Preface: (102 out of max 100 words)

The gasdermins are a new family of pore-forming cell death effectors that cause membrane permeabilization and pyroptosis, a lytic pro-inflammatory type of cell death. Gasdermins consist of a cytotoxic N-terminal domain and a C-terminal repressor domain connected by a flexible linker. Proteolytic cleavage between these two domains releases the intramolecular inhibition on the cytotoxic domain, allowing it to insert into cell membranes and to form large oligomeric membrane pores, which disrupt ion homeostasis and induce cell death. In this review, we discuss the recent developments in gasdermin research with a focus on the mechanisms that control gasdermin activation, pore formation and the consequences of gasdermin-induced membrane permeabilization.

Key points (list max 6)

- The gasdermins are evolutionary conserved family of cell death effectors, which comprises 6 members (gasdermin A, B, C, D, E and Pejvakin) in humans and 10 members in mice (gasdermin A1-3, C1-4, D, E and PJVK). They derive their name from the distinct expression pattern of gasdermin A in the gastrointestinal tract and the dermis.

- The archetypical member of the family is gasdermin D, which was shown to cause a necrotic type of cell death known as 'pyroptosis' that is initiated after inflammasome complex assembly.

- All gasdermins are defined by a distinct two-domain architecture, consisting of a N-terminal cytotoxic domain, a flexible linker and a C-terminal inhibitory domain. Interaction between the N- and C-terminal domains keeps the gasdermins in an autoinhibited state.

- Several proteases promote gasdermin activation by cleaving within the internal linker and thereby relieving autoinhibition by the C-terminus. Most prominent among these are the inflammatory caspases, a family of cysteine proteases activated within inflammasome complexes.

- Following cleavage, the N-terminal gasdermin domain targets and inserts into cellular membranes by interacting with the negatively charged headgroups of certain phospholipids, phosphatidylinositol phosphates and cardiolipin. Upon membrane insertion the N-terminal domain oligomerizes to form large anti-parallel β-barrel pores with 27-fold symmetry.

- Gasdermin-induced pyroptosis play a prominent role in many hereditary diseases, (auto)inflammatory disorders and in cancer, highlighting the importance of gasdermins as a novel therapeutic target.

59

Introduction

61   The gasdermins are a family of genes first reported in the early 2000s as candidate genes for several

62   alopecia-like skin mutations in mice[1,2]. The name gasdermin was coined based on the exclusive

63   expression profile of the gasdermin A (GSDMA) proteins in the mouse gastrointestinal tract and the

64   epithelium of the skin. Early studies also noted that the gasdermins share strong sequence similarity in

65   their N-terminal region with Deafness autosomal dominant nonsyndromic sensorineural 5 (DFNA5), a

66   protein that was linked in 1998 to autosomal dominant nonsyndromatic hearing loss in humans[3]. Based

67   on this homology several other gasdermin family members and gasdermin-like proteins were identified

68   and currently the family comprises 6 paralogous genes in humans: *GSDMA*, *GSDMB*, *GSDMC*,

69   *GSDMD*, *GSDME* (a.k.a *DFNA5*) and *PJVK (a.k.a DFNB59*). By contrast, rodents lack *Gsdmb,* but mice

70   have three *GSDMA* homologues (*Gsdma1–3*), four *GSDMC* homologues (*Gsdmc1–4*), *Gsdmd, Gsdme*

71   and *Pjvk*.

72   While the gasdermin family members were easily identified based on sequence homology, the exact

73   biological function of these proteins remained unknown for over 15 years. Still, links to cell death and

74   inflammation started to emerge soon after their identification. For example, over the years a total of

75   nine mutations in *Gsdma3* were reported to cause inflammation and alopecia in the mouse[4]. Gene

76   deletion of *Gsdma3* on the other hand did not cause any discernible skin phenotype[4], indicating that

77   these mutations conferred a gain-of-function that caused bulge stem cell depletion, hyperkeratosis and

78   inflammation. The most direct evidence for a role of gasdermins in cell death came from studies showing

79   that expression of the mutated, C-terminally truncated form of human GSDME, which causes autosomal

80   dominant nonsyndromatic hearing loss and results from exon 8 skipping, causes cell cycle arrest in

81   yeast cells and necrotic death in human cells[5,6]. Yet, how gasdermins induce cell death and what type

82   of cell death is controlled by these proteins remained unclear.

83   The mechanism of gasdermin function was revealed by two studies in 2015 that identified GSDMD

84   as the sole executor of pyroptosis[7,8]. Pyroptosis was initially defined as a caspase-1-dependent necrotic

85   death first reported in the late 1990s and early 2000s in pathogen-infected cells[9–11]. Later studies

86   showed that pyroptosis is the main effector mechanism of pro-inflammatory caspases, a group of

87   proteases that is activated within so-called inflammasome complexes[12]. Two distinct pathways, named

88   the canonical and non-canonical inflammasome, sense pathogen- or host-derived danger signals and

89   initiate the activation of caspase-1 and -4 in humans, or caspase-1 and -11 in mice. These caspases

90   cleave GSDMD, thereby releasing the N-terminal domain of GSDMD from an intramolecular inhibitory

91   interaction with its C-terminal domain[7,8,13]. The N-terminal domain targets cellular membranes such as

92   the plasma membrane, where it assembles large pores that permeabilize the membrane and eventually

93   induce pyroptosis[14–17].

94   Since the discovery of the gasdermins as the executors of pyroptosis, a host of literature started to

95   characterize their function in inflammasome biology, apoptosis and beyond. In this review, we discuss

96   the latest insights into gasdermin activation and regulation, the assembly of the gasdermin pore and

97   the biological functions of the gasdermin protein family.

The gasdermins, a family of membrane pore forming proteins

The human gasdermin protein family is encoded by six genes whose overall sequence similarity ranges from 23.9 to 49.4% (**Figure 1a**). The family can be further subdivided, since GSDME and PJVK also belong to the deafness associated genes (DFN) and their protein sequences cluster together, apart from the other human gasdermins (GSDMA-D) (**Figure 1a**). Evolutionarily, GSDME and PJVK are also the most ancient gasdermin members, since similar sequences are found in lower vertebrates and in some invertebrates[18,19]. *GSDMA* genes sequences are found in mammals as well as in birds and reptiles, while *GSDMB*, *GSDMC* and *GSDMD* genes are exclusively found in mammalian genomes and are closely related to *GSDMA* (**Figure 1a**), indicating that they arose through gene duplication[18]. Mice and rats lack *Gsdmb*, but mice feature several orthologues of *Gsdma* and *Gsdmc* (**Figure 1a**)[20].

Structurally, gasdermins consist of two distinct domains connected by a flexible linker (**Figure 1b**), except for PJVK that present a smaller C-terminal domain. The N-terminal gasdermin domain (GSDM^{NT}) displays the highest sequence similarity among all family members (similarity ranging from 28.8 to 50.5%). By contrast, the C-terminal gasdermin domains (GSDM^{CT}) present variable lengths and lower similarity (ranging from 1.3 to 46.3%) (**Figure 1c**)[7,8]. GSDMD^{NT} harbors the intrinsic pore-forming/pyroptosis-inducing activity, while GSDM^{CT} interacts with GSDMD^{NT} and thereby inhibits its activity in the absence of an activating signal[7,8,14].

