ABSTRACT

We study the evolution of the dust temperature of galaxies in the SFR– M_* plane up to $z \sim 2$ using far-infrared and submillimetre observations from the *Herschel* Space Observatory taken as part of the PACS Evolutionary Probe (PEP) and *Herschel* Multi-tiered Extragalactic Survey (HerMES) guaranteed time key programmes. Starting from a sample of galaxies with reliable star-formation rates (SFRs), stellar masses (M_*) and redshift estimates, we grid the SFR– M_* parameter space in several redshift ranges and estimate the mean dust temperature (T_{dust}) of each SFR– M_* – z bin. Dust temperatures are inferred using the stacked far-infrared flux densities (100–500 μm) of our SFR– M_* – z bins. At all redshifts, the dust temperature of galaxies smoothly increases with rest-frame infrared luminosities (L_{IR}), specific SFRs ($SSFR$; i.e., SFR/ M_*), and distances with respect to the main sequence (MS) of the SFR– M_* plane (i.e., $\Delta \log(SSFR)_{\text{MS}} = \log[SSFR(\text{galaxy})/SSFR_{\text{MS}}(M_*, z)]$). The $T_{\text{dust}} - SSFR$ and $T_{\text{dust}} - \Delta \log(SSFR)_{\text{MS}}$ correlations are statistically much more significant than the $T_{\text{dust}} - L_{\text{IR}}$ one. While the slopes of these three correlations are redshift-independent, their normalisations evolve smoothly from $z = 0$ and $z \sim 2$. We convert these results into a recipe to derive T_{dust} from SFR, M_* and z , valid out to $z \sim 2$ and for the stellar mass and SFR range covered by our stacking analysis. The existence of a strong $T_{\text{dust}} - \Delta \log(SSFR)_{\text{MS}}$ correlation provides us with several pieces of information on the dust and gas content of galaxies. Firstly, the slope of the $T_{\text{dust}} - \Delta \log(SSFR)_{\text{MS}}$ correlation can be explained by the increase in the star-formation efficiency (SFE; SFR/ M_{gas}) with $\Delta \log(SSFR)_{\text{MS}}$ as found locally by molecular gas studies. Secondly, at fixed $\Delta \log(SSFR)_{\text{MS}}$, the constant dust temperature observed in galaxies probing wide ranges in SFR and M_* can be explained by an increase or decrease in the number of star-forming regions with comparable SFE enclosed in them. And thirdly, at high redshift, the normalisation towards hotter dust temperature of the $T_{\text{dust}} - \Delta \log(SSFR)_{\text{MS}}$ correlation can be explained by the decrease in the metallicities of galaxies or by the increase in the SFE of MS galaxies. All these results support the hypothesis that the conditions prevailing in the star-forming regions of MS and far-above-MS galaxies are different. MS galaxies have star-forming regions with low SFEs and thus cold dust, while galaxies situated far above the MS seem to be in a starbursting phase characterised by star-forming regions with high SFEs and thus hot dust.

Key words. galaxies: evolution – infrared: galaxies – galaxies: starburst

1. Introduction

Over the last 10 Gyr of lookback time, we observed a clear correlation between the star formation rate (SFR) and the stellar mass (M_*) of star-forming galaxies, $SFR \propto M_*^\alpha$, with $0.5 < \alpha < 1.0$ (Brinchmann et al. 2004; Schiminovich et al. 2007; Noeske et al. 2007; Elbaz et al. 2007; Daddi et al. 2007; Pannella et al. (2009) Pannella Carilli; Dunne et al. 2009; Rodighiero et al. 2010; Oliver et al. 2010; Magdis et al. 2010b; Karim et al. 2011; Mancini et al. 2011; Whitaker et al. 2012). The existence of this so-called “main sequence” (MS) of star formation, whose normalisation declines from $z = 2.5$ to 0, is usually taken as evidence that the bulk of the star-forming galaxy (SFG) population is evolving through a steady mode of star formation, likely sustained by the accretion of cold gas from the intergalactic medium (IGM) or along the

cosmic web (e.g., Dekel et al. 2009). In that picture, occasional major merger events create extreme systems with intense short-lived starbursts, which are offset from the MS of star formation (see e.g., Engel et al. 2010). One strong observational confirmation of this interpretation is that the physical properties of star-forming galaxies are fundamentally linked to their positions with respect to the MS of star formation (i.e., $\Delta \log(SSFR)_{\text{MS}} = \log[SSFR(\text{galaxy})/SSFR_{\text{MS}}(M_*, z)]$). On one hand, galaxies situated on the MS of star formation typically have a disk-like morphology, relatively low SFR surface density (Wuyts et al. 2011b), high ratio of mid-infrared polycyclic aromatic hydrocarbon (PAHs) to far-infrared (FIR) emission (Elbaz et al. 2011; Nordon et al. 2012), and a high C II-to-FIR ratio (Graciá-Carpio et al. 2011). On the other hand, off-MS galaxies (throughout, the term “off-MS galaxies” refers to galaxies situated above the MS) have cusper morphology, higher SFR surface density, smaller PAH-to-FIR ratio and C II-to-FIR ratios. Additionally, on- and off-MS galaxies exhibit fundamental differences in the physical conditions prevailing in their giant molecular clouds (GMCs). MS galaxies have high CO-to- H_2 conversion factors, consistent with star-forming regions that

* *Herschel* is an ESA space observatory with science instruments provided by European-led Principal Investigator consortia and with important participation from NASA.

** Appendices are available in electronic form at <http://www.aanda.org>

are mainly constituted by well virialized GMCs, while off-MS galaxies have low CO-to-H₂ conversion factors, consistent with star-forming regions being constituted by unvirialized GMCs, as observed in local major mergers (Magnelli et al. 2012b; Genzel et al. 2010; Daddi et al. 2010; Magdis et al. 2012).

The task at hand is now to confirm this interpretation of on- and above-MS galaxies, but also to understand the evolutionary scenario linking this population of star-forming galaxies with the large population of massive (i.e., $M_* > 10^{10.5} M_\odot$) and passive (i.e., $\text{SFR} < 1 M_\odot \text{ yr}^{-1}$) galaxies constituting the “red sequence” of the optical colour-magnitude diagram (e.g., Baldry et al. 2004; Faber et al. 2007), and which exists over the full redshift range covered by our study (Fontana et al. 2009).

In this context, we study here the evolution of the dust temperature (T_{dust}) of galaxies in the $\text{SFR}-M_*$ plane up to $z \sim 2$. Such an analysis is crucial, because estimates of T_{dust} provide us with information on the physical conditions prevailing in the star-forming regions of galaxies. In particular, because there is a link between T_{dust} , the radiation field, dust and gas content (via the gas-to-dust ratio), the existence of a positive correlation between dust temperature and $\Delta \log(\text{SSFR})_{\text{MS}}$ would give strong support to the usual interpretation of the MS of star formation. Indeed, MS galaxies with their low SFR surface densities and star-formation efficiencies (SFE, i.e., $\text{SFR}/M_{\text{gas}}$; Saintonge et al. 2012) should have relatively low dust temperatures, while off-MS galaxies with their high SFR surface densities and SFEs should have hotter dust temperatures. In addition, we note that studying variations of the dust temperature in the $\text{SFR}-M_*$ plane is also important to test the accuracy of FIR spectral energy distribution (SED) libraries routinely used to infer total infrared luminosities from monochromatic observations, or used in backward evolutionary models (see e.g., Valiante et al. 2009; Béthermin et al. 2012a).

Estimating T_{dust} for a large sample of galaxies up to $z \sim 2$ was only made possible by the *Herschel* Space Observatory (Pilbratt et al. 2010). With the Photodetector Array Camera and Spectrometer (PACS; Poglitsch et al. 2010) instrument and the Spectral and Photometric Imaging REceiver (SPIRE; Griffin et al. 2010), it is possible to probe the peak of the rest frame FIR/submillimetre emission of galaxies. Here, we use the deepest PACS and SPIRE observations obtained as part of the PACS Evolutionary Probe (PEP¹; Lutz et al. 2011) and the *Herschel* Multi-tiered Extragalactic Survey (HerMES²; Oliver et al. 2012) guaranteed time key programmes covering an area of $\sim 2.0 \text{ deg}^2$. The combination of these PACS and SPIRE observations, together with a careful stacking analysis, provide a very powerful tool to study the FIR/submillimetre SEDs of high-redshift galaxies. In particular, we are able to grid the $\text{SFR}-M_*$ plane in several redshift bins, extending up to $z \sim 2$, and to estimate the dust temperature of each $\text{SFR}-M_*$ - z bin. Based on these estimates, we study the correlation between the dust temperature of galaxies and their infrared luminosities (see also Symeonidis et al. 2013), specific SFRs (SSFR, i.e., SFR/M_*) and their distances with respect to MS of star formation. Then, using a simple model to link T_{dust} with the dust and gas content of galaxies, we ascribe these correlations to variations in the physical conditions prevailing in their star-forming regions.

The paper is structured as follows. In Sect. 2 we present the *Herschel* data and the multi-wavelength sample used in our study. Section 3 presents the method used to infer the evolution of the dust temperature in the $\text{SFR}-M_*$ plane from individual de-

tections and a careful stacking analysis. We discuss the selection function of our sample in Sect. 4.1 and present the variation of the dust temperature in the $\text{SFR}-M_*$ plane in Sect. 4.2. Results³ are discussed in Sect. 5. Finally, we summarise our findings in Sect. 6.

Throughout the paper we use a cosmology with $H_0 = 71 \text{ km s}^{-1} \text{ Mpc}^{-1}$, $\Omega_\Lambda = 0.73$ and $\Omega_M = 0.27$. A Chabrier (2003) initial mass function (IMF) is always assumed.

2. Data

2.1. *Herschel* observations

In order to derive the dust temperature of our galaxies, we use deep PACS 100 and 160 μm and SPIRE 250, 350 and 500 μm observations provided by the *Herschel* Space Observatory. PACS observations were taken as part of the PEP (Lutz et al. 2011) guaranteed time key programme, while the SPIRE observations were taken as part of the *Herschel* Multi-tiered Extragalactic Survey (HerMES; Oliver et al. 2012). The combination of these two sets of observations provides a unique and powerful tool to study the FIR SEDs of galaxies. The PEP and HerMES surveys and data reduction methods are described in Lutz et al. (2011) and Oliver et al. (2012), respectively. Here, we only summarise the properties relevant for our study.

From the PEP and HerMES programmes, we used the observations of the Great Observatories Origins Deep Survey-North (GOODS-N) and -South (GOODS-S) fields and the Cosmological evolution survey (COSMOS) field. *Herschel* flux densities were derived with a point-spread-function-fitting analysis, guided using the position of sources detected in deep 24 μm observations from the Multiband Imaging Photometer (MIPS; Rieke et al. 2004) on board the *Spitzer* Space Observatory. This method has the advantage that it deals in large part with the blending issues encountered in dense fields and provides a straightforward association between MIPS, PACS and SPIRE sources as well as with the IRAC (Infrared Array Camera) sources from which the MIPS-24 μm catalogues were constructed (Magnelli et al. 2011; Le Floch et al. 2009). This MIPS-24 μm -guided extraction is reliable because it has been shown that, even in the deepest PACS/SPIRE field, our MIPS-24 μm catalogues are deep enough to contain almost all PACS/SPIRE sources (Magdis et al. 2011; Lutz et al. 2011; Roseboom et al. 2010; Béthermin et al. 2012b).

In PEP, prior source extraction was performed using the method presented in Magnelli et al. (2009), while in HerMES it was performed using the method presented in Roseboom et al. (2010), both consortia using consistent MIPS-24 μm catalogues. In GOODS-N and -S, we used the GOODS MIPS-24 μm catalogue presented in Magnelli et al. (2009, 2011) reaching a 3σ limit of $20 \mu\text{Jy}$. In COSMOS, we used the deepest MIPS-24 μm catalogue available, reaching a 3σ limit of $45 \mu\text{Jy}$ (Le Floch et al. 2009). The reliability, completeness and contamination of our PACS and SPIRE catalogues were tested via Monte-Carlo simulations. All these properties are given in Berta et al. (2011) and Roseboom et al. (2010, see also Lutz et al. 2011; and Oliver et al. 2012). Table 1 summarises the depths of the PACS and SPIRE catalogues in each of the three fields.

Our IRAC-MIPS-PACS-SPIRE catalogues were cross-matched with our multi-wavelength catalogues (Sect. 2.2), using their IRAC positions and a matching radius of $1''$.

³ A simple IDL code implementing our results is available from the author at http://www.mpe.mpg.de/ir/Research/PEP/Tdust_sSFR. This code predicts the dust temperature and the FIR/mm flux densities of a galaxy from its SFR, M_* and z .

Notes. ^(a) In the deep 160, 250, 350 and 500 μm observations, rms values include confusion noise.

2.2. Multi-wavelength observations

In this study we make extensive use of the large wealth of multi-wavelength observations available for the GOODS-N/S and COSMOS fields. The full set of multi-wavelength data used in our study is described in Wuyts et al. (2011a,b). Here, we only summarise the properties relevant for our study.

