the 7.8” diameter of Backman et al. [1992]), and therefore *Spitzer* detects more flux from extended material than in previous observations.¹¹

The nature (e.g., size, composition, and morphology) of the dust and its spatial distribution in protoplanetary and debris disks is mostly revealed through the interaction of the dust with the electromagnetic radiation of the central star: absorbing, scattering, and polarizing the stellar radiation and reradiating the absorbed UV/visible photons at longer wavelengths, ranging from the IR to submillimeter and millimeter. Since the disk around β Pictoris subtends more than 100”, it has been studied in great detail. There exists a vast variety of observational data for the dust in this disk (see Mann et al. 2006), including (1) imaging observations of scattered light (Smith & Terrile 1984; Paresce & Burrows 1987; Golimowski et al. 1993; Lecavelier des Etangs et al. 1993; Kalas & Jewitt 1995; Mouillet et al. 1997; Heap et al. 2000; Kalas et al. 2000; Golimowski et al. 2006); (2) imaging observations of dust thermal emission in the mid-IR (Lagage & Pantin 1994; Pantin et al. 1997; Heinrichsen et al. 1999; Wahhaj et al. 2003; Telesco et al. 2005) and submillimeter (Holland et al.

¹¹ Indeed, as shown in Fig. 1a, the SL point-source-extracted spectrum centered on the star (with a beam diameter of ~ 3.6 ”, approximately the same as Knacke et al. (1993)’s spectroscopic observation) is close to that of Knacke et al. (1993).

1998); (3) mid-IR narrowband photometry (Telesco & Knacke 1991), as well as broadband photometry in the mid-IR (Gillett 1986; Backman et al. 1992) and millimeter (Chini et al. 1991; Liseau et al. 2003); (4) optical (Gledhill et al. 1991; Wolstencroft et al. 1995) and near-IR (Tamura et al. 2006) imaging of polarized light; and (5) mid-IR spectroscopy (Aiken et al. 1993; Knacke et al. 1993; Weinberger et al. 2003; Okamoto et al. 2004).

To accurately describe the dust grains in the β Pictoris disk, all of the aforementioned observational data must be modeled *simultaneously*. While recognizing the importance of a comprehensive, simultaneous modeling of all of the β Pictoris observations, in this paper we present a simple model focusing on our *Spitzer* IRS spectrum. We defer the comprehensive modeling of the dust around β Pictoris that attempts to simultaneously fit all of the observed data to a separate paper (A. Li et al. 2007, in preparation).

We model the *Spitzer* IRS spectrum of β Pictoris building on the work of Li & Greenberg (1998), which includes (1) a population of cometary dust, composed of low-density porous aggregates of amorphous silicate core-carbonaceous mantle grains,¹² and (2) a population of crystalline olivine aggregates with the same size and spatial distributions as the amorphous cometary grains (but actually we do not require crystalline dust outside ~ 60 AU from the star since at distances >60 AU from the star silicate grains are too cold to emit at the characteristic mid-IR bands).

For the amorphous cometary and crystalline olivine fluffy aggregates, we assume a vacuum volume fraction $P = 0.90$ (see § 2 of Li et al. 2003 for justification) and approximate the porous grains as spheres with radii a . We assume a power-law dust size distribution $dn(a)/da \propto a^{-\alpha}$, with a minimum grain radius $a_{\min} = 1 \mu\text{m}$, and a maximum grain radius $a_{\max} = 10,000 \mu\text{m}$ (see Li et al. 2003 for justification).

Similar to Artymowicz & Clampin (1997), we assume a modified power-law spatial distribution for the dust, $n(r) \propto 1/[f(r/r_p)^{-1} + (r/r_p)^\gamma]$. This functional form, peaking at $r_p(f/\gamma)^{1/(\gamma+1)}$, behaves like a power law $n(r) \propto r^{-\gamma}$ at large distances ($r > r_p$). At $r < r_p$, the $(r/r_p)^{-1}$ term dominates, approximating an increasing profile in the inner, relatively dust-depleted region. We take $r_p = 100$ AU and $\gamma = 2.7$ as derived from scattered light modeling (Artymowicz et al. 1989). The inner boundary r_{\min} of the disk is taken to be the location inside which silicate dust sublimates. For the β Pictoris disk, micron-sized silicate grains possess an equilibrium temperature $T \approx 1500$ K at $r \approx 0.2$ AU; therefore, we take $r_{\min} = 0.2$ AU. We take $r_{\max} = 2000$ AU.