GSDMA (a.k.a. gasdermin-1, GSDM, GSDM1, or FKSG9, UniProt #Q96QA5) was first cloned from the mouse skin, and its expression is mainly restricted in humans to epithelial cells of the esophagus, bladder and skin[2,21] (**Table 1**). T and B lymphocytes also express detectable GSDMA protein[22]. Mice feature three *GSDMA* orthologous genes (*Gsdma1*, *Gsdma2*, and *Gsdma3*), but the expression is also restricted to epithelia and the skin, including epidermis, hair follicles, and stomach[4,23–25].

GSDMB (a.k.a. gasdermin-like, GSDML, PP4052, or PRO2521; UniProt #Q8TAX9) was found by database homology searches using the GSDMA sequence[26]. GSDMB is the most divergent member of the gasdermin family (**Figure 1a**) and is not present in the mouse and rat genome, although some species of rodents have a *Gsdmb* ortholog. GSDMB expression has been mainly detected in airway epithelium, esophagus, stomach, liver, small intestine, and colon, among other tissues[27,28] (**Table 1**). Different GSDMB splice variants have been detected in humans, with one transcript encoding a GSDMB with caspase-1 cleavage site in the interdomain linker (encoded on exon 6)[28]. Consequently, caspase-1 has been found to cleave this isoform in a recombinant cellular system and induce lytic cell death[28].

GSDMC (a.k.a. melanoma-derived leucine zipper-containing extranuclear factor, or MLZE; UniProt #Q9BYG8) was first identified as a gene with an upregulated expression in metastatic mouse melanoma cells[29] and latter it was identified as a member of the gasdermin family[25]. The mouse genome presents four *Gsdmc* orthologue genes[25] (**Figure 1a**). The expression of GSDMC is restricted to esophagus, skin, spleen and vagina (**Table 1**)[27]. Artificially truncated GSDMC^{NT} is able to induce pyroptosis[14], but so far it is still unknown what protease could cleavage and activate GSDMC.

GSDMD (a.k.a. gasdermin domain-containing 1, GSDMDC1, deafness, autosomal dominant 5-like, DFNA5L, or FKSG10; UniProt #P57764) was first identified by searching the human genomic database

using the GSDMA sequence[26]. GSDMD is expressed in different human tissues, as well as different subsets of leukocytes (**Table 1**)[22,27]. *GSDMD* orthologous genes are only present in mammalian genomes and all contain a large central domain with a cleavage site for inflammatory caspases (caspase-1/-4/-5) (**Figure 1b**). It is however worth noting that in lower vertebrates, as in zebrafish caspase-a or caspase-b (caspy and caspy2, respectively), the homologs of mammalian caspase-1 and caspase-4/-5, are reported to induce cell death and participate in immunity [30–32], suggesting that an unidentified functional homolog of GSDMD might be present in these lower vertebrates. However, additional or alternative cell death pathways in fish (as necroptotic- or apoptotic-like) could be also responsible of this inflammatory phenotype. In mammals, caspase-1 cleaves the precursor pro-IL-1β to generate the mature and bioactive IL-1β cytokine. In parallel, the cleavage of GSDMD by caspase-1/-4/-5 results in the formation of the highly lytic GSDMD[NT] protein fragment that allows the release of mature IL-1β (**Figure 2**)[7,8,33]. Lower vertebrate sequences for IL-1β lack a conserved caspase-1 processing site[32,34], albeit inhibition of fish caspase-a/-b, as well as, fish IL-1β is detrimental for the host during infection[32,35,36]. The appearance of GSDMD and pro-IL-1β, both with a caspase-1 processing site in mammals, could thus have conferred to the inflammasome the control over the two key steps for IL-1β signaling, its processing and release. By contrast, these two steps might be controlled by homologous proteases (as caspase-a/-b) and a GSDMD homolog in lower vertebrates.

GSDME (a.k.a. inversely correlated with estrogen receptor expression 1, ICERE-1, non-syndromic hearing impairment protein 5, or DFNA5; UniProt #O60443) was initially cloned as a candidate gene for autosomal dominant non-syndromic hearing loss[3] and lately was found to possess sequence and structural similarities to the gasdermins[6]. GSDME is variably expressed in different human cells and tissues, including brain, endometrium, placenta and intestine, among others (**Table 1**). In mice and humans, GSDME is processed by caspase-3 and was proposed to induce pyroptosis with apoptotic morphology [14,37]. GSDME is also expressed in different species of lower vertebrates, and for example two orthologous genes for GSDME (*GsdmEa* and *GsdmEb*) can be found in bony fish. Caspase-3 cleavage site is present in zebrafish *GsdmEa*, but not in *GsdmEb*, suggesting that *GsdmdEa* could be considered as the functional homolog of GSDME[14]. It is yet unknown if *GsdmEb* is processed in fish, but if it is processed by fish caspy or caspy2 it might act as a functional homologue of mammalian GSDMD (see above). Interestingly, deletion of *GsdmEb* in zebrafish results in a malformation of the semicircular canals of the ear[38], suggesting that *GsdmEb* could confer the hearing loss associated with human GSDME.

PJVK (a.k.a. autosomal recessive deafness type 59 protein, DFNB59, or GSDMF; UniProt #Q0ZLH3) is also a protein with mutations associated to deafness, but was initially cloned from human testis[39]. PJVK shares a high similarity with GSDME, and PJVK orthologous genes are present in early chordates and invertebrates, suggesting that gasdermin family of proteins could have evolved from these antecessors. PJVK expression is high in testis, but it is also broadly expressed in other tissues, including the hair cells of the inner ear and other cells of the auditory system (**Table 1**)[39–41]. So far, it is unknown if PJVK is able to be processed by a protease or if the N-terminus or full-length PJVK forms membrane pores.

Signaling pathways controlling gasdermin activation

In 2015, several studies independently identified GSDMD as the executor of pyroptosis, a type of necrotic cell death that is induced after the activation of the canonical or non-canonical inflammasome pathways (**Figure 2**)[7,8,13]. Inflammasomes are multi-protein signaling complexes that are assembled in the cytosol upon detection of host- or pathogen-derived danger signals and that promote cytokine release, pyroptotic cell death and inflammation[12]. Signaling downstream of inflammasomes is controlled by a family of cysteine protease that known as inflammatory caspases, and that comprise caspase-1/-4/-5 in humans and caspase-1/-11 in mice[12]. These proteases induce pyroptosis by cleaving GSDMD within its central linker domain (**Figure 1b**), resulting in the generation of a 31 kDa N-terminal and a 22 kDa C-terminal fragment[7,8,13]. Pyroptosis is induced by GSDMD^{NT}, since expression of the N-terminal fragment alone is sufficient to induce pyroptosis[7,8,13]. By contrast, the C-terminal fragment acts as a repressor as it is able to bind GSDMD^{NT} when overexpressed and thereby block cell death[8].

These results gave rise to a model, in which caspase-mediated cleavage releases the cytotoxic GSDMD^{NT} from an intramolecular auto-inhibition by GSDMD^{CT} and thus allows it to induce pyroptosis[7,8,20]. In support of this model, it was found that the defining two-domain architecture consisting of an N-terminal cytotoxic and a C-terminal inhibitory domain connected by a linker is shared by all gasdermin family members (with the exception of PJVK that features a truncated C-terminal domain), and that ectopic expression of the N-terminal domain of GSDMA, -B, -C or -E induces necrosis with similar morphology as GSDMD-induced cell death[14]. Thus, the gasdermin family emerged as new group of cell death effectors, that is defined by its N-terminal pyroptosis-inducing domain (**Box 1**).