In the COSMOS field, we used the public multi-wavelength photometry described in Ilbert et al. (2009) and Gabasch et al. (2008). These catalogues provide photometry in a total of 36 medium and broad bands covering the SEDs from GALEX to IRAC wavelengths. In order to obtain reliable photometric redshifts, stellar masses and SFRs, we restricted these catalogues to $i < 25$ (Wuyts et al. 2011b) and to sources not flagged as problematic in the catalogue of Ilbert et al. (2009), i.e., mostly excluding objects which are nearby bright stars). To identify X-ray AGN we used the *XMM-Newton* catalogue released by Cappelluti et al. (2009). Finally, this multi-wavelength catalogue was restricted to the COSMOS area covered by our deep MIPS-PACS-SPIRE catalogue. This leads to an effective area of 1.9 deg².

In the GOODS-S field we used the K_s (< 24.3 , 5σ) selected FIREWORKS catalogue of Wuyts et al. (2008), which provides photometry in 16 bands from *U* to IRAC wavelengths. X-ray observations were taken from the *Chandra* 2-Ms source catalogue of Luo et al. (2008). In the common region covered by our deep MIPS-PACS-SPIRE observations, our GOODS-S multi-wavelength catalogue covers an effective area of 132 arcmin².

The GOODS-N field also benefits from extensive multi-wavelength coverage. A $z+K$ selected PSF-matched catalogue was created for GOODS-N as part of the PEP survey⁴ (Berta et al. 2010, 2011), with photometry in 16 bands from GALEX to IRAC wavelengths, and a collection of spectroscopic redshifts (mainly from Barger et al. 2008). For uniformity with the GOODS-S catalogue, we restrict our analysis in GOODS-N to sources with $K_s < 24.3$ (3σ). We complemented this multi-wavelength catalogue with the X-ray *Chandra* 2-Ms catalogue of Alexander et al. (2003). In the common region covered by our deep MIPS-PACS-SPIRE observations, our GOODS-N multi-wavelength catalogue covers an effective area of 144 arcmin².

2.3. Spectroscopic and photometric redshifts

We use spectroscopic redshifts coming from a combination of various studies (Cohen et al. 2000; Wirth et al. 2004; Cowie et al. 2004; Le Fèvre et al. 2004; Mignoli et al. 2005; Vanzella et al. 2006; Reddy et al. 2006; Barger et al. 2008; Cimatti et al. 2008; Lilly et al. 2009). For sources with no spectroscopic redshifts, we instead use photometric redshift estimates. Photometric redshifts

were computed using EAZY (Brammer et al. 2008) and all optical and near infrared data available. The quality of our photometric redshifts was tested by comparing them with the spectroscopic redshifts of spectroscopically confirmed galaxies. The median and scatter of $\Delta z/(1+z)$ are (–0.001; 0.015) at $z < 1.5$ and (–0.007; 0.052) at $z > 1.5$. Full details are presented in Wuyts et al. (2011a,b).

2.4. Stellar masses

Stellar masses were calculated by fitting all photometric data with $\lambda_{\text{obs}} \leq 8 \mu\text{m}$ to Bruzual & Charlot (2003) templates using FAST (Fitting and Assessment of Synthetic Templates; Kriek et al. 2009). The rest-frame template error function of Brammer et al. (2008) was also used to down-weight data points with $\lambda_{\text{rest}} \geq 2 \mu\text{m}$. In addition, we used prescriptions from Wuyts et al. (2011b) limiting the Bruzual & Charlot (2003) templates to models with exponentially declining star-formation histories and a minimum e -folding time of 300 Myr. This allows for a much better agreement between SFRs derived from optical-to-near-infrared SED fits and those derived using mid/FIR observations. Full details are given in Wuyts et al. (2011a,b).

2.5. Final sample

Our final sample is K_s -selected in GOODS-N ($K_s < 24.3$, down to a 3σ significance) and GOODS-S ($K_s < 24.3$, down to a 5σ significance) but is i -selected in COSMOS ($i < 25$, down to a 3σ significance). The choice of a i -selected sample for COSMOS was driven by the properties of the observations publicly available for this field. Indeed, the K -selected COSMOS catalogue of McCracken et al. (2010) is relatively shallow (i.e., $K_s < 23$) and is almost fully included in the deep i -selected catalogue used here (McCracken et al. 2010).

Our three multi-wavelength catalogues are not homogeneously selected and not uniform in depth, which naturally translates into different completeness limits in the SFR– M_* plane. This incompleteness could prevent us from drawing strong conclusions on the absolute number density of sources in a given SFR– M_* bin and could also jeopardise the characterisation of their FIR properties. However, we decided here not to apply complex and very uncertain incompleteness corrections for the following reasons.

In the GOODS fields, the selection wavelength of our multi-wavelength catalogues, the K_s band, nearly translates into pure mass completeness limits. Ilbert et al. (2013) have studied the mass completeness limits of a K_s -selected sample with a magnitude limit of $K_s = 24$. They found that, up to $z \sim 2$, such sample was complete down to $M_* = 10^{10} M_\odot$. Therefore, we conclude that with a selection limit of $K_s < 24.3$, our deep GOODS samples should provide us with a complete sample of galaxies with

⁴ Publicly available at <http://www.mpe.mpg.de/ir/Research/PEP/>

$M_* > 10^{10} M_\odot$ and up to $z \sim 2$. In the COSMOS field, the situation is somehow different because the selection wavelength, the i -band, does not translate into pure mass completeness limits. In a given SFR– M_* bin, dusty systems will have fainter i -band magnitudes than unobscured systems, and will be more easily missed by our sample. In this case, the source of incompleteness might correlate with the FIR properties of galaxies and thus bias our results. Wuyts et al. (2011b) studied the region of the SFR– M_* plane strongly affected by incompleteness in the COSMOS $i < 25$ catalogue. They used an ultra-deep WFC3-selected catalogue of the GOODS-S field (down to $H = 27$), and looked at the fraction of galaxies in a given SFR– M_* bin that had $i < 25$ (see Fig. 10 of Wuyts et al. 2011b). At $M_* > 10^{10} M_\odot$ (i.e., the mass range of interest of our study; see Sect. 4.1), they found that the COSMOS $i < 25$ selected catalogue is affected by incompleteness only at $z > 1.5$ and that these large incompleteness mainly affect passive galaxies (completeness $< 30\%$) and not the SFGs situated on and above the MS of star formation (completeness $> 60\%$). From this analysis, we conclude that up to $z \sim 1.5$ and for $M_* > 10^{10} M_\odot$, incompleteness in SFR– M_* bins should not bias the characterisation of their FIR properties. At $z > 1.5$ and $M_* > 10^{10} M_\odot$, incompleteness in the COSMOS field becomes more problematic but should not significantly affect the FIR properties of SFR– M_* bins situated on or above the MS of star formation. We nonetheless verified that our results are reproduced when limiting our analysis to the GOODS fields (Appendix B).

Our final sample contains 8 846, 4 753 and 254 749 sources in the GOODS-N, GOODS-S⁵ and COSMOS fields, respectively. Of these sources, 29%, 26% and 3% have a spectroscopic redshift, the rest photometric redshift estimates. Because we study here the dust properties of galaxies, most of our results rely on the subset of sources with mid/FIR detections. In GOODS-N, GOODS-S and COSMOS, 19%, 28% and 12% of the galaxies have mid- or FIR detections, respectively. Among those sources, 60%, 45% and 11% have a spectroscopic redshift.

2.6. Star-formation rates

We take advantage of the cross-calibrated “ladder of SFR indicators” established in Wuyts et al. (2011a) and used in Wuyts et al. (2011b). This “ladder of SFR indicators” has the advantage of taking the best SFR indicator available for a given galaxy, and establishes a consistent scale across all these indicators. This “ladder” consists of three components: first, a step where galaxies are detected both in the rest-frame UV and the FIR wavelengths covered by the PACS/SPIRE *Herschel* observations; second, a step where galaxies are detected both in the rest-frame UV and the mid-infrared wavelengths (i.e., in the MIPS-24 μm passband) but are undetected in the FIR; third, a step where galaxies are only detected in the rest-frame UV to near infrared wavelengths. In our final sample, 7216, 26 727 and 234 405 sources are in the first, second and third steps of the “ladder of SFR indicators”.

For galaxies with no infrared detection (i.e., galaxies of the third step), we used the SFRs estimated from the best fits obtained with FAST (see Sect. 2.4). In the regime where reference SFR_{UV+IR} are available, these SED-modelled SFRs are fully consistent with those SFR_{UV+IR} estimates (Wuyts et al. 2011a).

For the first and second steps, SFRs were estimated by combining the unobscured and re-emitted emission from young stars. This was done following Kennicutt (1998) and adopting a Chabrier (2003) IMF:

$$SFR_{UV+IR}[M_\odot \text{ yr}^{-1}] = 1.09 \times 10^{-10} (L_{\text{IR}}[L_\odot] + 3.3 \times L_{2800}[L_\odot]), \quad (1)$$

where $L_{2800} \equiv \nu L_\nu(2800 \text{ \AA})$ is computed with FAST from the best-fitting SED (see Sect. 2.4) and the rest-frame infrared luminosity $L_{\text{IR}} \equiv L(8\text{--}1000 \mu\text{m})$ is derived from our mid/FIR observations. For galaxies with FIR detections, L_{IR} was inferred by fitting their FIR flux densities (i.e., PACS and SPIRE) with the SED template library of Dale & Helou (2002, DH), leaving the normalisation of each SED template as a free parameter. Examples of these fits are given in Fig. A.1. We note that using the SED template library of Chary & Elbaz (2001) instead of that of DH to derive L_{IR} (again leaving the normalisation as a free parameter), has no impact on our results. Indeed, the $L_{\text{IR}}^{\text{DH}}/L_{\text{IR}}^{\text{CE01}}$ distribution has a mean value of 1 and a dispersion of 13%. The infrared luminosity of galaxies with only a mid-infrared detection was derived by scaling the SED template of MS galaxies (Elbaz et al. 2011) to their MIPS-24 μm flux densities. This specific SED template was chosen because it provides good 24 μm -to- L_{IR} conversions over a broad range of redshifts for the vast majority of star-forming galaxies (i.e., the MS galaxies; Elbaz et al. 2011). Figure 1 shows the localisation on the SFR– M_* plane of galaxies with FIR+UV, mid-infrared+UV and UV-only detections (i.e., galaxies from the first, second and third step of the ladder, respectively). At $M_* > 10^{10} M_\odot$, galaxies with only mid-infrared+UV detections are mostly situated on or below the MS of star formation. For these galaxies, the use of a 24 μm -to- L_{IR} conversion based on the SED template of MS galaxies should thus be a fairly good approximation. To further check the quality of this approximation, we verified that in all SFR– M_* bins analysed here, the mean infrared luminosities inferred from our FIR stacking analysis (see Sect. 3.2) agrees within 0.3 dex with those inferred from our “ladder of SFR indicators”.

2.7. The main sequence of star formation

Figure 2 shows the number density of sources in the SFR– M_* plane. At $M_* < 10^{11} M_\odot$, we observe that in a given stellar mass bin, most of the galaxies have the same SFR and this characteristic SFR increases with stellar mass. In contrast, at $M_* > 10^{11} M_\odot$, SFRs seems to follow a bimodal distribution; with high SFRs extending the SFR– M_* correlation observed at low stellar masses, and low SFRs forming a “cloud” situated far below this correlation. This bimodal distribution echoes that observed in the optical colour-magnitude diagram (e.g., Baldry et al. 2004; Faber et al. 2007), galaxies with low SFRs corresponding to galaxies from the “red sequence”, and galaxies with high SFRs corresponding to galaxies from the “blue cloud”. Focusing our attention on galaxies with relatively high SFRs, we note that over a large range of stellar masses (i.e., $10^9 < M_* [M_\odot] < 10^{11}$), they follow a clear SFR– M_* correlation. This correlation is called “the main sequence” (MS) of star formation (Noeske et al. 2007).

At $M_* > 10^{10} M_\odot$, there is a good agreement between the MS observed in our sample and those inferred by Rodighiero et al. (2010) or Elbaz et al. (2011). However, taking into account the full range of stellar masses available, we observe a significant difference between our MS and those of Rodighiero et al. (2010) or Elbaz et al. (2011): the slopes of our main sequences change

⁵ Although the GOODS-S and -N multi-wavelength catalogues both correspond to $K_s < 24.3$, the GOODS-S catalogue contains less sources than the GOODS-N catalogue because it includes sources with $> 5\sigma$ while the GOODS-N multi-wavelength catalogue extends down to a 3σ significance.