In modeling the dust IR emission, we—with all other parameters (i.e., r_p , γ , r_{\min} , r_{\max}) prechosen—are therefore left with only two free parameters: α , the dust size distribution power index; and f , which determines the amount of dust in the inner disk region $r < r_p$ (we note that Artymowicz & Clampin 1997 took $f = 1$). It is found that, with $\alpha \approx 3.2$ and $f \approx 0.15$, we are able to obtain a reasonably good fit to the overall SED and the *Spitzer* IRS spectrum including the silicate emission features at 10, 28, and 33.5 μm (see Fig. 2).¹³ The required dust masses

are approximately $1.63 \times 10^{27} \text{ g} \approx 0.27 M_\oplus$ and $4.89 \times 10^{25} \text{ g} \approx 0.0082 M_\oplus$ for the amorphous and crystalline components, respectively.

As shown in Figure 2*b*, the model is somewhat deficient at $\lambda \sim 5\text{--}8$ and $\lambda \sim 17\text{--}24 \mu\text{m}$. This is due to the oversimplified dust spatial distribution function adopted above. By including two rings or clumps of dust at $r < 10$ and at $r \sim 20\text{--}30$ AU, as implied by Telesco et al. (2005) and Okamoto et al. (2004), it is expected that the model will account for the excess emission at 5–8 and 17–24 μm (see Li et al. 2007, in preparation). The oversimplification of the assumed dust spatial distribution is also reflected by the model-predicted IR emission from the dust within a 3.6'' diameter (corresponding to ~ 35 AU; see Fig. 2*a*): the model-predicted emission from the inner 35 AU region accounts for almost all the observed $\lambda < 15 \mu\text{m}$ emission for the entire disk. Although this is consistent with the previous spatially resolved mid-IR spectroscopy, which shows that 10 μm silicate emission originates from the inner ~ 20 AU (Weinberger et al. 2003; Okamoto et al. 2004), it appears to contradict the IRS detection of an appreciable amount of silicate emission from the outer ~ 35 AU (see Fig. 1*a*). This will be investigated in detail in a subsequent paper (see A. Li et al. 2007, in preparation).

4. GAS MASS UPPER LIMITS

Core-accretion models suggest that giant planets accrete their gaseous envelopes on timescales between 1 and 20 Myr. Therefore, the β Pictoris disk, with an age of ~ 12 Myr, is an excellent source to search for bulk gas. If the gas has a solar composition, then the bulk gas is expected to be hydrogen. *ISO* observations indicated line emission from $\text{H}_2 S(0)$ at 28.2 μm and $S(1)$ at 17.0 μm , suggesting that the disk possesses 54 M_\oplus warm H_2 with an excitation temperature $T_{\text{ex}} = 110$ K (Thi et al. 2001). However, apparently conflicting *FUSE* observations constrain the circumstellar H_2 Lyman series absorption and place a 3 σ upper limit of $N(\text{H}_2) \leq 10^{18} \text{ cm}^{-2}$ on the H_2 column density, significantly lower than $(5\text{--}500) \times 10^{20} \text{ cm}^{-2}$ expected if the *ISO*-detected H_2 were uniformly distributed in an edge-on disk in the beam (Lecavelier des Etangs et al. 2001), an assumed geometry that is consistent with observations of the atomic gas. Detailed studies of gas drag on the dust dynamics suggest that the gas/dust ratio is less than 1 (or $< 0.4 M_\oplus$ molecular hydrogen exists in the disk). For example, if the disk possessed 40 M_\oplus gas, then small grains would collect at distances > 200 AU and would increase the scattered light surface brightness by more than a factor of 10 (Thébaud & Augereau 2005). Searches for $\text{H I } 21 \text{ cm}$ emission constrain the mass of atomic hydrogen $M_{\text{H I}} \leq 0.5 M_\oplus$ (Freudling et al. 1995); recent chemical models constrain the total mass of hydrogen $\leq 15 M_\oplus$ including the molecular component based on these observations (Kamp et al. 2007).

We searched for emission from $\text{H}_2 S(2)$, $S(1)$, $S(0)$, and $[\text{S I}]$, Fe II , and Si II but did not detect any of these species. We place 3 σ upper limits on their line fluxes toward β Pictoris (see Table 1). Our 3 σ upper limit on the $\text{H}_2 S(1)$ line flux is $< 1.2 \times 10^{-14} \text{ ergs s}^{-1} \text{ cm}^{-2}$, a factor of ~ 6.4 times lower than the reported *ISO* detection (see Fig. 3). Although the *Spitzer* IRS SH slit is a factor of 2 shorter than the *ISO* SWS slit ($14'' \times 27''$), our upper limits effectively constrain the H_2 line emission because the warm, bulk H_2 is expected to be located at radii < 100 AU ($< 6''$).