Consistent with being a substrate of inflammatory caspases, GSDMD features a caspase cleavage motif (FLTD in humans, LLSD in the mouse) in its interdomain linker (**Figure 1b**)[7,8]. Such a caspase-1 cleavage site is not found in the other gasdermins with the exception of a minor splice variant of GSDMB[28], but other protease cleavage sites might be present. In fact, human and mouse GSDME feature a caspase-3 cleavage motif in their linker region (**Figure 1b**), and consequently GSDME was reported to be cleaved at this site upon induction of apoptosis (**Figure 3**)[37,42]. Based on this finding, Rogers *et al.* proposed that GSDME causes secondary necrosis[37], a process whereby late apoptotic cells progress to necrosis and lose their membrane integrity. Subsequent studies have now challenged this hypothesis and shown that GSDME can only induce pyroptosis with apoptotic features upon overexpression or in cells types that have naturally high GSDME levels[42–44], and that *Gsdme*-deficient macrophages still undergo secondary necrosis[43,44]. Interestingly, GSDME is not the only gasdermin that can get activated after apoptosis induction. Pharmacological or pathogen-induced inhibition of TAK-1 or the treatment with SMAC mimetics can elicit GSDMD cleavage independently of caspases-1 or -11[44–46]. It has been proposed that under these conditions GSDMD is directly processed by caspase-8 (**Figure 3**)[44,45], consistent with the fact that caspase-8 can process GSDMD *in vitro,* albeit with slower kinetics[44]. It has been also suggested that caspase-8-driven GSDMD pore formation is the cause for potassium efflux and NLRP3 inflammasome activation in apoptotic cells[45], but other findings suggest that this is mediated by caspase-driven activation of pannexin-1 channels[44]. Interestingly, GSDMD activity in apoptotic cells is negatively regulated by caspase-3 which inactivates the protein by cleaving within the N-terminal domain (**Figure 3**)[37,44,47], and thereby generating an inactive p20 fragment. These

218 findings reveal a potential role for GSDMD in causing lytic cell death and inflammation after apoptosis
219 induction, but the physiological function of this new signaling pathway and the negative regulation by
220 caspase-3 still remain to be determined.

221 The repertoire of pathways leading to gasdermin activation has lately been expanded beyond the
222 caspase family. Two studies show that in activated neutrophils GSDMD can be cleaved by neutrophil
223 elastase[48,49], a serine protease that is important for the maturation and the anti-microbial function of
224 neutrophils. Although elastase cleaves GSDMD at several sites upstream of the FLTD motif cleaved by
225 inflammatory caspases (LLSD in mouse), the cleavage still generates a functional pore-forming
226 fragment[49]. The exact function of GSDMD in neutrophils is still debated: *Gsdmd*-deficient mice for
227 example are more resistant to *E. coli* challenge, probably due to the extended lifetime of neutrophils[49].
228 On the other hand, GSDMD was proposed to be required for NETosis[48,50], a process involving the
229 release chromatin structures, so-called neutrophil extracellular traps (NETs), to the extracellular space
230 by activated neutrophils. Thus, GSDMD could have both detrimental and beneficial functions in
231 neutrophils, depending on the type of infection and whether neutrophil survival or death is required for
232 pathogen restriction.

233 Although so far proteolysis is the only known physiological mechanism by which gasdermins get
234 activated, several lines of evidence indicate that the removal GSDM^{CT} is not an absolute requirement
235 for gasdermin activation. Disruption of the auto-inhibitory interdomain interaction by certain mutations
236 can also result in gasdermin activation[14], indicating that the presence of the C-terminal domain *per se*
237 does not interfere with pore formation. The crystal structure of GSDMA3 reveals that key features of
238 the interdomain interaction are the α1 helix and β1-β2 hairpin loop of GSDMA3^{NT} that insert deeply into
239 a groove with a hydrophobic core within the GSDMA3^{CT14}. Consistently, mutations in the hydrophobic
240 core of the C-terminal domains of GSDMA, GSDMA3, GSDMC, GSDMD and GSDME all cause
241 pyroptosis[14], and several of the alopecia-causing *Gsdma3* mutations map to the C-terminal domain and
242 the interdomain interaction interface. It is thus possible that physiological signaling pathways could
243 similarly elicit gasdermin activation by relieving autoinhibition, for example by phosphorylation or other
244 post-translational modifications.

245

246 **Mechanism of gasdermin pore formation**
247 Pyroptosis features plasma membrane rupture caused by gasdermin pore formation[51–53]. *In vitro*
248 binding assays demonstrate that the Gasdermin N-terminus can directly interact with membrane lipids.
249 [14–17]. The GSDMD^{NT} has been shown to preferably target acidic phospholipids, phosphoinositides and
250 cardiolipin, albeit it can also weakly bind to phosphatidic acid and phosphatidylserine[14,16]. Other
251 gasdermin-N domains, such as those of GSDME, GSDMA and murine GSDMA3 exhibit the similar
252 lipid-binding property[14,42], suggesting a common membrane-targeting mechanism for the entire
253 gasdermin family. Phosphoinositides are only present in the cytoplasmic leaflet of plasma membrane.
254 In line with this, the GSDM^{NT} domain can only cause pyroptosis from inside of cells (extracellular
255 addition of an activated gasdermin does not cause membrane lysis)[14] Cardiolipins, resembling the
256 phosphoinositides in bearing the negatively charged head groups, are present in the inner membrane
257 of the mitochondria in eukaryotes as well as that of the bacteria. Consistently, expression of a GSDM^{NT}

258   domain in *E. coli* exhibits severe toxicity, and recombinant GSDM[NT] protein can lyse the protoplasts of

259   *Bacillus megaterium*[14]. It has been shown that the unleashed GSDMA3[NT] and GSDMD[NT] can disrupt

260   mitochondria[54,55] and that exposure of bacteria to recombinant GSDMD[NT] inhibits cell growth[16], but it

261   remains to be clarified how the gasdermin pore-forming domain can get access to the inner membrane

262   location in both situations. Besides phospholipids being sufficient for the membrane targeting of the

263   GSDM[NT] domain, other membrane lipids, even showing no specific and robust binding to GSDM[NT],

264   might also impact the action of the GSDM[NT] domain through influencing the physical properties of a

265   membrane[51]. For instance, the presence of sphingomyelin can greatly promote the liposome binding of

266   GSDMD[NT], whereas inclusion of cholesterol into the lipid membrane notably reduces the association

267   with GSDMD[NT] [17,56]. While lipid binding can only be observed with free GSDM[NT] domain for most

268   gasdermins, full-length GSDMB exhibits the similar lipid-binding ability as its GSDMB[NT] alone,

269   suggesting that the GSDMB[CT] domain does not impede the lipid binding of GSDMB. In addition to

270   phosphoinositide binding, GSDMB shows an exclusive specificity to sulfatide[57], but the physiological

271   relevance remains to be determined.