Fig. 1. Type of SFR indicator used in each SFR– M_* bin. Red colours correspond to SFR– M_* bins in which all galaxies have a FIR (i.e., PACS/SPIRE) detection, i.e., galaxies of the first step of the “ladder of SFR indicator”. Green colours correspond to SFR– M_* bins in which galaxies are not detected in the FIR but are detected in the mid-infrared, i.e., galaxies of the second step of the “ladder of SFR indicator”. Black colours correspond to SFR– M_* bins in which galaxies are only detected in the optical/near-infrared, i.e., galaxies of the third step of the “ladder of SFR indicator”. Short-dashed lines on a white background show the MS of star formation (see Sect. 2.7).

with stellar mass. Such a curved MS, not well described by a simple power-law function, has also been observed at $z \sim 1.25$ by Whitaker et al. (2012). Their main sequence, fitted with a second order polynomial function, agrees with that observed in our sample. Whitaker et al. (2012) argue that the change in the slope of the MS at high stellar masses also corresponds to a change in the intrinsic properties of the galaxies: at high stellar masses, sources are more dust rich and follow a different MS slope than lower mass galaxies with less extinction (traced by the $L_{\text{IR}}/L_{\text{UV}}$ ratio).

At high stellar masses ($M_* > 10^{10} M_{\odot}$), where our results are focused, the slight disagreements observed between our MS and those from the literature could come from several types of uncertainties and/or selection biases (see, e.g., Karim et al. 2011). To study all these uncertainties and selection biases is beyond the scope of this paper. Nevertheless, because we want to investigate variations of the FIR SED properties of galaxies in the SFR– M_* plane, we need to precisely define the localisation of the MS of star formation in each redshift bin. To be self-consistent, we derived the localisation of the MS using our sample. In each redshift bin we proceeded as follows: (i) we fitted a Gaussian function to the $\log(\text{SFR})$ distribution of sources in each stellar mass bin. To avoid being affected by passive galaxies, we excluded from the fit all galaxies with $\text{SFR} < \text{SFR}_{\text{MS}}(M_*^{i-1}) - 3 \times \sigma_{\text{SFR}_{\text{MS}}}(M_*^{i-1})$ and $\sigma_{\text{SFR}_{\text{MS}}}(M_*^{i-1})$ are the localisation and dispersion of the MS in the next lowest stellar mass bin, respectively. (ii) The localisation of the peak and the FWHM of the Gaussian function were then defined as being, respectively, the localisation (i.e., $\text{SFR}_{\text{MS}}(M_*^i)$) and the dispersion (i.e., $\sigma_{\text{SFR}_{\text{MS}}}(M_*^i)$) of the MS in this stellar

Table 2. Main sequence parameters.

Redshift	A_1	A_2	A_3
$0.0 < z < 0.2$	–15.11	2.27	–0.073
$0.2 < z < 0.5$	–20.98	3.66	–0.152
$0.5 < z < 0.8$	–26.96	4.77	–0.199
$0.8 < z < 1.2$	–26.51	4.77	–0.202
$1.2 < z < 1.7$	–13.18	2.18	–0.073
$1.7 < z < 2.3$	–9.62	1.60	–0.050

Notes. $\log(\text{SFR}_{\text{MS}}) = A_1 + A_2 \times \log(M_*) + A_3 \times (\log(M_*))^2$.

mass bin. (iii) We fitted the peak and dispersion of the MS in every stellar mass bin with a second order polynomial function. Results of these fits are shown in Fig. 2 and are summarised in Table 2. In the rest of the paper these lines are used as the MS of star formation. We note that the typical dispersion around these best fits is ~ 0.3 dex, in agreement with previous estimates of the width of the MS of star formation (e.g., Noeske et al. 2007).

Because there is a good overall agreement between our fits and those from the literature at $M_* > 10^{10} M_{\odot}$, the main results of our paper are essentially unchanged if using the MS defined by Elbaz et al. (2011, see Appendix C). However, at $M_* < 10^{10} M_{\odot}$, our fits significantly differ from the very steep MS defined by Elbaz et al. (2011). Although our results seem to be confirmed by Whitaker et al. (2012), further investigations will be required in this stellar mass range.

Fig. 2. Number density of sources in the SFR– M_* plane. Shadings are independent for each stellar mass bin, i.e., the darkest colour indicates the highest number density of sources in the stellar mass bin and not the highest number density of sources in the entire SFR– M_* plane. Short-dashed lines on a white background show the second order polynomial function fitted to MS of star formation (see text for details). Dotted lines present the MS found in Elbaz et al. (2011). The red triple-dot-dashed lines represent the MS found in Rodighiero et al. (2010). The green dot-dashed lines in the $0.8 < z < 1.2$ and $1.2 < z < 1.7$ panels show the MS found in Whitaker et al. (2012) at $z \sim 1.25$.

3. Data analysis

3.1. Dust temperatures

In order to obtain a proxy on the dust temperature of a galaxy, one can fit its PACS/SPIRE flux densities with a single modified blackbody function using the optically thin approximation:

$$S_\nu \propto \frac{\nu^{3+\beta}}{\exp(h\nu/kT_{\text{dust}}) - 1}, \quad (2)$$

where S_ν is the flux density, β is the dust emissivity spectral index and T_{dust} is the dust temperature. However, we decided not to use this method for two reasons. Firstly, a single modified blackbody model cannot fully describe the Wien side of the FIR SED of galaxies, because short wavelength observations are dominated by warmer or transiently heated dust components. Therefore, one would have to exclude from this fitting procedure all flux measurements with, for example, $\lambda_{\text{rest}} < 50 \mu\text{m}$ (see e.g., Hwang et al. 2010; Magnelli et al. 2012a). At high-redshift (e.g., $z > 1.0$), the exclusion of some valuable flux measurements (e.g., PACS-100 μm) would lead to an un-optimised use of our PACS/SPIRE observations. Secondly, while the exclusion of short wavelengths would prevent the fits from being strongly biased by hot dust components, this sharp rest-frame cut would potentially introduce a redshift dependent bias in our dust temperature estimates. Indeed, depending on the redshift of the source, the shortest wavelength kept in the fitting procedure (i.e., with $\lambda_{\text{rest}} > 50 \mu\text{m}$) would be close, or very close, to the wavelength cut, in which case the derived dust temperature would be affected, or strongly affected, by hotter dust components. In the

analysis done in this paper this effect would result in an artificial increase in T_{dust} with redshift of up to ~ 8 K.

For these reasons, we derived the dust temperature of a galaxy using a different approach. (i) We assigned a dust temperature to each DH SED templates by fitting their $z = 0$ simulated PACS/SPIRE flux densities with a single modified blackbody function (see Eq. (2)). (ii) We searched for the DH SED template best-fitting the observed PACS/SPIRE flux densities of the galaxy. (iii) The dust temperature of this galaxy was then defined as being the dust temperature assigned to the corresponding DH SED template. This method makes an optimal use of our PACS/SPIRE observations and does not introduce any redshift biases. We also note that this method introduces a self-consistency between our dust temperature and infrared luminosity estimates for galaxies in the first step of the “ladder of SFR indicators” (see Sect. 2.6). Indeed both estimates are inferred using the DH SED templates best-fitting their PACS/SPIRE flux densities.

To fit the simulated $z = 0$ PACS/SPIRE flux densities of the DH SED templates with a modified blackbody function (i.e., step (i)), we fixed $\beta = 1.5$ and used a standard χ^2 minimisation method. Results of these fits are provided in Table A.1. We note that using $\beta = 1.5$ systematically leads to higher dust temperatures than if using $\beta = 2.0$ (i.e., $\Delta T_{\text{dust}} \sim 4$ K). This $T_{\text{dust}}-\beta$ degeneracy further highlights the limits of a single modified blackbody model in which one has to assume, or fit, an *effective* dust emissivity. Here, we fixed $\beta = 1.5$ because it will provide fair comparisons with most high-redshift studies in which the lack of (sub)mm observations does not allow clear constraints on β

and in which the *effective* dust emissivity is usually fixed to 1.5 (e.g., Magdis et al. 2010a; Chapman et al. 2010; Magnelli et al. 2010, 2012a). We note that leaving β as a free parameter in our fitting procedure leads, qualitatively and quantitatively, to nearly the same $T_{\text{dust}}-\Delta \log(SSFR)_{\text{MS}}$, $T_{\text{dust}}-SSFR$ and $T_{\text{dust}}-L_{\text{IR}}$ relations (Sect. 4.2). However, due to this limitation, we stress that the absolute values of our dust temperature estimates should not be over-interpreted.

To fit the observed PACS/SPIRE flux densities of a galaxy with the DH SED templates (i.e., step (ii)), we used a standard χ^2 minimisation method. Examples of such fits are given in Fig. A.1. The dust temperature of a galaxy was then defined as being the mean dust temperature assigned to the DH SED templates satisfying $\chi^2 < \chi_{\text{min}}^2 + 1$, and from which we also defined the 1σ uncertainties. This definition symmetrises our errors bars. We note, however, that defining the dust temperatures as the best-fit point (i.e., where $\chi^2 = \chi_{\text{min}}^2$) does not change our results.

To ensure that our dust temperature estimates are based on reliable fits and well-sampled FIR SEDs, we used three criteria:

- the reduced χ^2 should be lower than 3 (i.e., typically, $\chi^2 < 6$ for $N_{\text{dof}} = 2$).
- there were at least 3 PACS/SPIRE data points with $S/N > 3$ to be fitted.
- PACS/SPIRE data points with $S/N > 3$ should encompass the peak of the fitted DH SED templates.

In the rest of the paper, we only use and discuss dust temperatures inferred from fits fulfilling these three criteria. In Sect. 4.1 we will see that this restriction does not affect our ability to study the evolution with redshift of the $T_{\text{dust}}-L_{\text{IR}}$, $T_{\text{dust}}-\Delta \log(SSFR)_{\text{MS}}$ and $T_{\text{dust}}-SSFR$ correlations.

3.2. Stacking

In order to probe the dust temperature of galaxies below the SFR completeness limit of our PACS/SPIRE observations we used a stacking analysis. This allows us to obtain the mean flux density of an individually undetected galaxy population by increasing their effective integration time using their stacked images.

3.2.1. The stacking method

Later in this paper, we demonstrate on direct detections (see Sect. 4) that the main parameter controlling the FIR properties of galaxies is their localisation in the SFR– M_* plane. Consequently, the most suitable way to obtain meaningful results for our stacking analysis is to separate galaxies in different SFR– M_* bins. For each redshift bin, our stacking analysis was thus made as follows. First, we gridded the SFR– M_* plane. The size of the SFR– M_* grid was optimised to obtain the best balance between a large enough number of sources per grid cell to improve the noise in the stacked stamps ($\sigma_{\text{stack}} \propto \sqrt{N}$), and a fine enough grid to meaningfully sample the SFR– M_* plane. Then, for each *Herschel* band (100, 160, 250, 350 and 500 μm), we stacked all undetected galaxies in a given SFR– M_* bin using the residual images⁶. Because our galaxy sample was drawn from fields with different PACS/SPIRE depths, the stacked image of each galaxy was weighted by the RMS map of our observations at the position of the source. Finally, the flux density was measured in each stacked image using the PSF-fitting

method described in Sect. 2.1. The mean flux density (F_{bin}) of the SFR– M_* bin was then computed combining the fluxes of undetected and detected sources:

$$S_{\text{bin}} = \frac{m \times S_{\text{stack}} + \sum_{i=1}^n S_i}{n + m}, \quad (3)$$

where S_{stack} is the stacked flux density of the m undetected sources within the SFR– M_* bin in the specific *Herschel* band, and S_i is the flux density of the i th detected source (out of a total of n) within the SFR– M_* bin.

The uncertainty of the mean flux density of a given SFR– M_* bin was computed using a standard bootstrap analysis among detections and non-detections. Allowing for repetitions, we randomly chose $(n + m)$ sources among detections and non-detections in a given SFR– M_* bin and computed their mean flux density. This was repeated 100 times and the flux uncertainty of the SFR– M_* bin was defined as the standard deviation of these 100 flux densities. This uncertainty has the advantage of taking into account both measurement errors and the dispersion in the galaxy population.

From the mean PACS/SPIRE flux densities in each SFR– M_* bin we derived a mean dust temperature using the same procedure as for galaxies with individual FIR detections and applying the same criteria to assess the accuracy of the T_{dust} estimates (see Sect. 3.1). In addition, we rejected dust temperature estimates in SFR– M_* bins where the infrared luminosity inferred from the stacking analysis did not agree within 0.3 dex with the infrared luminosity inferred using our “ladder of SFR indicators”. This additional criterion rejects SFR– M_* bins with potentially wrong T_{dust} estimates and ensure a self consistency with our “ladder of SFR indicators” (see Sect. 4.1 and Fig. 4).

We note that we find similar results if we repeat the stacking analysis using the original PACS/SPIRE maps and combining all sources in a given SFR– M_* bin, regardless of whether they are individually detected or not.

3.2.2. The effect of clustering

While very powerful, a stacking analysis has some limitations. In particular, it assumes implicitly that the stacked sources are not clustered, neither within themselves (auto-correlation), nor with sources not included in the stacked sample (cross-correlation). However, this assumption is not always verified and if, for example, all stacked galaxies are situated in the vicinity of a bright infrared source, their inferred stacked flux density will be systematically overestimated. Because our dust temperatures would be strongly affected by such biases, the effect of clustering on our stacking analysis must be investigated.

In the recent literature many techniques have been used to estimate the effect of clustering on stacked flux densities. For example, Béthermin et al. (2012b) used an approach based on simulations where the clustering effect is estimated by comparing the mean flux density measured by stacking a simulated map to the mean flux density in the corresponding mock catalogue. Here, we adopted the same approach and evaluated the clustering effect using simulated maps of our fields.