Converting 3 σ upper limits on the line fluxes from any species into gas masses depends sensitively on the assumed gas temperature. Detailed models of the heating and cooling of molecular and atomic gas via gas-grain collisions, cosmic rays, line emission, etc., have been used to infer the temperature and chemical structure of the β Pictoris disk. However, these models depend

¹² The mass ratio of the silicate core to the carbon mantle is assumed to be $m_{\text{Ca}}/m_{\text{Si}} \approx 0.7$ based on the cosmic abundance consideration (see Appendix A of Li & Lunine 2003).

¹³ The amount of dust in the inner disk ($r < r_p$) is inverse proportional to f . With $f = 0.15$ and $\gamma = 2.7$, the dust spatial distribution peaks at $0.46 r_p \approx 46$ AU. At a first glance, this appears inconsistent with the scattered light images which suggest a dust spatial distribution slope change at $\sim 80\text{--}120$ AU (e.g., see Golimowski et al. 1993, 2006). However, the dust spatial distribution from 46 AU ($\approx \frac{1}{2} r_p$) to r_p is rather flat: $n(r)$ only changes by a factor of ≈ 2.3 from $\frac{1}{2} r_p$ to r_p , while it drops much more steeply from r_p to $2r_p$ (by a factor of ≈ 5.8). In a subsequent paper (A. Li et al. 2007, in preparation), we will investigate in detail whether the present dust spatial distribution is able to reproduce the scattered light images.

TABLE 1
Spitzer IRS LINE FLUX UPPER LIMITS FOR β PICTORIS

GAS SPECIES	WAVELENGTH (μm)	LINE FLUX ($\text{ergs s}^{-1} \text{cm}^{-2}$)	$M_{\text{gas}} (M_{\oplus})$		ATOMIC/MOLECULAR DATA REFERENCES

on the initial gas/dust ratio or gas mass assumed. For example, a $2 M_{\oplus}$ disk (with an interstellar gas/dust ratio of ~ 100) heated primarily by gas-grain collisions may possess gas as warm as 100–150 K at intermediate heights at distances of 300–500 AU where [O I] fine structure emission at $63.2 \mu\text{m}$ is the dominant coolant; while, a $0.2 M_{\oplus}$ disk may possess gas as warm as 300 K at lower heights and similar radii in the disk where [O I] and H₂ rotational/vibrational emission are the dominant coolants (Kamp & van Zadelhoff 2001). Estimates of the total gas mass, inferred from the measured column densities of atomic species and the scattered light gas density profile of Na I, suggest that the β Pictoris disk contains $\sim 7.4 \times 10^{-4} M_{\oplus}$ measured gas, corresponding to a gas/dust ratio ~ 0.019 , significantly less than assumed in many detailed chemical models. Even if the gas has a solar hydrogen abundance relative to the heavy elements, then the disk possesses $\sim 3.7 \times 10^{-3} M_{\oplus}$ gas, corresponding to a gas/dust ratio ~ 0.093 (A. Roberge 2006, private communication), still significantly less than the gas/dust ratios of 100 or 10 assumed in these models.

To estimate an upper limit on the mass of H₂ based on our S(1) line flux upper limit, we must assume a gas excitation temperature. Gas temperatures can be inferred from (1) detailed models of gas in thermal balance that calculate the composition and density structure of disks in addition to the temperature structure (as

described above) or (2) observations if multiple electronic transitions are observed. Far-UV observations of β Pictoris have constrained the bulk circumstellar gas temperature. Analysis of the C I (³P) $\lambda 1613$ and $\lambda 1561$ multiplets suggest that the excitation temperature of the stable C I component, $T_{\text{ex}} = 50\text{--}100$ K (Roberge et al. 2000). Since bulk hydrogen with a gas/dust ratio of 100 has not been directly detected (as assumed for the Kamp & van Zadelhoff models), we rely on the measured C I excitation temperature to act as a guide for the bulk gas kinetic temperature $T_{\text{kin}} = 50\text{--}100$ K. Therefore, we place 3σ upper limits on the mass in each of the listed species assuming gas temperatures $T_{\text{ex}} = 50$ and 100 K (see Table 1). The total flux produced by N atoms or molecules

$$F = \frac{h\nu N \chi_u A_{ul}}{4\pi d^2}, \quad (1)$$

where d is the distance to the star, $E = h\nu$ is the energy of the radiated photons, χ_u is the fraction of atoms or molecules in level u , and A_{ul} is the transition probability. Since the temperature of any H₂ is uncertain, we plot the 3σ upper limits on the H₂ mass obtained from our S(1) and S(0) line fluxes as a function of temperature (see Fig. 4). If $T_{\text{gas}} = 100$ K, we estimate that