272   Given the high sequence similarity among all GSDM[NT] domains, it is perceivable that most if not all

273   gasdermins shall employ a similar mechanism to form pores on the membrane (**Figure 4.**). The high-

274   resolution crystal structure of full-length GSDMA3[14] and the recently determined cryo-EM structure of

275   GSDMA3[NT] pore extracted from the reconstituted liposomes[14,58] provide an excellent template to derive

276   a detailed understanding of gasdermin pore formation. In the GSDMA3 crystal structure, the GSDMA3[NT]

277   domain adopts an extended twisted β-sheet structure flanked by several helices, which represents a

278   novel globular fold distinct from known pore-forming proteins. The helical GSDM[CT] domain is juxtaposed

279   closely at the side of the GSDM[NT] domain. Within the GSDM[NT] domain, helix α1 and a short β hairpin

280   located at the concave of the β-sheet structure interact strongly with the GSDM[CT] domain. A long loop

281   stretches out from one end of the β-sheet to connect to the GSDM[CT] domain. At the other end of the β-

282   sheet is a short helix held by two flexible loops, which protrudes from the globular fold and interacts

283   with another part of the GSDM[CT] domain[14]. The two inter-domain interactions lock full-length GSDMA3

284   into an autoinhibited state. Upon disruption of the autoinhibition, the GSDM[CT] domain is released from

285   the concave surface to free the GSDM[NT] domain for membrane pore formation. Compared with that in

286   the autoinhibited state, the GSDMA3[NT] pore structure shows drastic conformational changes, mainly in

287   two structural elements[58]. The short helix that contacts the GSDM[CT] domain in the autoinhibited

288   structure, together with its flanking loops, refolds into two β strands, forming a β hairpin. In the

289   neighboring region, another β strand and its flanking loops also refold into β strands and form an

290   additional β hairpin. The four newly formed β strands each merge with an existing β strand in the core

291   β-sheet structure. The two anti-parallel β-hairpins form a long four-stranded amphiphilic β-sheet that

292   extends away from the core globular fold of the gasdermin-N domain. These conformational changes

293   generate three oligomerization interfaces, which drives the GSDM[NT] domains to form a ring-shaped

294   pore with their amphiphilic β-sheets bundling together to assemble a membrane-inserting β barrel.

295   Mutations in the β barrel or at the oligomerization interfaces, such as E15K and L192D in GSDMD[14],

296   severely compromises the pore-forming activity of the GSDM[NT] domain[58]. Each of the GSDMA3 pores

297   contains about 26 to 28 GSDM[NT] protomers with a predominant 27-fold symmetry[58] (**Figure 4**). The

298   inner and outer diameters of the GSDMA3 pore are about 18 and 28 nm, respectively, which is roughly

299   consistent with that measured by other methods[14–17]. The GSDMD pores are more heterogeneous with

300   an inner diameter ranging from 10 to 20 nm[14,56,58], suggesting a context-dependent stoichiometry in

301   pores formed by different GSDM[NT] domains. The size of GSDMD pore is spacious enough to allow

302   mature IL-1β to pass through upon canonical inflammasome activation[14,33,59].

303   The conformational changes leading to pore formation are triggered by binding of the GSDM[NT]

304   domain to membrane phospholipids. A possible lipid-binding site has been observed in the cryo-EM

305   structure of GSDMA3 pore[58]. A deep and positively charged pocket between helix α1 and the

306   membrane-inserting β sheet is filled with extra electron densities that can be modeled with the head

307   group of cardiolipin used to reconstitute the GSDMA3 pore. The surface of this pocket is fully masked

308   by the GSDM[CT] domain in the autoinhibited GSDMA3 structure[57]. As interdomain cleavage does not

309   unlock the autoinhibitory interaction (in the case of GSDMD and GSDME)[14,42], it remains to be

310   determined how the charged phospholipid heads can access the completely buried pocket to trigger

311   subsequent conformational changes. Alternatively, there might exist another lipid binding site in the

312   GSDM[NT] domain that serves as a priming role for full binding to the phospholipids in the membrane.

313   The structural changes observed in the GSDMA3 pore are reminiscent of those seen with the

314   membrane attack complex perforin-like/cholesterol dependent cytolysin (MACPF/CDC) family although

315   overall structures of the two types of pore-forming proteins are quite different[14,58,60]. For the

316   MACPF/CDC family, the monomeric pore-forming domain oligomerizes into a soluble prepore prior to

317   subsequent conformational changes-mediated membrane insertion and formation of mature pores[61,62].

318   Using high-resolution atomic force microscopy (AFM) method, a recent study analyzed the dynamic

319   process of GSDMD pore formation, which reveals a mechanism of direct pore growing in the

320   membrane[56]. GSDMD[NT] monomers are embedded into the lipid membranes and assemble arc- or slit-

321   shaped intermediate oligomers in the membrane before growing into a ring-shaped transmembrane

322   pore (**Figure 4c**). The process is continuous and does not involve a prepore transition stage[56], a feature

323   distinct from the MACPF/CDC family.

324

325   **Consequences of gasdermin pore formation: membrane permeabilization and**

326   **pyroptosis**

327   ***Sub-lytic pore formation.*** Although gasdermin pores eventually cause pyroptosis in experimental

328   systems, it is possible that cell lysis is not always the main function of these pores. Such 'lysis-

329   independent' functions have to date only been described for GSDMD pores, but it is conceivable that

330   this mechanism applies to other family members. Research over the last couple of years has shown

331   that the results of GSDMD pore formation can differ depending on cell type, the level of GSDMD

332   expression, activation and timing, and the efficiency of counteracting mechanisms. In mouse

333   macrophages, for example, activation of the NLRP3 inflammasome with the N-acetyl glucosamine

334   (NAG) fragment of bacterial peptidoglycan (PGN) or OxPAPC can elicit a GSDMD-dependent release

335   of mature IL-1β from live cells, i.e. in absence of detectable cell lysis[33,59,63,64]. Similarly, LPS induces IL-

336   1 release from living human monocytes[65–68], and neutrophils also release IL-1 in a lysis-independent

337   manner after canonical inflammasome activation[33,69]. These studies not only suggest that sublytic

GSDMD pore formation can occur, but also that sublytic GSDMD pores may be a pathway for direct unconventional secretion of the leaderless cytokines IL-1β and IL-18, allowing their release in absence of cell lysis.

This lysis-independent function of gasdermin pores might also be used to release other proteins or regulate signaling pathways[33]. The relatively large size of the GSDMD pores (estimated inner diameter up to 20 nm) did not only allow the direct release of IL-1β/-18 (~5 nm molecular diameter), but also of other small cytosolic proteins, such as small GTPases, galectins or the cysteine-type endopeptidase inhibitor cystatins[33,70]. Furthermore, as gasdermin pores are large unselective membrane channels, ion fluxes caused by gasdermin pores can have profound impact on cellular signaling pathways even before cell death become detectable. For example, potassium efflux caused by GSDMD pores triggers NLRP3 after LPS-induced activation of the non-canonical inflammasome pathway[71,72]. Since potassium-driven NLRP3 activation is a cell-intrinsic mechanism[7,72], potassium efflux and NLRP3 activation must occur before the cell undergoes GSDMD-driven pyroptosis. Similarly, it has been proposed that GSDMD-dependent potassium efflux activates NLRP3 after sublytic activation of AIM2 by *Legionella pneumophila*[73], and that potassium efflux impairs type I interferon responses independently of terminal cell death .