The main principle of this method is to construct PACS and SPIRE simulated maps reproducing as well as possible the intrinsic FIR emission of the Universe in our fields. To do so, we used our multi-wavelength galaxy sample which contains the positions, redshifts and SFRs of at least all galaxies with $M_* > 10^{10} M_{\odot}$ and $z < 2$ (see Sect. 2.5). This galaxy sample is particularly suitable because in term of intrinsic FIR emission, it contains sources with SFRs a factor at least 10 below the

⁶ Original maps from which we removed all 3σ detections.

SFR thresholds equivalent to the noise level of our FIR images. This ensures that simulated PACS and SPIRE maps created from this galaxy sample would contain all galaxies that can introduce some clustering biases in our FIR stacking analysis.

From the redshift and SFR of each galaxy in our multi-wavelength sample, we inferred their simulated PACS and SPIRE flux densities using the MS galaxy SED template of [Elbaz et al. \(2011\)](#). The use of this particular SED template is appropriate because it was built to reproduce the mean FIR emission of main sequence star-forming galaxies ([Elbaz et al. 2011](#)). Of course, real SEDs of star-forming galaxies present variations around this mean SED. However, there are always at least 100 simulated sources in SFR– M_* – z bins where T_{dust} is estimated through stacking such that the central-limit theorem applies.

From the position and simulated FIR flux densities of each galaxy, we then created PACS and SPIRE simulated maps using the appropriate pixel scales and PSFs. Because the real stacking analysis was done on residual maps, galaxies with direct FIR detections were not introduced in these simulated “residual” maps. We note that these simulations are of course not perfect, but could be considered as the best representation we have so far of the intrinsic FIR properties of our fields, in particular of their clustering properties.

Using these simulated “residual” maps, we estimated the effect of clustering on our stacked samples. For each SFR– M_* – z bin and for each PACS and SPIRE band, this was done as follows:

- (i) we stacked in the real residual maps the m sources of this specific bin and measured the PACS and SPIRE stacked flux densities (S_{stack});
- (ii) we stacked in the simulated “residual” maps the same m sources and measured their stacked simulated PACS and SPIRE flux densities ($S_{\text{stack}}^{\text{simu}}$);
- (iii) we computed, using the simulated PACS/SPIRE catalogues, the expected stacked simulated PACS and SPIRE flux densities ($S_{\text{stack}}^{\text{expected}}$);
- (iv) we compared $S_{\text{stack}}^{\text{simu}}$ and $S_{\text{stack}}^{\text{expected}}$ and if $\text{ABS}((S_{\text{stack}}^{\text{simu}} - S_{\text{stack}}^{\text{expected}})/S_{\text{stack}}^{\text{expected}}) > 0.5$ then the real stacked flux densities were identified as being potentially affected by clustering. This 0.5 value was empirically defined as being the threshold above which the effect of clustering would not be captured within the flux uncertainties of our typical $S/N \sim 3$ stacked photometries.

Dust temperatures estimated using one of these affected stacked flux densities were flagged and *not used in the rest of our analysis*. We adopted this very conservative approach knowing the limits of our simulations: if one band is affected by clustering, the other bands might also be affected, even if formally there are not identified as such by our simulations. In the stellar mass range of our study, $M_* > 10^{10} M_{\odot}$, and in each of our redshift bins, fewer than 10 SFR– M_* bins are rejected due to this clustering effect. Most of these SFR– M_* bins are situated in the border between bins with low SFRs, and thus no stacked detections, and bins with high SFRs and thus clear stacked detections.

We stress that these tests are not perfect, but we believe that they are better than any other tests that would treat our sample in a redshift independent way. The reliability of these tests is strengthened by the accuracy of our simulated “residual” maps. Indeed, in SFR– M_* – z bins not affected by clustering and with $S_{\text{stack}}/N_{\text{stack}} > 3$, the $\log(S_{\text{stack}}^{\text{simu}}/S_{\text{stack}})$ values follow a Gaussian distribution with a median value of 0.1 dex and a dispersion of 0.1 dex. We note that even though our simulated maps appear to

be accurate, we did not use the $S_{\text{stack}}^{\text{simu}}/S_{\text{stack}}^{\text{expected}}$ ratio as a correction factor for S_{stack} because the uncertainties on these correcting factors (at least ~ 0.1 dex from the $\log(S_{\text{stack}}^{\text{simu}}/S_{\text{stack}})$ dispersion) would be equivalent to the flux uncertainties of our typical $S/N \sim 3$ stacked fluxes.

3.2.3. The effect of averaging on dust temperature

Finally, we tested whether or not the stacking procedure used to produce the mean FIR SED of a galaxy population delivers reliable mean T_{dust} estimates, given that the galaxies follow a particular L_{IR} and T_{dust} distribution. In other words, is the mean dust temperature of a galaxy population computed from individual dust temperature measurements in agreement with the value inferred from their mean FIR SED? To perform this test, we assumed that the FIR SEDs of a galaxy population are well described by the DH SED template library and that this galaxy population follows the local $T_{\text{dust}}-L_{\text{IR}}$ correlation ([Chapman et al. 2003](#), see also [Dunne et al. 2000](#)).

We first created a simulated catalogue containing 1000 galaxies. The redshift of each galaxy was randomly selected using a uniform redshift distribution within our redshift bins (i.e., $0 < z < 0.2$, $0.2 < z < 0.5$...), the infrared luminosity from uniform logarithmic distribution with $10 < \log(L_{\text{IR}}[L_{\odot}]) < 13$, and T_{dust} from a Gaussian distribution reproducing the local $T_{\text{dust}}-L_{\text{IR}}$ correlation and its dispersion ([Chapman et al. 2003](#)). Next, we assign to each simulated galaxy the appropriate DH SED template, based on our pairing between dust temperature and DH templates (see Sect. 3.1). Finally, simulated galaxies are separated in L_{IR} bins of 0.15 dex, the typical size of our SFR– M_* bins, and in each L_{IR} bin we compute the mean T_{dust} value in two ways: (1) using the mean PACS/SPIRE flux densities, and (2) directly averaging the values of T_{dust} assigned to each galaxy. The two sets of mean T_{dust} values are compared, as shown in Fig. 3 for two redshift bins.

We find that the mean dust temperatures and those inferred from the mean FIR SEDs only differ by a few degrees. Moreover, we do not find any strong systematic biases as a function of either L_{IR} or redshift, and therefore conclude that the dust temperatures inferred from the stacked mean FIR SEDs accurately represent the underlying galaxy population. We note that a flattening of the $T_{\text{dust}}-L_{\text{IR}}$ correlation with redshift as found in [Symeonidis et al. \(2013\)](#) does not change our results, as they do not strongly depend on the slope of the $T_{\text{dust}}-L_{\text{IR}}$ correlation but rather on its dispersion.

4. Results

4.1. The SFR– M_* – z parameter space

We have seen in Sect. 2.7 that incompleteness in our initial sample should not affect our ability to study variations of T_{dust} in the SFR– M_* plane. However, one additional source of incompleteness might still affect our study: our ability to derive accurate T_{dust} for each SFR– M_* – z bin. Therefore, before presenting the variations of dust temperature in the SFR– M_* plane, we examine which regions of the SFR– M_* – z parameter space have accurate T_{dust} estimates from individual detections, and from our stacking analysis. The left panel of Fig. 4 presents the fraction of sources (i.e., the completeness) in a given SFR– M_* – z bin with *individual* FIR detections and *accurate* dust temperature estimates (see Sect. 3.1). The right panel of Fig. 4 presents the same quantity for the stacking analysis. There, each SFR– M_* – z bin corresponds to only one set of stacked FIR flux densities and

Fig. 3. Simulations revealing the effects of stacking on our dust temperature estimates. Empty black circles represent our 1000 simulated galaxies following the $T_{\text{dust}}-L_{\text{IR}}$ correlation of Chapman et al. (2003). Large filled orange circles represent the mean dust temperature of galaxies in a given infrared luminosity bin. Large filled red stars represent the dust temperature inferred from the mean PACS/SPIRE flux densities of galaxies in a given infrared luminosity bin. The Chapman et al. (2003) derivation of the median and interquartile range of the $T_{\text{dust}}-L_{\text{IR}}$ relation observed at $z \sim 0$ is shown by solid and dash-dotted lines, linearly extrapolated to $10^{13} L_{\odot}$. In the *top panel*, simulated galaxies are in the $0.2 < z < 0.5$ redshift bin, while in the *bottom panel* simulated galaxies are in the $1.2 < z < 1.7$ redshift bin.

thus one dust temperature estimate. Consequently, in the right panel of Fig. 4, the completeness can only take two different values: 0% if the dust temperature estimate is inaccurate; 100% if the dust temperature estimate is accurate.

For galaxies individually detected in our PACS/SPIRE images reliable dust temperatures are only obtained in SFR– M_* bins situated above a given SFR threshold. This SFR threshold increases with redshift and translates into a threshold in L_{IR} . If keeping above this threshold, the $T_{\text{dust}}-L_{\text{IR}}$ relation can therefore be studied without biases. However, because the region of the SFR– M_* plane with high completeness in all redshift bins is relatively small, we conclude that the PACS/SPIRE detections are not sufficient to draw strong conclusions on the redshift evolution of the $T_{\text{dust}}-L_{\text{IR}}$ relation. The prognostic for using the PACS/SPIRE detections to study the $T_{\text{dust}}-\Delta \log(SSFR)_{\text{MS}}$ and $T_{\text{dust}}-SSFR$ relations is even worse. Indeed, in all but our first redshift bin, the dust temperature of MS galaxies is only constrained for those with very high stellar masses. The stacking analysis is therefore required.

The right panel of Fig. 4 illustrates the regions of the SFR– M_* – z parameter space reachable with our stacking analysis. The SFR completeness limit of the stacking analysis depends on the stellar masses: it is nearly constant at intermediate stellar masses, but increases at both very high and low stellar masses. These variations are caused by changes in the number of galaxies in the SFR– M_* bins. At fixed SFR, the SFR– M_* bins with low stellar masses are located above the MS and thus contain far fewer sources than those with intermediate stellar masses and which probe the bulk of the MS. Similarly, at fixed SFR, SFR– M_* bins with very high stellar masses are located below the MS of star formation and thus contain far fewer sources than those with intermediate stellar masses and which probe the MS of star formation. The decrease in the number of sources in these SFR– M_* bins naturally translates into higher SFR completeness limits in our stacking analysis ($\sigma_{\text{stack}} \propto \sqrt{N_{\text{sources}}}$). Due to the very strong increase in the SFR completeness limits at low stellar masses, we restrict our study to galaxies with $M_* > 10^{10} M_{\odot}$.

Figure 5 illustrates our ability to study the variations of T_{dust} in the SFR– M_* plane for galaxies with $M_* > 10^{10} M_{\odot}$ through the stacking analysis. In these figures we show the fraction of SFR– M_* bins with reliable dust temperature estimates (see Sect. 3.1) as a function of their $\Delta \log(SSFR)_{\text{MS}}$, L_{IR} and SSFR. In the rest of the paper, we consider that the mean dust temperature in a given $\Delta \log(SSFR)_{\text{MS}}$, L_{IR} or SSFR bin is fully constrained if and only if the completeness in this bin is at least 80%.

In each redshift bin, our stacking analysis allows us to fully constrain the mean dust temperature of galaxies situated on and above the MS of star formation at such a completeness level, and therefore to reliably study the redshift evolution of the $T_{\text{dust}}-\Delta \log(SSFR)_{\text{MS}}$ correlation. The stacking analysis furthermore allows us to constrain the mean dust temperature of galaxies over more than an order of magnitude in L_{IR} and SSFR. However, because our L_{IR} and SSFR completeness limits increase with redshift, the L_{IR} and SSFR ranges probed in our different redshift bins do not fully overlap. Thus while we can robustly constrain the $T_{\text{dust}}-L_{\text{IR}}$ and $T_{\text{dust}}-SSFR$ correlations in all our redshift bins, the study of their evolution with redshift is somewhat limited.

4.2. Dust temperature in the SFR– M_* – z parameter space

Figures 6 and 7 show the mean dust temperatures of galaxies in our SFR– M_* – z bins as inferred using individual detections and our stacking analysis, respectively. In these figures, we only used accurate dust temperature estimates (see Sect. 3.1). For the detections, the black contours indicate regions where at least 50% of the galaxies in a given SFR– M_* bin have reliable dust temperature estimates. Outside these regions, results have to be treated with caution, because they rely on very incomplete samples. Both figures clearly show that in any given redshift bin, T_{dust} does not evolve simply with their SFR or with their stellar mass, but instead with a combination of these two parameters. In other words, tracks of iso-dust temperature are not characterised by vertical or horizontal lines, but instead by diagonal lines.