FIG. 3.—(a) Portion of the observed *Spitzer* SH spectrum of β Pictoris around H₂ S(1) with a model for unresolved H₂ emission (overplotted in red) inferred from *ISO* detection. (b) Same as (a), but for the *Spitzer* LH spectrum around H₂ S(0).

FIG. 4.— The 3σ upper limits on the hydrogen gas mass as a function of disk gas temperature, estimated from the line fluxes of H_2 $S(1)$ (solid line), and H_2 $S(0)$ (dotted line).

$<17 M_{\oplus}$ H_2 hydrogen remains in the disk from our H_2 $S(1)$ upper limit.

The nondetection of H_2 , $[\text{S I}]$, Fe II , and Si II emission toward β Pictoris is consistent with *Spitzer* observations of other 10–30 Myr old disks. *ISO* observations of the 20 Myr old dusty A1 V star 49 Ceti have indicated line emission from H_2 $S(0)$ at $28.2 \mu\text{m}$, suggesting that the 49 Ceti disk possesses $>110 M_{\oplus}$ warm H_2 with an excitation temperature $T_{\text{ex}} < 100$ K (Thi et al. 2001). However, high-resolution *Spitzer* IRS observations place 3σ upper limits on the H_2 $S(0)$ line flux that are a factor of ~ 9 lower than the reported detection (Chen et al. 2006). A recent *Spitzer* IRS search for H_2 emission from warm gas and millimeter search for ^{12}CO from cool gas around eight Sun-like systems with ages <30 Myr measured upper limits $<0.04 M_{\text{Jup}}$ gas within a few AU of the disk inner radius (1–40 AU) and $<0.04 M_{\oplus}$ gas at 10–40 AU (Pascucci et al. 2006). *Spitzer* IRS observations place 5σ upper limits on the line flux from H_2 $S(1)$ and $S(0)$ toward HD 105, a G0 V member of the Tucana-Horologium association at 40 pc from the Sun, suggesting that less than 1500, 12, and $0.95 M_{\oplus}$, respectively, at $T_{\text{gas}} = 50, 100,$ or 200 K remains in this disk at an age of 30 Myr (Hollenbach et al. 2005). Together, these observations suggest that warm molecular hydrogen, with $T_{\text{ex}} = 100$ K, dissipates from circumstellar disks on timescales <10 Myr.

5. THE ORIGIN OF THE ATOMIC GAS

The origin of the observed stable atomic gas in Keplerian rotation around β Pictoris (described in § 1), like the micron-sized dust grains, is currently not well constrained. There have been suggestions in the literature that the stable gas component is produced by infalling refractory bodies (Beust & Valiron 2007) or by collisions between dust grains (Czechowski & Mann 2007; Fernandez et al. 2006). We consider these possibilities and hypothesize that some of the observed atomic sodium is generated by photon-stimulated desorption from SiO_2 -like surfaces.

Infalling refractory bodies undoubtedly contribute at least some portion of the observed gas but whether all of the gas is generated by the evaporation of parent bodies is uncertain. The

spatial distribution of the gas may provide a clue to its origin. The atomic gas is detected to distances of 150–200 AU on the southwest side and distances of 300–350 AU on the northeast side of the disk. These distances correspond to the inner regions of the dusty disk that has been detected in thermal emission and scattered light to distances >1400 AU. The southwest/northeast dust brightness asymmetry observed in scattered light is also seen in the resonantly scattered gas emission lines; however, the asymmetry in the Na I emission is more pronounced. Finally, the gas and dust populations share an inner disk that is tilted $\sim 5^\circ$ with respect to the outer disk (Brandeker et al. 2004). If infalling refractory bodies produce all of the observed gas, why are the spatial distributions of the gas and dust so similar?