So how do cells regulate the level of gasdermin activation or pore formation to extend their lifetime, and could membrane pore formation even be reversible? GSDMD expression is strongly regulated by IRF2[75], which could allow cells to reduce overall GSDMD levels to avoid cell death. Furthermore, caspase activity varies considerably between cell types and activation triggers, which could give rise to conditions of sublytic GSDMD activation. In addition, studies on pore forming toxins, or mechanical or laser-induced membrane damage have demonstrated that plasma membrane damage is not a terminal event, and identified several types of membrane repair mechanism that restore membrane integrity within seconds or minutes[76]. Consistently, it was reported that GSDMD pores on the plasma membrane can be removed by the recruitment of the endosomal sorting complexes required for transport (ESCRT) machinery to the areas of damaged plasma membrane[77]. ESCRTs are recruited to the plasma membrane in response to the influx of Ca^{2+} through the GSDMD pores and promote the budding and release of vesicles that contain the damaged membrane[77]. If ESCRTs or other membrane repair systems are active in neutrophils or under conditions of sublytic inflammasome activation still needs to be demonstrated on a case-by-case basis.

Of note, vesicle release by ESCRTs[77] or other membrane budding mechanism[78], could also represent an alternative pathway for unconventional protein secretion. Early studies into inflammasome activation noted that cells exosome shedding increases quickly after inflammasome activation and that mature IL-1β can be found in exosomes shed from inflammasome-activated cells[79–81]. Newer studies also show that such exosome formation and exosome-mediated IL-1β release is dependent on GSDMD[77,82]. If such vesicles unspecifically release cytosolic proteins, or if IL-1β and other protein are preferentially packed into such vesicles remains to be determined. In summary, gasdermin pores have emerged as master regulators of unconventional protein secretion, which depending on the level of GSDMD activation promote the release of leaderless proteins by either 1) direct membrane

377 translocation (pore function), 2) vesicle release (induction of membrane repair) or 3) passive release
378 by membrane lysis (pyroptosis).

379

380 ***Pyroptotic cell death.*** In most circumstances, the increasing levels of GSDMD processing and
381 GSDMD pores will eventually overcome regulatory mechanism and induce cell death. This specific type
382 of necrotic cell death controlled by the activation of inflammatory caspases was originally known as
383 pyroptosis[11], however since the GSDM[NT] domains all induce pyroptosis without caspase activation[14],
384 the term 'pyroptosis' could be redefined as a gasdermin-dependent type of cell death (**Box 1**). In cell
385 culture, pyroptotic cells are characterized by extensive membrane blebbing followed by ballooning of
386 the membrane and eventual loss of membrane integrity, probably due to osmotic lysis[8383]. The exact
387 events that lead to cell lysis are not yet fully understood, and it is possible that gasdermin pore formation
388 in organellar membranes, such as in mitochondrial or nuclear membranes[50,84], contributes to cell death
389 execution and to the morphological changes associated with pyroptotic cells. The GSDMD[NT], for
390 example, binds cardiolipin[14,16] and has been found to target the mitochondrial membrane to enhance
391 the production of reactive oxygen species[85]. GSDMA3[NT] is also able to damage the mitochondria and
392 induce mitophagy[55]. In neutrophils, GSDMD is also able to bind an disrupt nuclear membrane thereby
393 promoting DNA extrusion during NETosis[50]. Therefore, even under conditions of highly efficient plasma
394 membrane repair[77], gasdermin pores affecting intracellular organelles might still elicit cell death.

395 Evidences for pyroptotic cell death *in vivo* comes from the study of autoinflammatory patients
396 suffering Cryopyrin Associated Periodic Syndrome (CAPS), where inflammasome oligomers were
397 detected systemically in the blood during inflammatory flares [86,87], denoting a potential pyroptosis of
398 cells with activated inflammasomes. The activation of inflammasome *ex vivo* in monocytes from CAPS
399 patients result in a small percentage of cells with active inflammasomes [88], suggesting that not all
400 monocytes will undergo pyroptosis and will not result in a dramatic reduction of blood monocytes. In
401 fact, GSDMD-driven pyroptosis influences the pathogenesis in a mouse model of CAPS[89]. More studies
402 are needed to evaluate the contribution of pyroptosis *in vivo*.

403 Pyroptosis is often referred to as an inflammatory form of cell death[11], but there is little experimental
404 evidence showing that pyroptosis per se causes more inflammation than apoptosis or other types of
405 necrotic cell death. Similarly to apoptotic or necroptotic cells, pyroptotic cells release a number of
406 molecules that can act as 'find me' signals, and present 'eat me' signals like phosphatidyserine on their
407 surface[77,90]. Thus, it can be presumed that pyroptotic corpses are efficiently removed by efferocytosis.
408 However, unlike other types of necrotic cell death, pyroptosis is in most cases caused by inflammatory
409 caspases and thus associated with the release of mature IL-1β and other IL-1 family members[12]. It is
410 likely, that it is the release of these factors that confers a highly pro-inflammatory phenotype to GSDMD-
411 dependent pyroptosis and makes it distinct from other types of necrosis. However, it cannot be excluded
412 that pyroptotic cells also release other unique danger signals that are generated for example as a result
413 of organellar rupture or caspase activity. Several studies have characterized the secretome associated
414 to pyroptosis, with the identification of >900 proteins released upon caspase-1 activation and plasma
415 membrane permeabilization[70,91]. However, systematic studies comparing the secretome and
416 immunological outcome of pyroptosis to other types of death are not available for the moment. In

conclusion, it can be assumed that pyroptosis results in different immunological outcomes, resulting in a low- or high-level inflammatory response (**Figure 5**), and that this inflammatory response will also depend the type of gasdermin that is activated, the mechanism of activation (protease driven or other), the cellular environment and cell type where pyroptosis is executed and how efficiently are gasdermin damaged-membrane repaired.

Role of gasdermins in health and disease

Gasdermin A. The expression of GSDMA is elevated in the gastrointestinal tract and skin, but silenced in primary gastric cancers and in gastric cancer cell lines[2]. Restoration of GSDMA in human gastric cancer cell lines induce apoptosis[21], suggesting that GSDMA could act as a tumor suppressor gene. However, it is unknown if GSDMA require a cleavage for its pro-apoptotic activity in cancer cells or what is the physiological function of GSDMA in the healthy gastric epithelia. The expression of GSDMA3[NT] in cultured cells induce cell death by plasma membrane permeabilization, and interestingly there is also an upregulation of the class-II LC3, suggesting that GSDMA3 induced pyroptosis could be paralleled by an autophagy component [8,55]. Cell death induced by the GSDMA3[NT] could be suppressed by the co-expression of the GSDMA3[CT], conferring to this domain an inhibitory function similarly to other gasdermins[55]. Different mutations in *Gsdma3* are associated with skin-related phenotypes, including keratosis and hair-loss[4,23,92,93]. However, *Gsdma3*[−/−] mice had no visible developmental skin abnormalities, suggesting that these mutations function as gain-of-function[55]. The physiological function of *Gsdma3* in the skin seems associated with the development of the hair follicle [94,95]. Gain-of-function mutations in *Gsdma3* disrupted the autoinhibition conformation of GSDMA3, allowing GSDMA3[NT] domain to induce cell death[8], and therefore these mutations in *Gsdma3*, similar to GSDMA3[NT], result in pyroptosis with an autophagy component due to a decrease in mitochondrial activity[8,55]. It is yet unknown if GSDMA3[NT] or *Gsdma3* gain-of-function mutations could directly target the mitochondrial membrane and form pores, inducing mitochondrial failure and promoting mitophagy in parallel to pyroptosis.