To investigate which parameter best correlates with the dust temperature of galaxies, we show in Figs. 8–10 the variation of the dust temperature of galaxies as function of their $\Delta \log(SSFR)_{\text{MS}}$, L_{IR} and SSFR, respectively. Because individual detections do not probe large ranges in the $\Delta \log(SSFR)_{\text{MS}}$, L_{IR} and SSFR parameter spaces, here we only rely on dust temperatures inferred from our stacking analysis. In these figures, the dashed regions indicate regimes of parameter space affected

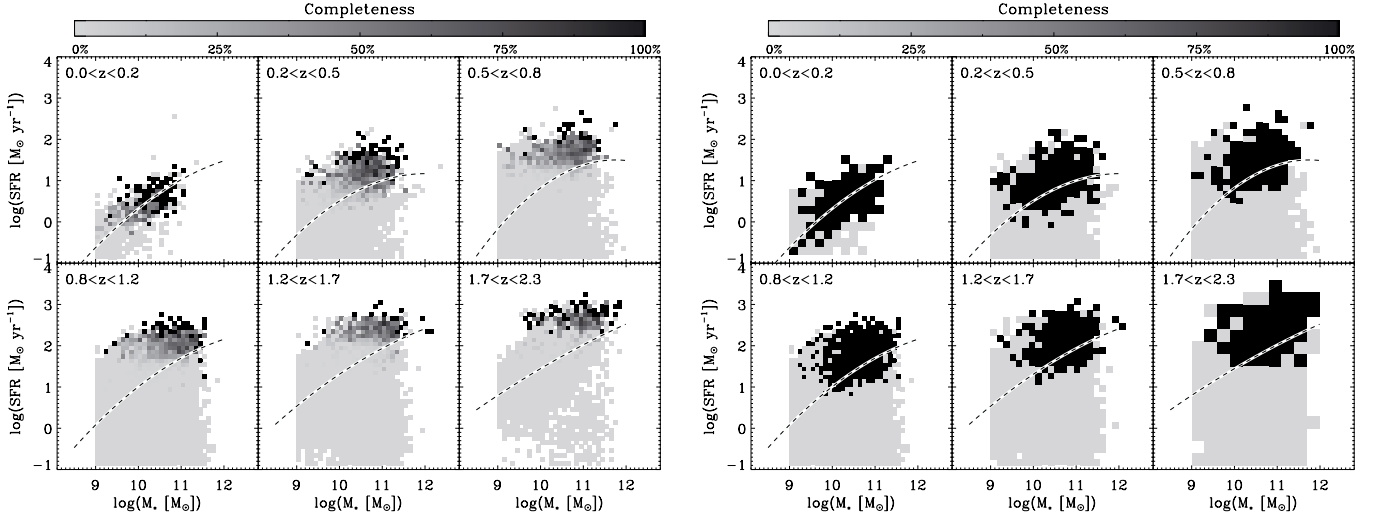

Fig. 4. *Left:* fraction of sources (i.e., completeness) in a given SFR– M_* bin with individual PACS/SPIRE detections and accurate dust temperature estimates. *Right:* SFR– M_* bins with accurate dust temperature estimates (i.e., completeness =100%), as inferred from our stacking analysis. Because each SFR– M_* bin corresponds to only one set of stacked FIR flux densities and thus one dust temperature estimate, here the completeness can only take two different values: 0% if the dust temperature estimate is inaccurate; 100% if the dust temperature estimate is accurate. The quality of our dust temperature estimates were evaluated using criteria presented in Sects. 3.1 and 3.2. Short-dashed lines on a white background show the MS of star formation.

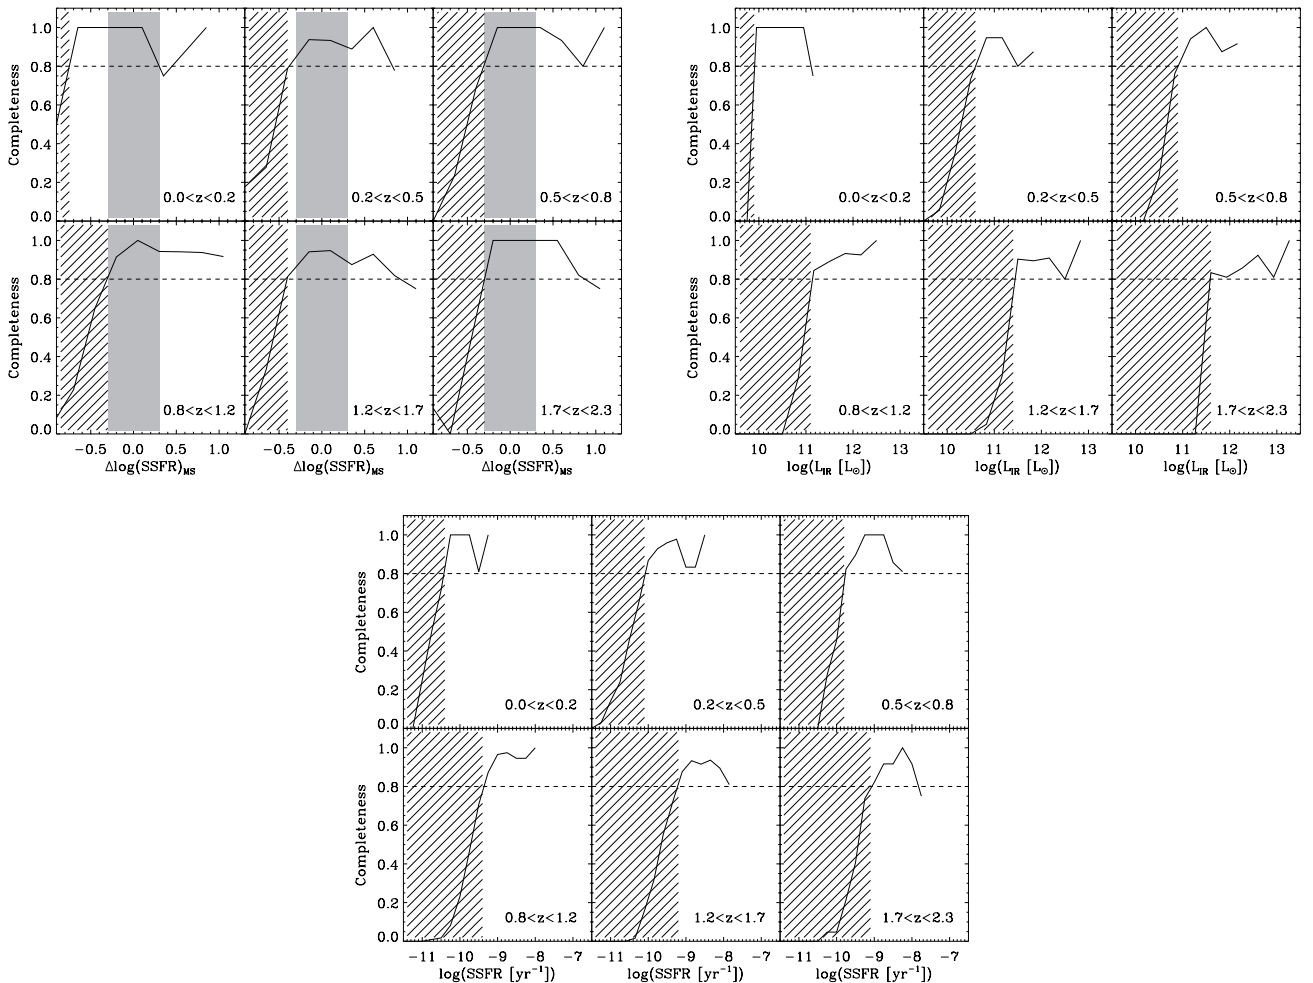

Fig. 5. Fraction of SFR– M_* bins with $M_* > 10^{10} M_\odot$ and with accurate dust temperature estimates (see Sect. 3.1) in our stacking analysis as function of their $\Delta \log(SSFR)_{MS}$ (top left panel), L_{IR} (top right panel) or SSFR (bottom panel). Horizontal dashed lines represent the 80% completeness limits. Hatched areas represent the regions of parameter space affected by incompleteness, i.e., where less than 80% of our SFR– M_* bins have accurate dust temperature estimates. Shaded regions in the top left panel show the location and dispersion of the MS of star formation.

Fig. 6. Mean dust temperature of galaxies in the SFR– M_* plane as found from individual detections. Short-dashed lines on a white background show the MS of star formation. Solid contours indicate the regions in which at least 50% of the galaxies have accurate dust temperature estimates. Outside these regions results have to be treated with caution, because they are inferred from incomplete samples. Tracks of iso-dust-temperature are not characterised by vertical or horizontal lines but instead by approximately diagonal lines.

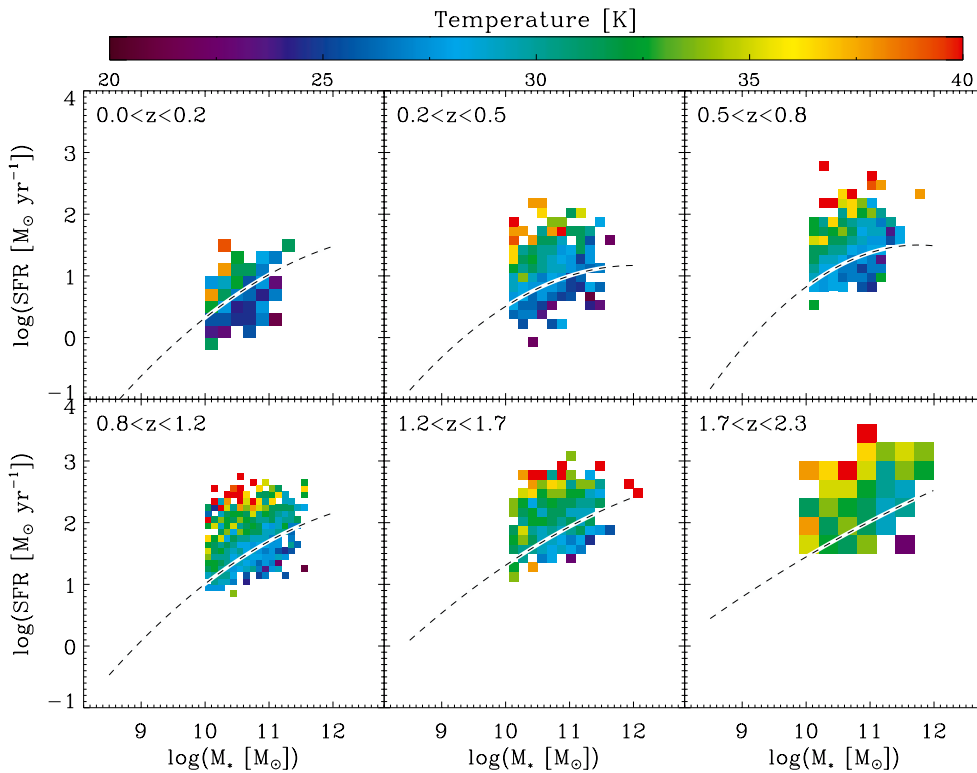

Fig. 7. Mean dust temperature of galaxies in the SFR– M_* plane as found from our stacking analysis. Short-dashed lines on a white background show the MS of star formation. Tracks of iso-dust-temperature are not characterised by vertical or horizontal lines but instead by approximately diagonal lines.

by large incompleteness as defined in Fig. 5. Constraints in these regions have to be treated with caution.

In each redshift interval, the dust temperature of galaxies better correlates with their $\Delta \log(SSFR)_{MS}$ and SSFR values than with L_{IR} , as revealed by the Spearman correlation factors of the relations between T_{dust} and these three quantities. The Spearman correlation factors of the T_{dust} – $\Delta \log(SSFR)_{MS}$ and T_{dust} –SSFR correlations are statically equivalent in all our redshift bins. From this analysis we can conclude that the dust

temperature of galaxies is more fundamentally linked to their SSFR and $\Delta \log(SSFR)_{MS}$ than to their L_{IR} .

To go further in our understanding of the T_{dust} – L_{IR} , T_{dust} – $\Delta \log(SSFR)_{MS}$ and T_{dust} –SSFR correlations, we also study their redshift evolution. We first fit the T_{dust} – L_{IR} , T_{dust} – $\Delta \log(SSFR)_{MS}$ and the T_{dust} –SSFR correlations in the $0.2 < z < 0.5$ redshift bin, where for all three correlations the Spearman correlation factor is highest, and the region of parameter space reliably probed is largest. The T_{dust} – L_{IR} correlation

Fig. 8. Dust temperature of galaxies as a function of $\Delta \log(SSFR)_{MS}$, as derived from our stacking analysis. Empty circles show results for SFR- M_* bins with low stellar masses, i.e., $M_* < 10^{10.5}, 10^{10.7}, 10^{10.7}, 10^{10.8}, 10^{10.8}$ and $10^{10.9} M_\odot$ in our $0 < z < 0.2, 0.2 < z < 0.5, 0.5 < z < 0.8, 0.8 < z < 1.2, 1.2 < z < 1.7$ and $1.7 < z < 2.3$ bins, respectively. Filled circles show results for SFR- M_* bins with high stellar masses. In each panel, we give the Spearman correlation factor derived from our data points. Dashed red lines correspond to a linear fit to the data points of the $0.2 < z < 0.5$ redshift bin. Triple-dot-dashed green lines represent predictions inferred from the variations of the SFE with $\Delta \log(SSFR)_{MS}$ and variations of the metallicity with redshift (see Eqs. (10) and (11)). Long-dashed light blue lines represent predictions inferred from the variations of the SFE with $\Delta \log(SSFR)_{MS}$ and variations of the normalisation of the SFE- $\Delta \log(SSFR)_{MS}$ relation with redshift (see Eqs. (10) and (13)). Dot-dashed dark blue lines represent predictions inferred from the variations of the SFE with $\Delta \log(SSFR)_{MS}$, and variations with redshift of the normalisation of the SFE- $\Delta \log(SSFR)_{MS}$ relation and of the metallicity (see Eqs. (10) and (14)). Hatched areas represented the regions of parameter space affected by incompleteness (see text and Fig. 5). Vertical solid and dot-dashed lines show the localisation and width of the MS of star formation. The lower panel of each redshift bin shows the offset between the median dust temperature of our data points and the red dashed line, in bins of 0.2 dex.