To explain the similarity in the spatial distributions of the dust and gas around β Pictoris, Czechowski & Mann (2007) recently proposed that the atomic gas is produced via collisions between dust grains that vaporize at least some portion of the dust. Vaporization of dust grains in energetic collisions is believed to produce atomic gas in supernovae shocks and may generate a nontrivial fraction of the gas observed in the exospheres of Mercury and the moon (Killen et al. 2001). In the Czechowski & Mann (2007) model, radiation pressure accelerates subblowout-sized grains (β meteoroids) to large radial velocities; these small particles then collide with bound, orbiting grains with relative velocities as high as 90 km s^{-1} (for carbonaceous grains). The observed abundances of the β Pictoris dust and atomic gas may provide a clue to the origin of the stable atomic gas. If the gas is liberated in vaporizing collisions and no atomic species are selectively removed (e.g., via outgassing or differentiation), then the gas composition should be the same as the grain composition. Our models for the dust grains around β Pictoris reproduce the *Spitzer* IRS spectrum assuming a carbon relative to silicon abundance ratio of ~ 8.9 , significantly smaller than the measured ratio of the column densities of atomic carbon and silicon gas, ~ 500 (Roberge et al. 2006).

Photon-stimulated desorption (PSD) may produce a substantial fraction of the sodium observed in the tenuous exospheres of Mercury and the Moon (Leblanc et al. 2006; Lammer et al. 2003; Yakshinskiy & Madey 1999) and may produce some of the spatially-extended sodium gas observed via resonant scattering toward β Pictoris. Since PSD produces gas directly from the dust, it might naturally explain the similarity in the gas and dust density distributions. The cross section for PSD jumps dramatically at UV wavelengths, becoming most efficient at $\lambda < 2500 \text{ \AA}$ (Yakshinskiy & Madey 1999). β Pictoris has been observed extensively in the far- and near-ultraviolet using *FUSE* (Lecavelier des Etangs et al. 2001; Roberge et al. 2006), *HST* GHRS, and STIS (Roberge et al. 2000), with a continuum flux at $2000 \text{ \AA} < \lambda < 2500 \text{ \AA}$ measured by *IUE*, $F_{\lambda} > 4 \times 10^{-11} \text{ ergs s}^{-1} \text{ cm}^{-2} \text{ \AA}^{-1}$ (Lanz et al. 1995). Fernandez et al. (2006) model the observed stellar ultra violet spectrum of β Pic using a rotationally broadened ($v_{\text{rot}} = 130 \pm 4 \text{ km s}^{-1}$) PHOENIX model with effective temperature $T_{\text{eff}} = 8000$ K, and surface gravity, $\log g = 4.2$, suggesting a stellar UV photon production rate, $L_{1000-2500 \text{ \AA}} = 2.0 \times 10^{44} \text{ s}^{-1}$.

The efficiency with which photons desorb sodium, averaged over the surface of a sphere, is

$$\epsilon = \frac{1}{4} Q\sigma \quad (2)$$

(Yakshinskiy & Madey 1999), where Q is the photon-stimulated desorption cross section and σ is the atomic surface coverage. Laboratory experiments measure $Q_{\text{Na}} \sim (3 \pm 1) \times 10^{-20} \text{ cm}^2$ for

lunar samples with temperatures of 250 K and using incident photons with $\lambda < 2500 \text{ \AA}$, suggesting an efficiency of $\epsilon_{\text{Na}, 250 \text{ K}} = 2.3 \times 10^{-8}$ for materials with a lunar temperatures and compositions, $\sigma_{\text{Na}} = 3 \times 10^{12} \text{ cm}^{-2}$ (Yakshinskiy & Madey 1999). In addition, the photon-stimulated desorption efficiency of sodium is also function of substrate temperature, T_{gr} . We estimate

$$\epsilon_{\text{Na}} = (6.93 \times 10^{-8}) 10^{-122.8 \text{ K}/T_{\text{gr}}} \quad (3)$$

from measurements of sodium desorption yields in the laboratory (Yakshinskiy & Madey 2004), normalized to the sodium desorption efficiency at the moon as discussed above.

The rate at which atomic sodium is produced in the β Pictoris disk is

$$\Gamma = \int_{R_{\text{min}}}^{R_{\text{max}}} 2\pi r dr \int_{z_{\text{min}}}^{z_{\text{max}}} dz \frac{L_{1000-2500 \text{ \AA}}}{4\pi r^2} \epsilon_{\text{Na}} [T_{\text{dust}}(r)] \pi a^2 n_{\text{dust}}(r, z), \quad (4)$$