Gasdermin B. GSDMB has been involved in tumor progression and its expression is increased in gastric, cervix and breast cancers, as well as in hepatocarcinomas[96–98]. In HER2-positive breast cancer patients, increased *GSDMB* gene expression in tumor cells has been linked to a poor prognosis, with reduced survival and increased metastasis, and also poor therapeutic responses to HER2-targeted therapy, being *GSDMB* a co-expressed gene with *ERBB2*[98,99]. GSDMB present several splice variants in humans, and in particular the isoform 2 is strongly associated to pro-tumorigenic and pro-metastatic phenotypes of breast cancer cells[98]. So far it is unknown how GSDMB could promote cancer cell survival, since the GSDMB[NT] is able to induce pyroptosis when over-expressed in cultured cells. Different genome-wide association studies have revealed a correlation between *GSDMB* SNPs and an increased susceptibility to diseases such as asthma, Crohn's disease, and ulcerative colitis[100–105]. The full length GSDMB as well as GSDMB[NT] are both able to bind to the acidic phospholipids phosphoinositides as well as the sulfoglycolipid sulfatide[57], and in particular GSDMB has been proposed to function in the cellular transport of sulfatide. Different mechanisms explain the role of

457 GSDMB SNPs in the pathogenesis of asthma, while some studies suggest that SNPs within GSDMB[CT]
458 result in an alteration of the GSDMB structure affecting the levels of sulfatide within cells[57], others found
459 that a splice variant in GSDMB associated with a lower risk of asthma, results in the deletion of an exon
460 that lack a caspase-1 cleavage site and therefore the ability of GSDMB to induce pyroptosis of the
461 airway epithelial cells[28]. Further studies are required to fully understand the role of GSDMB in cancer,
462 infection and autoimmune diseases.

463

464 ***Gasdermin C.*** GSDMC was originally found to be strongly expressed in metastatic melanoma cells,
465 and thus it has been initially named melanoma-derived leucine zipper-containing extranuclear factor
466 (MLZE)[29,106]. Along the same lines, it was recently reported that knock-down of GSDMC reduces the
467 proliferation of colorectal cancer cell lines[107]. However, another study suggested that GSDMC, which is
468 also expressed in the suprabasal region of the esophagus and the isthmus/neck region of the stomach,
469 is suppressed in many esophageal squamous cell carcinomas (ESCCs), suggesting that it could act as
470 a tumor suppressor gene[106]. Thus, so far, no clear picture has emerged whether GSDMC promotes or
471 suppresses cancer development, and whether this function require the activation of its N-terminal pore
472 forming domain.

473

474 ***Gasdermin D.*** Cell culture studies have shown that while GSDMD acts as the sole executor of cell
475 death downstream of the non-canonical inflammasome pathway, GSDMD is not essential for cell death
476 after canonical inflammasome activation, indicating the existence of an alternative or back-up cell death
477 program[7,13]. This difference is also highlighted by GSDMD functions *in vivo*. Kayagaki et al. for example
478 demonstrated that *Gsdmd*-deficient mice are as protected against LPS-induced lethality as *Casp11*-
479 deficient animals[7]. Furthermore, both *Casp11*- and *Gsdmd*-deficient mice showed increased
480 susceptibility compared to WT animals to infections with either *Salmonella enterica* serovar
481 Typhimurium $\Delta SifA$ or *Brucella abortus*[50,108], which both activate the non-canonical inflammasome *in*
482 *vivo*. By contrast to these findings, it is not as clear to what extent GSDMD is essential for caspase-1-
483 driven cell death and cytokine release. *Gsdmd*[-/-] mice are less susceptible to infection with *Francisella*
484 *novicida* compared to *Casp1*- or *Aim2*-deficient animals[109,110]. Similarly, it was reported that peritoneal
485 IL-1β levels are higher in *S*. Typhimurium-infected *Gsdmd*[-/-] mice than *Casp1Casp11*[-/-] controls[111]. By
486 contrast, *Gsdmd*-deficiency fully protected mice harboring the FMF-associated *Mefv* V276A allele of
487 Pyrin against autoinflammatory disease and completely abolished all NOMID-associated inflammatory
488 symptoms in mice expressing the D301N gain-of-function mutation of NLRP3[89,112]. It thus appears that
489 GSDMD might play a context-dependent role *in vivo*, and that under certain circumstances alternative
490 cell death pathways are engaged in *Gsdmd*[-/-] animals that allow to protect animals against microbial
491 challenge after canonical inflammasome activation.

492

493 ***Gasdermin E.*** *GSDME* was first reported as a gene associated with nonsyndromic hearing loss in
494 humans[3]. All known mutations in *GSDME* results in the skipping of exon 8, thereby producing a
495 truncated protein with cytotoxic activity. As GSDME[NT] has pore forming activity and exon 8 skipping
496 results in a loss of the GSDME[CT] repressor domain, it can be assumed that *GSDME*-associated hearing

497 loss is caused by cell death[6,42]. However, since GSDME is expressed in all tissues, it is unclear why
498 cells in the inner ear preferentially undergo cell death upon auto-activation of GSDME. It is possible
499 that differential expression levels (see below) of GSDME might render some cell types more susceptible
500 to active GSDME. The physiological activation mechanism of GSDME appears to be cleavage by
501 apoptotic caspases-3 and -7[37,42]. Chemotherapy drugs that activate caspase-3, such as topotecan,
502 etoposide, cisplatin and CPT-11, were subsequently shown to induce pyroptotic cell death in cell lines
503 expressing high levels of GSDME, while inducing apoptosis in GSDME-negative cells[42]. Thus mouse
504 BMDMs, which express low levels of GSDME[46], do not undergo GSDME-dependent pyroptosis upon
505 engagement of intrinsic or extrinsic apoptosis, even though the GSDME is processed[43,44]. Nevertheless,
506 GSDME might be responsible for some of the side effects of chemotherapy treatment, as mice deficient
507 in *Gsdme* are resistant to tissue damage and weight loss induced by cisplatin injection compared to
508 WT animals[42]. Thus, GSDME has the ability to convert apoptosis into a pyroptotic cell death in a highly
509 cell-type specific manner.
510
511 ***Pejvakin.*** Mutations in PJVK are also associated to hearing impairment in both humans and mice.
512 Unlike mutations in GSDME, which cause autosomal dominant hearing loss consistent with a gain-of-
513 function mutation, all known mutations *PJVK* cause autosomal recessive hearing impairment due to
514 dysfunctional outer hairs cells[39,40,113]. Interestingly, it was shown that *Pjvk*−/− mice display auditory
515 phenotypes with early-onset progressive hearing loss, similarly to patents carrying mutations in
516 *PJVK*[114]. This is distinct from all other gasdermin family members, where knock-out mice display no
517 discernible phenotype, and suggests that the mutations in *PJVK* actually cause a loss-of-function
518 phenotype. Although a pore-forming function for the PJVK[NT] has not yet been demonstrated, it might
519 be possible that its physiological function requires PJVK to be constantly active, i.e. forming channels,
520 even in absence of a stimulus. In fact, the PJVK[CT] is shorter and with no clear homology when compared
521 for other gasdermin family members (**Figure 1c**), and thus might not act as an inhibitory domain.
522 Interestingly, it has been suggested that PJVK localizes to the membrane of peroxisomes in inner hair
523 cells[114], and that it directly recruits LC3B to drive autophagy-mediated removal of damaged
524 peroxisomes (pexophagy) following oxidative stress caused by noise overexposure[115]. PJVK-driven
525 pexophagy is followed by peroxisome proliferation, thereby protecting auditory hair cells from oxidative
526 damage. *Pjvk*−/− mice show indeed signs of peroxisomal dysfunction and impaired antioxidant defenses,
527 and furthermore peroxisomes in *Pjvk*−/− hair cells show structural abnormalities after the onset of
528 hearing[114]. It is thought that this contributes to an exceptionally susceptibility of *Pjvk*−/− mice and human
529 patients to sound, and thus to progressive hearing loss.
530