Fig. 9. Dust temperature of galaxies as a function of L_{IR} , as derived from our stacking analysis. In each panel, we give the Spearman correlation factor derived from our data points. Red dashed lines correspond to a second order polynomial fit to the data points of the $0.2 < z < 0.5$ redshift bin. Hatched areas represented the regions of parameter space affected by incompleteness (see text and Fig. 5). The Chapman et al. (2003) derivation of the median and interquartile range of the relation observed at $z \sim 0$ is shown by solid and dot-dashed lines, linearly extrapolated to $10^{13} L_\odot$. The lower panel of each redshift bin shows the offset between the median dust temperature of our data points and the dashed red line, in bins of 0.3 dex.

Fig. 10. Dust temperature of galaxies as a function of SSFR, as derived from our stacking analysis. In each panel, we give the Spearman correlation factor derived from our data points. Dashed red lines correspond to a linear fit to the data points of the $0.2 < z < 0.5$ redshift bin. Dot-dashed orange lines show the redshift evolution of the $T_{\text{dust}}\text{--SSFR}$ relation, fixing its slope to that observed in the $0.2 < z < 0.5$ redshift bin (i.e., slope of the dashed red line) and fitting its zero point with a $A \times (1+z)^B$ function (see Eq. (5)). Hatched areas represent the regions of parameter space affected by incompleteness (see text and Fig. 5). The lower panel of each redshift bin shows the offset between the median dust temperature of our data points and the dashed red line, in bins of 0.3 dex.

is fitted with a second order polynomial function, while the $T_{\text{dust}}\text{--}\Delta \log(\text{SSFR})_{\text{MS}}$ and the $T_{\text{dust}}\text{--SSFR}$ correlations are fitted with linear functions. We note that Chapman et al. (2003) described the $T_{\text{dust}}\text{--}L_{\text{IR}}$ correlation using a double power-law function instead of a second order polynomial. However, this specific choice does not affect our results.

Once these best-fitting relations are established in the most reliable redshift interval, the fits are compared with the other intervals to track the redshift evolution of the normalisation of these relations. The $T_{\text{dust}}\text{--}\Delta \log(\text{SSFR})_{\text{MS}}$ correlation seems to smoothly evolve from $z = 0$ to $z = 2.3$, with dust temperatures increasing with redshift at fixed $\Delta \log(\text{SSFR})_{\text{MS}}$. Similarly, the $T_{\text{dust}}\text{--SSFR}$ correlation smoothly evolves up to $z \sim 2$, with the dust temperature of galaxies evolves towards colder values at high redshift at fixed SSFR. Finally, the $T_{\text{dust}}\text{--}L_{\text{IR}}$ correlation slightly evolves from $z = 0$ to $z = 2.3$, with high redshift galaxies exhibiting colder dust temperatures than their low redshift counterparts. We note that the $T_{\text{dust}}\text{--}L_{\text{IR}}$ correlations found here are consistent with those of Symeonidis et al. (2013) which are based on individual detections.

To reproduce the redshift evolution of the $T_{\text{dust}}\text{--}\Delta \log(\text{SSFR})_{\text{MS}}$ and $T_{\text{dust}}\text{--SSFR}$ relations, we fixed their slopes to those measured in the $0.2 < z < 0.5$ redshift bin and fitted their zero points using an $A \times (1+z)^B$ function. For the $T_{\text{dust}}\text{--}\Delta \log(\text{SSFR})_{\text{MS}}$ relation, we find

$$T_{\text{dust}} = 26.5 \times (1+z)^{0.18} + 6.5 \times \Delta \log(\text{SSFR})_{\text{MS}}, \quad (4)$$

while for the $T_{\text{dust}}\text{--SSFR}$ relation we find

$$T_{\text{dust}} = 98 \times (1+z)^{-0.065} + 6.9 \times \log(\text{SSFR}). \quad (5)$$

Because the $T_{\text{dust}}\text{--}\Delta \log(\text{SSFR})_{\text{MS}}$ and $T_{\text{dust}}\text{--SSFR}$ correlations are statistically very significant, they supersede the $T_{\text{dust}}\text{--}L_{\text{IR}}$ correlation classically used to predict the dust temperature of galaxies. In particular, Eq. (5), which only relies on the stellar masses, SFRs and redshifts of galaxies, could be used to improve

FIR predictions from semi-analytical or backward evolutionary models.

5. Discussion

Using deep *Herschel* observations and a careful stacking analysis, we found, over a broad range of redshift, that the dust temperature of galaxies better correlates with their SSFRs or their $\Delta \log(\text{SSFR})_{\text{MS}}$ values than with L_{IR} . This finding supersedes the $T_{\text{dust}}\text{--}L_{\text{IR}}$ correlation classically implemented in FIR SED template libraries. These results also provide us with important information on the conditions prevailing in the star-forming regions of galaxies and the evolution of these conditions as a function of redshift.

5.1. T_{dust} variations in the SFR– M_* plane at fixed redshift

In a given redshift bin, our results unambiguously reveal that the dust temperature of galaxies correlates with their SSFR or equivalently with their $\Delta \log(\text{SSFR})_{\text{MS}}$ (at a given redshift, SSFR and $\Delta \log(\text{SSFR})_{\text{MS}}$ are nearly equivalent because the slope of the MS is close to unity; $\log(\text{SFR}_{\text{MS}}) = \log(M_*) + C(z)$, so $\log[\text{SSFR}_{\text{MS}}(M_*, z)] = C(z)$ and $\Delta \log(\text{SSFR})_{\text{MS}} = \log[\text{SSFR}(\text{galaxy})] - C(z)$). The universality of the dust temperature at fixed $\Delta \log(\text{SSFR})_{\text{MS}}$ indicates that galaxies with a given $\Delta \log(\text{SSFR})_{\text{MS}}$ are composed of the same type of star-forming regions and that the increase in SFR with stellar mass is only due to an increase in the number of such star-forming regions. In that picture, galaxies situated on the MS are dominated by star-forming regions with relatively low radiation fields and thus relatively cold dust temperatures, while galaxies situated far above the MS are dominated by star-forming regions exposed to extremely high radiation fields, yielding hotter dust temperatures.

As a first approximation, and in the case where star-forming regions are optically thick in the rest-frame UV and optically thin in the rest-frame FIR, one can link the dust temperature of a galaxy to the radiation field seen per unit of dust mass:

$$L_{\text{IR}}/M_{\text{dust}} \propto T_{\text{dust}}^{4+\beta}, \quad (6)$$

i.e., the dust temperature of a galaxy increases if the input radiation is delivered to fewer dust grains. In that approximation, one can then link the dust temperature of galaxies to the radiation field seen per unit of gas mass (i.e., $L_{\text{IR}}/M_{\text{gas}}$), via the gas-to-dust ratio relation:

$$\log(M_{\text{gas}}/M_{\text{dust}}) = -0.85 \times \mu + 9.4, \quad (7)$$

where μ is the metallicity (Leroy et al. 2011). At fixed stellar mass (equivalent to fixed metallicity, assuming a mass-metallicity relation), the smooth increase in dust temperature with $\Delta \log(SSFR)_{\text{MS}}$ could thus be interpreted as an increase in $L_{\text{IR}}/M_{\text{gas}}$, i.e., the star-formation efficiency (SFE) of galaxies. Using direct molecular gas observations, several studies have effectively observed a significant increase in the SFE with $\Delta \log(SSFR)_{\text{MS}}$ (Saintonge et al. 2011a,b, 2012; Genzel et al. 2010; Daddi et al. 2010). In their local Universe sample, Saintonge et al. (2012) found

$$\log(\text{SFE}) = 0.5 \times \Delta \log(SSFR)_{\text{MS}} + C_1, \quad (8)$$

for $-0.5 < \Delta \log(SSFR)_{\text{MS}} < 1$. Combining Eqs. (6)–(8), assuming that $\Delta \log(SSFR)_{\text{MS}}$ and μ are independent, and assuming that the gas-to-dust relation of Leroy et al. (2011) holds at high redshift, we can thus predict from the gas phase the evolution of the dust temperature as a function of $\Delta \log(SSFR)_{\text{MS}}$ and μ :

$$\log(T_{\text{dust}}) = 0.5 \times 1/(4 + \beta) \times \Delta \log(SSFR)_{\text{MS}} - 0.85 \times 1/(4 + \beta) \times \mu + C_2. \quad (9)$$

Over the range of stellar masses probed by our sample (i.e., ~ 1.5 dex), we expect, based on the mass-metallicity relation, an increase in metallicity of ~ 0.25 dex (~ 0.4 dex) at $z = 0$ ($z = 2$) (Tremonti et al. 2004; $z = 2$, Erb et al. 2006; see also Genzel et al. 2012). At fixed $\Delta \log(SSFR)_{\text{MS}}$, the dust temperatures of galaxies with high stellar masses should thus be lower by a factor 1.09 (1.15) than those of galaxies with low stellar masses (see Eq. (9) and assuming $\beta = 1.5$). On the MS, this corresponds to a dust temperature variation of ~ 2 K (5 K). Differentiating galaxies by stellar masses in Fig. 8 supports this prediction. As a consequence, we can assume that:

$$\log(T_{\text{dust}}) = 0.5 \times 1/(4 + \beta) \times \Delta \log(SSFR)_{\text{MS}} + C_3, \quad (10)$$

with variations in metallicities (equivalently M_*) creating a dispersion of a few degrees around this relation. In Fig. 8, we compare the prediction from Eq. (10), assuming $\beta = 1.5$, with the observed $T_{\text{dust}} - \Delta \log(SSFR)_{\text{MS}}$ relations. There is a very good agreement between the slope of our predictions and the observations. We conclude that variations in dust temperature with $\Delta \log(SSFR)_{\text{MS}}$ can be, qualitatively and quantitatively, explained by the variation of the SFE with $\Delta \log(SSFR)_{\text{MS}}$, as observed by Saintonge et al. (2012). We note that the smooth evolution of the dust temperature (equivalently SFE) with $\Delta \log(SSFR)_{\text{MS}}$ could correspond to a smooth evolution of the ISM conditions with $\Delta \log(SSFR)_{\text{MS}}$, or to a linear combination of two types of star-forming regions, i.e.: (i) cold star-forming

regions formed in secularly evolving galaxies; and (ii) hot star-forming regions formed in starbursting galaxies via large gravitational instabilities (e.g., major mergers). Unfortunately, using our unresolved observations we cannot discriminate between these two interpretations.

We note that Magdis et al. (2012) report no dust temperature variations between galaxies situated on the lower and upper part of the MS (i.e., $-0.4 < \Delta \log(SSFR)_{\text{MS}} < 0.4$). Based on this finding, they argue that across the MS, the main parameter controlling $\Delta \log(SSFR)_{\text{MS}}$ is $f_{\text{gas}} \equiv M_{\text{gas}}/M_*$ (i.e., SFE being roughly constant): at fixed stellar mass, galaxies situated on the lower part of the MS would contain less molecular gas (i.e., have lower f_{gas}) than galaxies situated on the upper part of the MS. While Saintonge et al. (2012) qualitatively confirmed the increase in f_{gas} across the MS, they also found a significant increase in SFE which leads to the increase in T_{dust} across the MS found in our sample. Thus, our results, as well as those of Saintonge et al. (2012), support the hypothesis that the localisation of a galaxy across the MS is not only controlled by f_{gas} but rather by both SFE and f_{gas} .

5.2. T_{dust} variations in the SFR– M_* plane as function of the redshift

While the slope of the $T_{\text{dust}} - \Delta \log(SSFR)_{\text{MS}}$ correlation is the same in all our redshift bins, its normalisation evolves towards hotter dust temperatures at higher redshift. In our simple description, the dust temperature of a galaxy only depends on its SFE and metallicity; therefore one should also observe variations of these parameters with redshift.