where $R_{\text{min}} = 3 \text{ AU}$ and $R_{\text{max}} = 232 \text{ AU}$ are the minimum and maximum radii, and $z_{\text{min}} = -100 \text{ AU}$ and $z_{\text{max}} = 100 \text{ AU}$ are the minimum and maximum heights at which the atomic sodium gas is observed. Since the Na I gas in the β Pic disk is located at distances of up 350 AU, well beyond our IRS slit, we use a dust density distribution inferred based on observations of the disk on large scales (rather than the dust density profile that we derive in § 3). P. Artymowicz (2006, private communication) has inferred the quantity $\pi a^2 n_{\text{dust}}$, summed over all grain sizes, from *HST* STIS observations (Heap et al. 2000) assuming a grain albedo 0.5:

$$\pi a^2 n_{\text{dust}} = \frac{\tau_o}{W} \left[\left(\frac{r}{r_o} \right)^{-4} + \left(\frac{r}{r_o} \right)^6 \right]^{-1/2} \exp \left[- \left(\frac{z}{W} \right)^{0.7} \right], \quad (5)$$

where $r_o = 120 \text{ AU}$, $W = 6.6(r/r_o)^{0.75}$, and $\tau_o = 2 \times 10^{-3}$. We assume that the bulk of the surface area is contained in $1 \mu\text{m}$ amorphous olivine grains and estimate the grain temperature as a function of distance using Mie theory (the grains are spherical) and using laboratory-measured indices of refraction (Dorschner et al. 1995). If $R_* = 1.69 R_{\odot}$ and $T_* = 8000 \text{ K}$, we estimate a sodium production rate $1.3 \times 10^{33} \text{ s}^{-1}$ from the grains via photon-stimulated desorption. We do not use the same dust spatial distribution as adopted in § 3 for modeling the IR emission because the desorption properties of porous aggregates invoked in § 3 are poorly known, while the desorption properties of compact grains (assumed in eq. [4]) are better quantified (e.g., experimental data are available). Moreover, the dust spatial distribution adopted in § 3 is already oversimplified.

We estimate the number of sodium atoms in the β Pictoris disk from observations of resonantly scattered Na I and infer the time required to produce the circumstellar sodium. Since the ionization potential of sodium is 5.1 eV and β Pic possesses a high UV luminosity, the majority of the circumstellar sodium is expected to be ionized. Fernandez et al. (2006) have written a photoionization code that calculates the densities of neutral and ionized elements from H to Ni, assuming that the β Pic disk is optically thin and has a solar composition; they estimate a sodium neutral fraction of 3×10^{-4} at the disk midplane at 100 AU from the central star. Since the sodium neutral fraction is a function of distance from the stellar ionizing source, we have written a simple

photoionization code which calculates the densities of neutral and ionized carbon and sodium in the disk as a function of position assuming that (1) the gas is optically thin, (2) the disk gas contains only carbon and sodium, (3) ionization of carbon produces the electron density in the disk, (4) the gas temperature, $T_{\text{ex}} = T_{\text{gr}}$, and (5) the circumstellar Na I possesses a density distribution

$$n_{\text{Na I}} = n_o \left[\left(\frac{r}{r_o} \right)^a + \left(\frac{r}{r_o} \right)^b \right]^{-1/2} \exp \left[- \left(\frac{z}{\alpha r} \right)^2 \right] \quad (6)$$

(Brandeker et al. 2004), where $n_o = (1.02 \pm 0.04) \times 10^{-5} \text{ cm}^{-3}$, $r_o = 117 \pm 3 \text{ AU}$, $a = 0.94 \pm 0.06$, $b = 6.32 \pm 0.04$, and $\alpha = 0.168 \pm 0.05$. We use published carbon and sodium photoionization cross sections (Verner et al. 1996) and radiative recombination coefficients (Verner & Ferland 1996; Nahar 1995) to estimate the carbon and sodium densities assuming that the atoms are in ionization equilibrium at each point in the disk. If the gas has a solar carbon/sodium abundance ratio, then the β Pictoris disk possesses 4.6×10^{44} sodium atoms and a time of $\sim 13,000 \text{ yr}$ is required to produce the sodium gas. Models of the breaking of atomic gas in the β Pic disk suggest that the lifetime of an atom in the disk is $\sim 10^4 - 10^5 \text{ yr}$ (Fernandez et al. 2006), suggesting that the sodium gas is in a steady state if it is produced by PSD and braked by Coulomb interactions.