531 **Inhibition of gasdermins and its application in inflammasome-associated diseases**
532 Given the key function of GSDMD in inflammasome-induced cell death and cytokine release, the
533 inhibition of the gasdermin pore is emerging as a novel target for anti-inflammatory therapy. The notion
534 that pyroptosis could be inhibited arose from the first studies on this type of cell death, which revealed
535 that cell lysis can be blocked by osmoprotectants or high concentrations of glycine (in the mM range)[116].
536 However, this strategy does not prevent the passage of molecules directly through the GSDMD pore

537 (like uptake of dyes or IL-1β release), and as such cannot be suitable when targeting GSDMD-
538 associated inflammation[33,59]. The first compound described to block the execution of pyroptosis and IL-
539 1β release was punicalagin, a complex antioxidant polyphenol found in pomegranate[117]. Punicalagin
540 reversibly inhibits plasma membrane permeabilization and mature IL-1β/IL-18 release after caspase-1
541 activation with an IC_{50} in the low micromolar range, without affecting the generation of GSDMD[NT 117,118].
542 Punicalagin does not affect NLRP3 or AIM2 inflammasome activation, but blocks plasma membrane
543 fluidity and could interfere with the correct insertion of the GSDMD[NT] into the plasma membrane, its
544 oligomerisation and/or pore formation [117]. Recently, a report suggested that punicalagin affects NLRP1
545 and NLRC4 inflammasome activation[119], however since punicalagin interfere with plasma membrane
546 fluidity and the uptake of exogenous particles and proteins to the cell, when applied before stimulation,
547 it might also interfere with the cellular delivery of flagellin or lethal factor as direct activators of the
548 inflammasome. However, further studies are needed to understand the mechanism of action of
549 punicalagin, and its potential specificity to GSDMD. After punicalagin wash-out, a rapid cell lysis is
550 observed, and this lysis was blocked by the use of lanthanides (La^{3+} and Gd^{3+})[117]. These metallic
551 chemical elements were also found to inhibit plasma membrane pores preceding pyroptosis in
552 macrophages[120], however it is not known if lanthanides affect GSDMD[NT] oligomerization on the plasma
553 membrane, since they do not block IL-1β release.

554 Recently, there are several compounds reported to directly target GSDMD. For example,
555 necrosulfonamide (NSA), a cysteine-reactive drug previously shown to inhibit the necroptosis executor
556 mixed lineage kinase domain like pseudokinase (MLKL) in human cells, also inhibits pyroptosis in
557 human and mouse cells[121]. NSA binds GSDMD and inhibits GSDMD[NT] oligomerization on the plasma
558 membrane without affecting Toll-like receptor signaling, inflammasome activation, GSDMD cleavage or
559 cytokine maturation. NSA block plasma membrane permeabilization and IL-1β release in the low
560 micromolar range upon inflammasome activation and protect mice in a model of sepsis. Mechanistically,
561 NSA covalently modifies Cys^{191} of GSDMD[121], a residue essential for pore formation[58]. Interestingly,
562 NSA did not affect cell death induced by GSDME[NT], consistent with the lack of a cysteine in a similar
563 position in GSDME to form pores in the plasma membrane. Another compound, LDC7559, was reported
564 to inhibit GSDMD in human neutrophils undergoing elastase-dependent NETosis or pyroptosis in
565 mouse or human cells[48], yet its mechanism of action is so far unknown.

566 Overall, the characterization of specific gasdermin blockers has just started and validates pyroptosis
567 as a viable pharmaceutical target. The clinical relevance of blocking the inflammasome-IL-1 pathway
568 has been demonstrated in numerous *in vivo* models as well as in trials, being some IL-1 blockers
569 already approved for the treatment of autoinflammatory and chronic inflammatory diseases. The
570 development of novel gasdermin blockers not only will be important to understand the role of the
571 pyroptotic pore in different disease scenarios, but will also pave the way to develop novel treatments
572 for inflammatory diseases.

573

574 **Conclusions and future perspectives**
575 Since the identification of GSDMD as the effector of pyroptosis, our understanding of this emerging
576 family of cell death effectors has rapidly progressed. Structural and mutagenesis studies on full-length

577 gasdermins, and the structure of the GSDMA3^{NT} pore, have revealed the mechanism of autoinhibition

578 and membrane insertion. Furthermore, a host of studies have revealed the involvement of gasdermins

579 in cell death beyond inflammasome-induced pyroptosis, such as in NETosis and during apoptotic cell

580 death. On the other hand, the known function of gasdermins have been extended by the identification

581 of lysis-independent function of gasdermin pores, pointing towards a critical role in unconventional

582 protein secretion.

583 It is clear that these studies only reveal the tip of the iceberg, and that in the coming years the gasdermin

584 family will assume a central player in immunity, cancer therapy and beyond. Nevertheless, many

585 questions still remain unanswered. For example, it is crucial to identify the mechanism by which the

586 different gasdermins are activated, what cell types produce these active gasdermins, and what

587 biological effects they elicit. It is unknown if different gasdermin elicit different effects, particularly the

588 function of GSDMB and GSDMC are largely unknown, and if all gasdermins function in inflammation

589 and host defense against microbial infection.

590 With these advances in knowledge, pharmacological modulation of gasdermin activity will become

591 essential to treat different diseases. GSDMD and GSDME play important roles in causing inflammation

592 after infection or chemotherapy, and mutations in gasdermins and inappropriate activation are

593 associated with a variety of clinical conditions, including alopecia, asthma, breast cancer, gastric

594 cancer, autoinflammation, colorectal cancer and hearing loss. Thus, the development of specific

595 gasdermin inhibitors could lay the foundation the development of new therapies for genetic and

596 inflammatory diseases.