In the stellar mass range of our study (i.e., $10^{10} M_{\odot} < M_* < 10^{11.5}$), the metallicity μ of galaxies systematically decreases by ~ 0.5 dex from $z = 0$ to $z = 2$ ($z = 0$, Tremonti et al. 2004; $z = 2$, Erb et al. 2006; Shapley et al. 2005; Liu et al. 2008; Zahid et al. 2013; see also Genzel et al. 2012). At fixed $\Delta \log(SSFR)_{\text{MS}}$ and assuming $\beta = 1.5$, this decrease in the metallicity should translate into an increase in the dust temperature by a factor ~ 1.2 . For MS galaxies, this corresponds to a rise from 26 K to 31 K between $z = 0$ to $z = 2$ (see Eq. (9)). More generally, on the MS we can predict:

$$\log(T_{\text{dust}}^{\text{MS}}[z]) = -0.85 \times 1/(4 + \beta) \times \Delta \mu[z] + C_4, \quad (11)$$

where $\Delta \mu[z] = -1.05 \times \log(1+z)$ describes the mean increase in the metallicity with redshift over the stellar mass range probed by our sample. This formula is used to normalise the predicted $T_{\text{dust}} - \Delta \log(SSFR)_{\text{MS}}$ correlation, assuming $T_{\text{dust}}^{\text{MS}}[z = 0] = 26$ K and $\beta = 1.5$ (see Fig. 8). Our predictions are perfectly in line with the observations. We thus conclude that the evolution of metallicity with redshift might be the main driver of the normalisation of the $T_{\text{dust}} - \Delta \log(SSFR)_{\text{MS}}$ correlation. We note that in the local Universe an evolution of the dust temperature with metallicity has already been observed (Engelbracht et al. 2008). In that study the slope of the $T_{\text{dust}} - \text{metallicity}$ relation roughly follows our predictions, i.e., $\log(T_{\text{dust}}) = -0.85 \times 1/(4 + \beta) \times \mu + C_4$.

Tacconi et al. (2013) found that the SFE of MS galaxies evolves from $z = 0$ to $z = 1.5$ following:

$$\log(\text{SFE}_{\text{MS}}) = \log(1 + z) + C_5, \quad (12)$$

This increase in the SFE should translate into an increase in the dust temperature by a factor ~ 1.2 between $z = 0$ to $z = 2$, i.e., for MS galaxies rising from 26 K to 31 K. More generally, on the MS we can predict:

$$\log(T_{\text{dust}}^{\text{MS}}[z]) = 1/(4 + \beta) \times \log(1 + z) + C_6, \quad (13)$$

This formula is also used to normalise the predicted $T_{\text{dust}}-\Delta \log(SSFR)_{\text{MS}}$ correlation, assuming $T_{\text{dust}}^{\text{MS}}[z=0] = 26$ K and $\beta = 1.5$ (see Fig. 8). Because these predictions are also in line with our observations, we conclude that the evolution of the SFE with redshift might also be the main driver of the normalisation of the $T_{\text{dust}}-\Delta \log(SSFR)_{\text{MS}}$ correlation.

Combining the evolution of both the SFE and metallicity with redshift, we can predict,

$$\log(T_{\text{dust}}^{\text{MS}}[z]) = (0.85 \times 1.05 + 1)/(4 + \beta) \times \log(1 + z) + C_7, \quad (14)$$

In Fig. 8, we present the predictions from this formula, assuming $T_{\text{dust}}^{\text{MS}}[z=0] = 26$ K and $\beta = 1.5$. We observe that it overestimates the normalisation with redshift of the $T_{\text{dust}}-\Delta \log(SSFR)_{\text{MS}}$ correlation.

In a simple optically thin model where T_{dust} directly traces the galaxy-integrated L_{IR} and M_{dust} , our findings can be summarised as follows:

- At fixed redshift, the main parameter controlling the variation of T_{dust} with $\Delta \log(SSFR)_{\text{MS}}$ is the SFE of galaxies: galaxies with high $\Delta \log(SSFR)_{\text{MS}}$ are more efficient in turning their gas into stars, which leads to higher input power per unit of dust mass and therefore higher dust temperatures.
- At fixed $\Delta \log(SSFR)_{\text{MS}}$, the increase in the metallicity with the stellar masses can explain some of the scatter observed in the $T_{\text{dust}}-\Delta \log(SSFR)_{\text{MS}}$ and $T_{\text{dust}}-SSFR$ correlations.
- The normalisation with redshift of the $T_{\text{dust}}-\Delta \log(SSFR)_{\text{MS}}$ correlation towards hotter dust temperatures can be explained by the global decrease in the metallicity of galaxies with redshift or by the global increase in the SFE of galaxies with redshift. However, combining the evolution of both the metallicity and SFE with redshift, we overestimate the normalisation towards hotter dust temperatures of the $T_{\text{dust}}-\Delta \log(SSFR)_{\text{MS}}$ correlation. This may indicate that the assumptions of our simple model do not hold. In particular, the scaling relations that we adopted for the evolution of the metallicity and SFE with redshift and with offset from the MS might be overall inconsistent. This will need future revision.

We note that using a sample of lensed galaxies to extend the study of the dust temperatures of MS galaxies to lower stellar masses and higher redshifts ($4 \times 10^9 < M_* < 10^{11} M_{\odot}$, $2 < z < 3$), Saintonge et al. (2013) also report higher T_{dust} values compared to lower redshift samples, and attribute this variation to lower metallicities and increased star-formation efficiencies in high redshift, low mass galaxies.

Finally, we note that Nordon et al. (2012) and Elbaz et al. (2011) found the PAH-to- L_{IR} ratio, parametrized as L_8/L_{IR} , to strongly correlate with $\Delta \log(SSFR)_{\text{MS}}$. This correlation appears to remain the same up to $z \sim 2$. Therefore, PAHs and dust temperatures do not evolve in the same manner as a function of redshift. This situation could arise from differences in the mechanics heating the PAHs and the dust components dominating the FIR emission of galaxies. In the model of Draine & Li (2007), the fraction of power radiated into the $7.9 \mu\text{m}$ band by the single-photon heated PAHs, observed as L_8/L_{IR} , is essentially proportional to q_{PAH} , the fraction of dust mass in the form of PAH grains with less than 10^3 carbon atoms. It does not appear to scale with $\langle U \rangle$, the mean intensity seen per unit of dust mass (see Figs. 19c and d of Draine & Li 2007). Consequently, in this model, a strong increase in the dust temperature can occur while the PAH-to- L_{IR} ratio remains constant, if q_{PAH} remains the same and the intensity of the radiation field seen by the dust increases. The question is thus: at fixed $\Delta \log(SSFR)_{\text{MS}}$, is q_{PAH}

affected by the evolution of the metallicity with redshift or by the evolution of the SFE with redshift? In local star-forming galaxies and in the metallicity range of our sample ($\mu > 8.1$), there is only a weak correlation between the metallicity and the PAH-to- L_{IR} ratio (Smith et al. 2007; Engelbracht et al. 2008; Hunt et al. 2010). Thus, the evolution of the metallicity with redshift might affect the normalisation of the $T_{\text{dust}}-\Delta \log(SSFR)_{\text{MS}}$ correlation but not significantly affect q_{PAH} and thus leads to the universal (PAH-to- $L_{\text{IR}})-\Delta \log(SSFR)_{\text{MS}}$ correlation observed in Elbaz et al. (2011) and Nordon et al. (2012). For the SFE, the situation is somewhat different. At fixed redshift, we have explained the $T_{\text{dust}}-\Delta \log(SSFR)_{\text{MS}}$ correlation using the $SFE-\Delta \log(SSFR)_{\text{MS}}$ correlation observed by Saintonge et al. (2012). Following a similar train of thought, one could thus also ascribe the (PAH-to- $L_{\text{IR}})-\Delta \log(SSFR)_{\text{MS}}$ correlation to the $SFE-\Delta \log(SSFR)_{\text{MS}}$ correlation. In this case, however, one would expect to observe an evolution with redshift of the normalisation of both the $T_{\text{dust}}-\Delta \log(SSFR)_{\text{MS}}$ and (PAH-to- $L_{\text{IR}})-\Delta \log(SSFR)_{\text{MS}}$ correlations, following the evolution with redshift of the normalisation of the $SFE-\Delta \log(SSFR)_{\text{MS}}$ correlation. Is the universality of the (PAH-to- $L_{\text{IR}})-\Delta \log(SSFR)_{\text{MS}}$ correlation to be interpreted as a proof that actually the $SFE-\Delta \log(SSFR)_{\text{MS}}$ correlation does not significantly evolve with redshift? And that the evolution of the metallicity with redshift is the main driver for the normalisation of the $T_{\text{dust}}-\Delta \log(SSFR)_{\text{MS}}$ correlation? To obtain answers to these questions, additional studies are required.

5.3. Towards a better understanding of the MS of star formation

The existence of the MS of star formation is currently interpreted as evidence that the bulk of the galaxy population is forming stars gradually with long duty cycles. In this picture, MS galaxies evolve with a secular mode of star formation, likely sustained by a continuous gas accretion from the IGM and along the cosmic web (Dekel et al. 2009; Davé et al. 2010), while star-forming galaxies located far above the MS evolve through strong starbursts with short duty-cycles, mainly triggered by major mergers. The strong correlation observed between T_{dust} and $\Delta \log(SSFR)_{\text{MS}}$ gives weight to this interpretation. It unambiguously reveals that the physical conditions prevailing in the star-forming regions of on- and far-above-MS galaxies are not the same. Furthermore, because the $T_{\text{dust}}-\Delta \log(SSFR)_{\text{MS}}$ correlation can be understood as a variation of the SFE with $\Delta \log(SSFR)_{\text{MS}}$, it also supports the hypothesis of different modes of star formation for these two populations of galaxies. Unfortunately, using our unresolved observations we cannot distinguish if galaxies lying at intermediate distance from the MS correspond to a linear combination or to a smooth evolution of the ISM conditions between these two extreme cases.

In line with our findings, Magnelli et al. (2012b) found that on- and above-MS galaxies exhibit different CO-to- H_2 conversion factors (i.e., α_{CO}), indicating differences in the physical conditions prevailing in their giant molecular clouds (GMCs, Genzel et al. 2010; Daddi et al. 2010). MS galaxies have high α_{CO} factors, consistent with star-forming regions mainly composed of well virialized GMCs, while above-MS galaxies have low α_{CO} factors consistent with star-forming regions being mainly unvirialized GMCs as observed in local major mergers. Combined with other independent observational properties, the current vision of the main-sequence of star formation can be summarised as follows. Galaxies situated on the MS of star formation have disk-like morphology (Wuyts et al. 2011b), have star-forming

regions mainly composed of virialized GMCs (Magnelli et al. 2012b), have relatively low SFR surface density (Wuyts et al. 2011b), high PAH-to- L_{IR} ratio (Elbaz et al. 2011; Nordon et al. 2012), high C II-to- L_{IR} ratio (Graciá-Carpio et al. 2011) and cold dust temperature. Galaxies situated far above the MS have bulge-like morphology, star-forming regions dominated by unvirialized GMCs, have relatively high SFR surface density, low PAH-to- L_{IR} ratio, low C II-to- L_{IR} and hot dust temperature. All these independent observations give strong weight to the interpretation where on- and above-MS galaxies evolve through different modes of star formation, a secular and a starbursting mode, respectively.

6. Summary

Using deep *Herschel* PACS and SPIRE observations of the GOODS-N, GOODS-S and COSMOS fields, we study variations of the dust temperature of galaxies in the SFR- M_* plane up to $z \sim 2$. Dust temperatures are inferred using the stacked PACS/SPIRE FIR photometries of each SFR- M_* - z bin. Based on this careful analysis, we constrain the dust temperature of galaxies over a broad range of redshifts, and study the evolution of the $T_{\text{dust}}-L_{\text{IR}}$, $T_{\text{dust}}-SSFR$ and $T_{\text{dust}}-\Delta \log(SSFR)_{\text{MS}}$ correlations. Then, using a simple model linking the dust temperature with the dust and gas contents of the ISM, we discuss these correlations in terms of variations of the physical conditions prevailing in the star-forming regions of galaxies. Our main conclusions are:

1. Over a broad range of redshifts, the dust temperature of galaxies smoothly increases with their infrared luminosities, SSFRs and $\Delta \log(SSFR)_{\text{MS}}$ values. The $T_{\text{dust}}-SSFR$ and $T_{\text{dust}}-\Delta \log(SSFR)_{\text{MS}}$ correlations are statistically much more significant than the $T_{\text{dust}}-L_{\text{IR}}$ correlation. The slope of the $T_{\text{dust}}-\Delta \log(SSFR)_{\text{MS}}$ correlation does not evolve up to $z \sim 2$, but its normalisation does: at a given $\Delta \log(SSFR)_{\text{MS}}$, high-redshift galaxies exhibit hotter dust temperatures than their local counterparts. Similarly, the normalisation of the $T_{\text{dust}}-SSFR$ correlation evolves towards colder dust temperatures up to $z \sim 2$. The $T_{\text{dust}}-L_{\text{IR}}$ correlation also evolves with redshift: at fixed L_{IR} , high-redshift galaxies exhibit slightly colder dust temperatures than their local counterparts.
2. Because the $T_{\text{dust}}-\Delta \log(SSFR)_{\text{MS}}$ and $T_{\text{dust}}-SSFR$ correlations are statistically very significant, they supersede the $T_{\text{dust}}-L_{\text{IR}}$ correlation classically used to predict the dust temperatures of galaxies. These correlations could be used to improve results of semi-analytical or backward evolutionary models.
3. In a simple optically thin model, where T_{dust} directly traces the galaxy-integrated L_{IR} and M_{dust} , the slope of the $T_{\text{dust}}-\Delta \log(SSFR)_{\text{MS}}$ (equivalently SSFR at fixed z) correlation can be explained, qualitatively and quantitatively, by the increase in the SFE with $\Delta \log(SSFR)_{\text{MS}}$ found locally by molecular gas studies (Saintonge et al. 2012). In addition, the normalisation with redshift of the $T_{\text{dust}}-\Delta \log(SSFR)_{\text{MS}}$ correlation can be explained by the global decrease in the metallicity of galaxies with redshift (Tremonti et al. 2004; Erb et al. 2006) or by the increase in the SFE of MS galaxies with redshift (Tacconi et al. 2013). However, combining the evolution of both the metallicity and SFE with redshift, we overestimate the normalisation towards hotter dust temperatures of the $T_{\text{dust}}-\Delta \log(SSFR)_{\text{MS}}$ correlation. This may indicate that the assumptions of our simple model do not hold. In particular, the scaling relations that we adopted for the

evolution of the metallicity and SFE with redshift and with offset from the MS might be overall inconsistent. This will need future revision.