We can estimate the radial dependence of the sodium number density and compare it to that inferred from resonantly scattered sodium observations (Brandeker et al. 2004). If atomic sodium produced in the disk does not migrate radially, then sodium gas generated by photon-stimulated desorption will have a number density distribution

$$n(r, z) \propto \frac{L_{1000-2500 \text{ \AA}}}{4\pi r^2} \epsilon_{\text{Na}} [T_{\text{dust}}(r, z)] \pi a^2 n_{\text{dust}}(r, z), \quad (7)$$

where r is the distance to the central star and $\pi a^2 n_{\text{dust}}$ is the surface area contained in the dust grains. The predicted PSD-produced sodium density distribution at the disk midplane falls too quickly as a function of radius compared to that inferred from observations (see Fig. 5). The rapid fall off in predicted sodium density is the result of the $1/r^2$ dilution of stellar photons. The sodium desorption efficiency is able to partially overcome this effect because $\epsilon_{\text{Na}} [T_{\text{dust}}(r, z)] \propto r$ if the grains are $1 \mu\text{m}$ olivine spheres. However, even taking into account the temperature dependence of the desorption efficiency, our predicted sodium number density falls off too quickly with radius by a factor of r . If PSD produces the bulk of the observed sodium, sodium atoms must migrate to larger distances via radiation pressure.

Our model for the origin of circumstellar sodium could be extended to other atomic species in the β Pictoris disk. At the current time, few laboratory measurements have been made for the photon-stimulated desorption rates of other atoms. Potassium is the only species, other than sodium, for which PSD rates have been measured. Madey et al. (1998) measure cross sections for potassium desorption from Cr_2O_3 surfaces, $Q_{\text{K}} = 2 \times 10^{-20} \text{ cm}^2$ at $2500-3500 \text{ \AA}$ and $2 \times 10^{-19} \text{ cm}^2$ at 1900 \AA . If photon-stimulated desorption of potassium has the same temperature dependence as observed for sodium and the β Pic circumstellar grains have a solar potassium/sodium abundance ratio, $\sigma_{\text{K}} = 2.1 \times 10^{11} \text{ cm}^{-2}$, then we estimate a potassium production rate in the β Pic disk of $3.3 \times 10^{32} \text{ K atoms s}^{-1}$, ~ 3000 times less than the sodium production rate. Atomic potassium has not yet been detected in the

FIG. 5.—Estimated number density distribution of Na I atoms at the midplane of the β Pic disk, inferred from observations of resonantly scattered Na I (Brandeker et al. 2004), is shown with triangles. For comparison, we overplot the number density distributions of Na gas produced via PSD, assuming that the grains are small ($2\pi a < \lambda$; dotted line), large (blackbodies; dashed line), or $1 \mu\text{m}$ olivine spheres (dashed-dotted line). Our models are normalized such that they contain the same mass as the fitted model.

β Pictoris disk and 3σ upper limits on the circumstellar potassium mass have not yet been reported in the literature.

6. DISCUSSION

The simple dust model presented in § 3, consisting of cometary grains with a power-law size distribution and a modified power-law spatial distribution, provides a reasonably good fit to the overall SED and the observed *Spitzer* IRS spectrum. At a first glance, the model has many free parameters: (1) a_{\min} , a_{\max} , and α for the dust size distribution dn/da ; and (2) r_{\min} , r_{\max} , f , r_p , and γ for the dust spatial distribution dn/dr . With general constraints from the disk structure and the dust absorption and emission properties, we actually have only two free parameters, α and f , left (see § 3 for details). In so doing, two assumptions have been made: (1) all grains have the same spatial distribution; and (2) the grains producing the IRS emission spectrum are also responsible for the optical scattered light or their spatial distribution follows that of the dust responsible for the optical scattered light. Admittedly, the former assumption is oversimplified since the response of the grains to the stellar radiation pressure and Poynting-Robertson drag varies with grain size and therefore the simple radial power law is probably not all that representative of the actual grain distribution uniformly with size. To justify the latter assumption, a simultaneous modeling of both the scattered light and IR emission is required. Nevertheless, the general conclusion for the dust (the presence of crystalline silicates and an inner warm dust component in the disk) remains valid.

We have presented a model for the production of circumstellar sodium gas around β Pictoris from dust via photon-stimulated desorption. Our model is able to generate the inferred circumstellar sodium within the residence time of the gas, but it is unable to reproduce the radial dependence of the number density distribution if the sodium atoms do not migrate to larger dis-

tances via radiation pressure. Our estimate for the time required to desorb the observed sodium is a function of (1) the circumstellar grain temperature, (2) the circumstellar gas temperature, and (3) the gas carbon/sodium abundance ratio.