597

598

608

BOXES:

Box. 1: Pyroptosis: a gasdermin-induced necrotic cell death

Pyroptosis was initially defined as 'caspase-1 dependent necrosis' by Cookson and Brennan, based on its morphological features and the strict requirement for caspase-1 but not for other caspases[11]. The term pyroptosis was chosen, from the Greek 'pyro' (meaning fire or fever) and 'ptosis' (meaning to fall), to underline the pro-inflammatory nature of this cell death, and its link to the release of mature IL-1β and IL-18. With the subsequent identification of the inflammasome complex in 2002[122] and the discovery of the non-canonical inflammasome pathway in 2011[71], pyroptosis was re-defined as an inflammasome dependent cell death and an effector mechanism of the inflammasome. However, it also became clear that pyroptosis is not necessarily linked to the release of mature IL-1β and IL-18, since caspase-11/-4 induce pyroptosis with all the characteristic morphological features even in absence of caspase-1 . This was further highlighted by the identification of GSDMD as the pyroptosis executor, and experiments showing that expression of the N-terminal domain of GSDMD or other gasdermins was sufficient to induce pyroptosis without the need for caspase activation[7,8,15].

Additional reports have started to even further uncouple pyroptosis and gasdermin activation from inflammatory caspases and inflammasomes. For example, it was shown that neutrophil elastase and caspase-8 can cleave and activate GSDMD to cause death[44,45,48,49] and that caspase-3 process GSDME to cause pyroptosis-like cell death[37,42]. Since in all cases cell death morphologically resembles pyroptosis and depends on the activation of a gasdermin-family member, it seems clear that the term pyroptosis again requires redefinition. We therefore propose to define 'pyroptosis' as a 'gasdermin-induced necrotic cell death', and propose to apply this term to all gasdermin family members that can cause cell death by membrane permeabilization. We also suggest to use this term independently of the actual mechanism of gasdermin activation and the cell type it occurs in. We acknowledge that the upstream signaling events or the type of cells affected can modify the ability of pyroptosis to provoke inflammation or an immune response – pyroptosis caused by caspase-1 will involve release of mature IL-1β while GSDME-dependent pyroptosis might not – however this is linked to the activation mechanism per se and not to the function of gasdermins as cell death executor.

FIGURES:

Fig. 1. The gasdermin protein family

a | Phylogenetic tree showing the divergence of the human, mouse and rat gasdermin proteins. Scale indicates the number of substitutions for each amino acid in the sequence. Phylogenetic tree was generated from UniProt sequences by the European Bioinformatics Institute (EMBL-EBI) Clustal Omega tool and drawn by FigTree software version 1.4.3. **b** | Domain structure of human GSDMD and GSDME featuring caspase cleavage sequences in the linker (top) and structure of the membrane inserted N-terminal domain (bottom). **c** | Alignment of human gasdermin proteins. Green and orange

649   (in b, c) mark the first α-helix that specifically interact with phospholipids and the four parallel β-strands

650   that insert into the membrane, respectively.

651

652   **Fig. 2. Role of GSDMD in canonical and non-canonical inflammasome activation**

653   **a** ∣ Canonical inflammasomes are assembled by cytosolic pattern recognition receptors Pyrin, AIM2,

654   NAIP-NLRC4, NLRP3 and NLRP1. These sensors recognize pathogen-associated molecular patterns,

655   endogenous danger signals or alteration to cellular homeostasis caused by cell death, injury or

656   infection. The receptors recruit the adaptor protein ASC and pro-caspase-1 through homotypic

657   interactions between PYDs and CARDs domains. Caspase-1 is activated within the inflammasome and

658   active caspase-1 processes GSDMD as well as cytokines such as pro-IL-1β and pro-IL-18 (not shown).

659   Upon permeabilization of the plasma membrane by GSDMD pores, cells undergo a lytic,

660   proinflammatory cell death (pyroptosis) that promotes the release of mature IL-1β/-18. In absence of

661   cell lysis, GSDMD pores can also allow direct release of cytokines. **b** ∣ The non-canonical

662   inflammasome pathway results in the activation of caspase-11 in mice or caspase-4 and caspase-5 in

663   humans. Binding of lipopolysaccharide (LPS) from Gram-negative bacteria induces the oligomerization

664   and activation of these caspases, allowing them to cleave GSDMD. The GSDMD pores allow in a first

665   step potassium release, resulting in the activation of the NLRP3 inflammasome and IL-1β/-18

666   maturation. In a second step GSDMD pores cause pyroptosis, thereby driving the release of mature

667   cytokines.

668

669   **Fig. 3. Activation of gasdermins by apoptotic caspases**

670   Certain extrinsic stimuli, such as genotoxic stress with concurrent IAP loss or pathogen-induced TAK-

671   1 inhibition, can promote the RIP1-dependent assembly of cytosolic caspase-8-activating complexes

672   (complex IIb/ripoptosome). Active caspase-8 drives apoptosis by activating effector caspases,

673   caspase-3 and caspase-7, but also cleaves GSDMD to generate an active N-terminal fragment. Active

674   GSDMD can induce pore formation, is however restricted by caspase-3-dependent cleavage at

675   aspartate D87 (D88 in mice), which generates the inactive p20/p10 fragments of GSDMD. Caspase-3

676   can also cleave and activate GSDME, which can convert apoptosis into pyroptosis in cells with high

677   GSDME expression levels. GSDME-induced death is distinct from secondary necrosis, which proceeds

678   in a GSDMD/GSDME-independent manner.

679

680   **Fig. 4. Mechanism of gasdermin membrane insertion and pore formation**

681   Interdomain interaction between the GSDM^{NT} and GSDM^{CT} keep the protein in an autoinhibited state.

682   Within the GSDM^{NT} domain, helix α1 and a short β hairpin located at the concave of the β-sheet

683   structure interact strongly with the GSDM^{CT} domain. In addition, a long loop stretches out from one end

684   of the b -sheet to connect to the GSDM^{CT}. Once autoinhibition is disrupted, such as by caspase

685   cleavage of GSDMD and GSDME, the GSDM^{CT} is released from the concave surface, thereby freeing

686   the GSDM^{NT} for membrane insertion and pore formation. Membrane-targeting requires phospholipids

687   with negatively charged head groups, as found on the inner leaflet of the plasma membrane. Compared

688   to the autoinhibited state, the pore conformation of GSDM^{NT} shows drastic conformational changes,

689 involving the refolding of new b-strands that merge with the twisted b -sheet structure. These changes
690 also generate new oligomerization interfaces that drive the assembly of a membrane-spanning b-barrel,
691 the GSDM^{NT} pore.
692
693
694 **Fig. 5. Immunological outcomes of gasdermin pore formation and pyroptosis.**
695 Pyroptotic cells release a number of intracellular molecules that can activate the immune system by
696 acting as alarmins and 'find me' signals. If gasdermin pores are repaired and the gasdermin activating
697 signal terminated, the release of intracellular content can be transient and restricted to small molecules
698 able to pass across gasdermin pores (DMAPs). In the presence of pathogens or damage associated
699 signals that activate NF-κB, pyroptosis will be the result of the activation of the NLRP3 inflammasome
700 and associates with the activation of caspase-1 and release of pro-inflammatory cytokines (IL-1β, IL-
701 18), as well as small intracellular proteins (DAMPs) that permeate across gasdermin pores. In this
702 situation, if gasdermin pores at the plasma membrane are not repaired, pyroptosis will terminate with a
703 burst in pro-inflammatory cytokine release, together with the release of large intracellular components
704 (as inflammasome oligomers), resulting in a highly pro-inflammatory pyroptosis. Therefore, pyroptosis
705 can most likely result in different immunological outcomes, resulting in a low- or high-level inflammatory
706 response.
707