All these results support the hypothesis that the conditions prevailing in the star-forming regions of MS and far-from-MS galaxies are different. MS galaxies have star-forming regions with low SFEs and thus cold dust temperatures, while galaxies situated far above the MS seems to be in a starbursting phase characterised by star-forming regions with high SFEs and thus hot dust temperatures. Galaxies lying at intermediate distance from the MS could correspond, for our unresolved observations, to a linear combination or to a smooth evolution of the physical conditions between these two extreme star-forming regions. In that picture, at fixed $\Delta \log(SSFR)_{\text{MS}}$, galaxies are dominated by the same type of star-forming regions and the increase in SFR with M_* is due to an increase in the number of such star-forming regions.

Appendix A: Far-infrared SEDs

Figure A.1 presents the FIR properties of some of our galaxies with individual FIR detections. In the first column, galaxies were randomly selected within a sample with $10^{10.8} < M_* [M_\odot] < 10^{11}$ and $-0.1 < \Delta \log(SSFR)_{MS} < 0.1$. In the second column, galaxies were randomly selected within a sample with $10^{10.8} < M_* [M_\odot] < 10^{11}$ and $\Delta \log(SSFR)_{MS} > \text{MAX}[\Delta \log(SSFR)_{MS}] - 0.1$. To derive the infrared luminosities and dust temperatures of these galaxies (see Sects. 2.6, 3.1 and Table A.1), we fitted their FIR flux densities with the DH SED template library.

Figure A.2 presents the mean FIR properties of some of our SFR– M_* bins, as inferred from our stacking analysis. In the first column, SFR– M_* bins were selected to have $10^{10.8} < M_* [M_\odot] < 10^{11}$ and $-0.1 < \Delta \log(SSFR)_{MS} < 0.1$, while in the second column, SFR– M_* bins were selected to have $10^{10.8} < M_* [M_\odot] < 10^{11}$ and $\Delta \log(SSFR)_{MS} = \text{MAX}[\Delta \log(SSFR)_{MS}]$. To derive the mean dust temperature of these SFR– M_* bins, we fitted their FIR flux densities with the DH SED template library (see Fig. A.2).

Table A.1. Dust temperatures assigned to the DH SED templates by fitting their simulated $z = 0$ PACS/SPIRE flux densities with a single modified (i.e., $\beta = 1.5$) blackbody function.

α^a	0.062	0.125	0.188	0.250	0.312	0.375	0.438	0.500

Notes. ^(a) α is the single parameter of the DH SED template library (Dale & Helou 2002).

Fig. A.1. FIR properties of some of our galaxies with individual FIR detections. All these galaxies have $10^{10.8} < M_* [M_\odot] < 10^{11}$. In the first column, galaxies have $-0.1 < \Delta \log(SSFR)_{MS} < 0.1$ while in the second column they have $\Delta \log(SSFR)_{MS} > \text{MAX}[\Delta \log(SSFR)_{MS}] - 0.1$. Black lines show the DH SED templates best-fitting these FIR flux densities. From these fits, we inferred the infrared luminosities and dust temperatures of our galaxies.

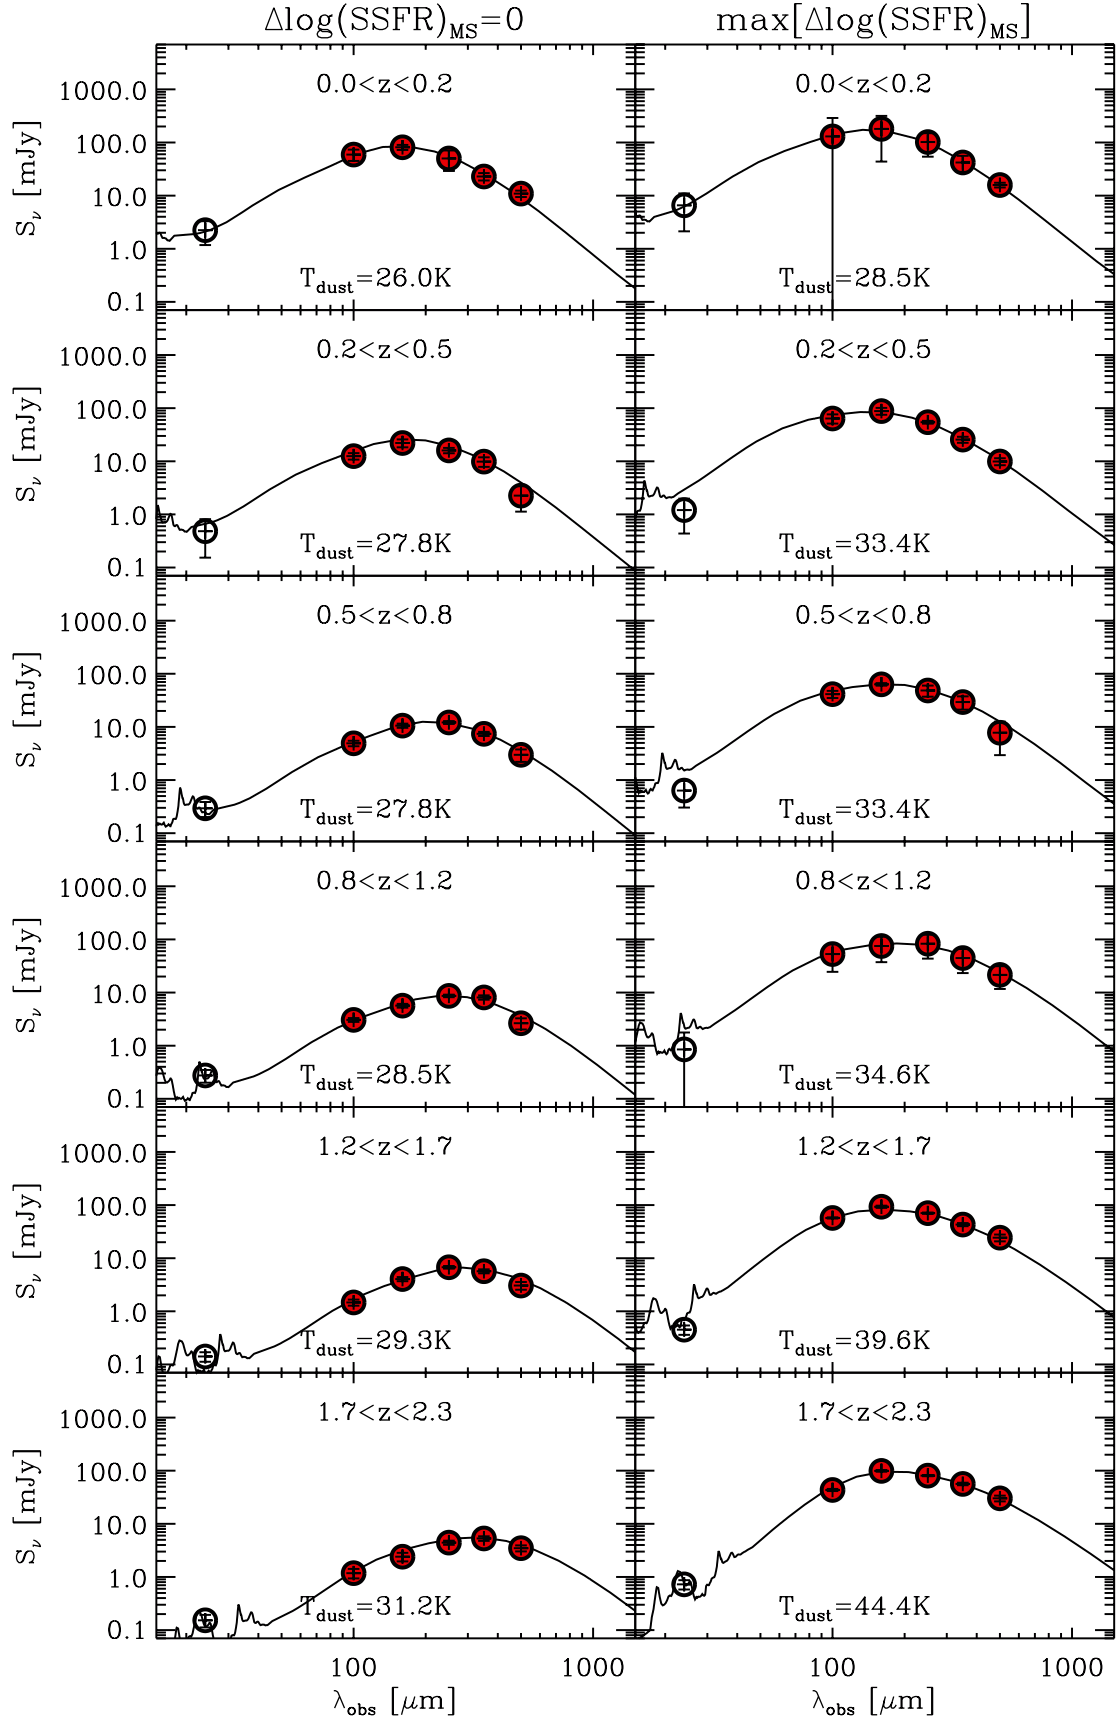

Fig. A.2. FIR properties of some of our SFR– M_* bins, as inferred from our stacking analysis. These SFR– M_* bins have $10^{10.8} < M_* [M_\odot] < 10^{11}$. In the first column, SFR– M_* bins have $-0.1 < \Delta \log(SSFR)_{MS} < 0.1$, while in the second column they have $\Delta \log(SSFR)_{MS} = \max[\Delta \log(SSFR)_{MS}]$. Black lines show the DH SED templates best-fitting these FIR flux densities. From these fits, we inferred the mean dust temperatures of galaxies in these SFR– M_* bins. We also verified that the infrared luminosities inferred from these fits agree, within 0.3 dex, with the mean infrared luminosities inferred from our “ladder of SFR indicators” (see Sect. 2.6).

Appendix B: The $T_{\text{dust}}-\Delta \log(SSFR)_{\text{MS}}$ relation in the GOODS fields

Figure B.1 presents the $T_{\text{dust}}-\Delta \log(SSFR)_{\text{MS}}$ relation, as inferred using the GOODS fields. Because we exclude the COSMOS observations from our stacking analysis, our ability

to probe and sample properly the $SFR-M_*$ parameter space decreases. Therefore, the number of data points available to study the $T_{\text{dust}}-\Delta \log(SSFR)_{\text{MS}}$ relation is significantly reduced. Despite this limitation, we still observe a $T_{\text{dust}}-\Delta \log(SSFR)_{\text{MS}}$ relation evolving with redshift.

Fig. B.1. Dust temperature of galaxies as a function of $\Delta \log(SSFR)_{\text{MS}}$, as derived from our stacking analysis using only the GOODS fields (i.e., excluding the COSMOS observations). Symbols and lines are the same as in Fig. 8.

Appendix C: The $T_{\text{dust}}-\Delta\log(SSFR)_{\text{MS}}$ relation using different definition of the MS

In this appendix we test the robustness of the $T_{\text{dust}}-\Delta\log(SSFR)_{\text{MS}}$ correlation against changes in the definition of the MS of star formation. Figure C.1 shows

the $T_{\text{dust}}-\Delta\log(SSFR)_{\text{MS}}$ correlation using the definition of the MS from Elbaz et al. (2011). We still observe a strong correlation between T_{dust} and $\Delta\log(SSFR)_{\text{MS}}$ as revealed by the high Spearman correlation factor found in all our redshift bins. Our results are thus robust against changes in the definition of the MS.

Fig. C.1. Dust temperature of galaxies as a function of $\Delta\log(SSFR)_{\text{MS}}$, as derived from our stacking analysis. In this figure, the definition of the MS of star formation is taken from Elbaz et al. (2011). Symbols and lines are the same as in Fig. 8.