The photon-stimulated desorption rate of sodium from orbiting dust grains is dependent on the grain temperature with sodium more efficiently desorbed from warmer surfaces. Since the bulk of the surface area of the dust is contained in the smallest grains, we estimated the grain temperature assuming that the grains have radii of $a = 1 \mu\text{m}$, are composed of amorphous silicates, and are spherical. However, if the grains are very small ($2\pi a < \lambda$) then the grain temperature, $T_{\text{gr}} = [0.25(R_*/r)^2]^{0.2} T_*$, and the sodium desorption rate, $\Gamma = 3.7 \times 10^{33} \text{ s}^{-1}$, and 4000 yr are required to produce the sodium gas. Or, if the grains are very large (blackbodies), then the grain temperature, $T_{\text{gr}} = [0.25(R_*/r)]^{0.5} T_*$, and the sodium desorption rate, $\Gamma = 2.5 \times 10^{32} \text{ s}^{-1}$, and 58,000 yr are required to produce the sodium gas.

In our simple model, we have assumed that the gas and dust have the same temperatures and have explored the possible range in dust temperature profiles. We also consider how changes in the gas temperature profile affect our estimates for the sodium neutral fraction and therefore the total number of sodium atoms in the disk. The estimated neutral fraction of sodium is weakly dependent on the gas temperature and composition. The radiative recombination coefficients for carbon and sodium decrease by factors of ~ 5 if the gas temperature increases from 10 to 100 or 100 to 1000 K. If the gas has a temperature profile similar to small grains or black bodies (instead of $1 \mu\text{m}$ olivine spheres), then we estimate that the β Pictoris disk possesses either 7.0×10^{44} or 5.4×10^{44} sodium atoms, respectively, similar to the 4.6×10^{44} sodium atoms expected if the gas has the temperature profile expected from $1 \mu\text{m}$ amorphous silicate grains. The assumed abundance of sodium relative to carbon also affects the total number of sodium atoms inferred from the neutral sodium observations. In our model, we have assumed that the gas has a solar composition; however, a recent inventory of the circumstellar atomic gas around β Pictoris suggests that carbon is enriched compared to iron and oxygen by factors of 16 and 18, respectively (Roberge et al. 2006). If the β Pictoris disk is enriched in carbon relative to sodium by a factor of 16, then the disk possesses 1.7×10^{44} sodium atoms, somewhat less than the number inferred if the gas has a solar composition.

7. CONCLUSIONS

We have obtained *Spitzer Space Telescope* IRS spectra of the 12 Myr old debris disk around β Pictoris. We find the following:

1. In addition to the $10 \mu\text{m}$ silicate emission feature originally detected in ground-based observations, we, for the first time, also observe weak crystalline silicate emission features at $28 \mu\text{m}$ and $33.5 \mu\text{m}$.

2. The IRS dust emission spectrum and the overall SED are well reproduced by a dust model consisting of fluffy cometary and crystalline olivine aggregates.

3. No H_2 , [S I], Fe II, or Si II emission is detected. Our 3σ upper limits suggest that $< 17 M_{\oplus} \text{H}_2$ remains in the disk significantly less than the previously reported detections of $\text{H}_2 S(1)$ and $S(0)$ emission. The circumstellar disk around β Pictoris has too little gas to support the formation of giant planets.

4. Some of the observed resonantly scattered Na I, observed at visual wavelengths, may be produced via photon-stimulated desorption; the timescale to generate all of the inferred circumstellar sodium is 13,000 yr, approximately the residence time of the gas in the disk if the gas is braked by Coulomb forces.

We would like to thank A. Brandeker for providing the rotationally broadened PHOENIX stellar atmosphere model for β Pictoris and I. Mann for providing us a preprint of their manuscript on their model for a collisional origin for the β Pic atomic gas prior to publication. We would also like to thank our two anonymous referees and E. Chiang, D. Hollenbach, M. Jura, J. Najita, A. Roberge, N. Samarasingha, W. Sherry, A. Weinberger, K. Willacy, and Y. Wu for their helpful comments and suggestions. Support for this work at NOAO was provided by NASA through the

Spitzer Space Telescope Fellowship Program, through a contract issued by the Jet Propulsion Laboratory, California Institute of Technology under a contract with NASA. Support for this work at the University of Missouri was provided in part by the University of Missouri Summer Research Fellowship, the University of Missouri Research Board, a NASA/*HST* Theory Program grant, and a NASA/*Spitzer* Theory Program grant. Support for this work at the University of Arizona was provided by NASA through contract 1255094 issued by JPL/Caltech.
