The Gaussian Hare and the Laplacian Tortoise: Computability of Squared-Error versus Absolute-Error Estimators

Stephen Portnoy and Roger Koenker

Abstract. Since the time of Gauss, it has been generally accepted that ℓ_2-methods of combining observations by minimizing sums of squared errors have significant computational advantages over earlier ℓ_1-methods based on minimization of absolute errors advocated by Boscovich, Laplace and others. However, ℓ_1-methods are known to have significant robustness advantages over ℓ_2-methods in many applications, and related quantile regression methods provide a useful, complementary approach to classical least-squares estimation of statistical models. Combining recent advances in interior point methods for solving linear programs with a new statistical preprocessing approach for ℓ_1-type problems, we obtain a 10- to 100-fold improvement in computational speeds over current (simplex-based) ℓ_1-algorithms in large problems, demonstrating that ℓ_1-methods can be made competitive with ℓ_2-methods in terms of computational speed throughout the entire range of problem sizes. Formal complexity results suggest that ℓ_1-regression can be made faster than least-squares regression for n sufficiently large and p modest.

Key words and phrases: ℓ_1, L_1, least absolute deviations, median, regression quantiles, interior point, statistical preprocessing, linear programming, simplex method, simultaneous confidence bands.

1. INTRODUCTION

Although ℓ_1-methods of estimation, which minimize sums of *absolute* residuals, have a long history in statistical applications, there is still some reluctance to adopt them for the analysis of large datasets because they are regarded as computationally highly demanding. In particular, the simplex algorithm of linear programming that is the mainstay of modern ℓ_1-computation has acquired a reputation as unwieldy in large problems. This reputation may be partially attributed to theoretical results on worst-case performance of the simplex algorithm, which establish that for certain pathological problems the number of simplex iterations required for a solution can increase exponentially with problem size over the range of problem dimensions typically encountered in statistical practice. However, *in practice* the simplex algorithm performs extremely well for problems of moderate size. Up to a few hundred observations ℓ_1-regression via the simplex algorithm is actually faster, for example, than conventional ℓ_2-regression in the standard implementations provided by S-PLUS. However, for problems exceeding a few thousand observations current implementations of simplex begin to live up to their slothful theoretical reputation.

Nevertheless, interest in the application of ℓ_1-estimation methods, and quantile regression more generally, in large-scale data analysis has grown steadily in recent years. Applications of quantile regression (Koenker and Bassett, 1978; Powell, 1986) in economics to problems with sample sizes in the range 10,000–100,000 are now almost routine. See, for example, Buchinsky (1994, 1995), Chamberlain (1994) and Manning, Blumberg and Moulton (1995). Interest in bootstrapped inference

Grandville from "Fables de La Fontaine" (published in Paris*, 1838). *The portrait of Gauss is taken from an* 1803 *portrait by J. C. A. Schwartz. The portrait of Laplace appears in "Cauchy: Un Mathématicien Légitimiste au XIXe Siècle," by Bruno Belhoste (Belin, Paris).*

in such applications makes the need for efficient computational methods acute. Nonparametric quantile regression using local polynomials (Welsh, 1996; Fan and Gijbels, 1996) or splines (Koenker, Ng and Portnoy, 1994; Green and Silverman, 1994), has also stimulated the demand for more efficient ℓ_1-computation. Chen and Donoho (1995) and Tibshirani (1996) have recently proposed application of ℓ_1-penalties as model selection devices for a broad range of applications including image processing. Finally, there has been considerable interest in multivariate analysis in problems like the Oja (1983) median, which can be formulated as ℓ_1-regression problems with pseudoobservations constructed as U-statistics from an initial sample. See Chaudhuri (1992) for a development of this approach. Taken together, these developments strongly motivate the search for improved methods of computing ℓ_1-type estimators when n is large.

Following Karmarkar (1984), there has also been intense interest among numerical analysts in alternative "interior point" methods for solving linear programs (LP's). Rather than moving from vertex to vertex around the outer surface of the constraint set as dictated by simplex, the interior point approach solves a sequence of quadratic problems in which the relevant interior of the constraint set is approximated by an ellipsoid. This approach, as shown by Karmarkar and subsequent authors, provides demonstrably better worst-case performance than the simplex algorithm and has also demonstrated impressive practical performance on a broad range of large-scale linear programs arising in commerce as well as in extensive numerical trials.

After a brief historical introduction to ℓ_1-computation, we compare recent interior point methods to existing simplex-based methods. We find, quite in accordance with recent literature on more general LP's, that the interior point approach is competitive with simplex in moderate-sized problems (say, n up to 1,000) and exhibits a rapidly increasing advantage over simplex for larger problems. We then propose a new form of statistical preprocessing for general quantile regression problems that also has the effect of dramatically reducing the computation burden. This preprocessing step is somewhat reminiscent of the subsampling approach in earlier $O(n)$ univariate quantile algorithms like that of Floyd and Rivest (1975). Taken

together, the preprocessing step and a careful choice of interior point versus simplex yields an algorithm that is 10 to 100 times faster than current simplex methods for a variety of test problems with sample sizes in the range 10,000–200,000. In practice, as we will see, combining the preprocessing step and interior point methods yields ℓ_1-computations which rival the speeds achievable with current ℓ_2-methods over the entire range of problem dimensions. In theory, the results of Section 6 imply that ℓ_1-computations can be made strictly faster than their ℓ_2 counterparts for problems with n sufficiently large.

2. INTRODUCTION TO ℓ_1-COMPUTATION

In 1760, the Croatian Jesuit Roger Boscovich, while on a visit to London, posed the following problem to Thomas Simpson:

Let there be any number of quantities a, b, c, d, e, all given, and let it be required to find corrections to be applied to them under these conditions:

1. that their differences may be in a given ratio;
2. that the sum of the positive corrections may be equal to the sum of the negative;
3. that the sum of the positive and sum of the negative corrections may be a minimum.

In modern notation the problem may be formulated as follows: find $\widehat{\alpha}, \widehat{\beta}$ such that

$$y_i = \widehat{\alpha} + \widehat{\beta} x_i + \widehat{u}_i$$

for given observations (y_i, x_i), $i = 1, \ldots, n$, the "corrections" $\widehat{u}_i$ satisfy

$$\sum \widehat{u}_i = 0$$

and

$$\sum |\widehat{u}_i| = \min!$$

Clearly the differences in the corrected observations

$$\widehat{y}_i - \widehat{y}_j = \widehat{\beta}(x_i - x_j)$$

would then satisfy the first requirement that they were in given ratios, determined solely by the x's.

Stigler (1984), in his lively commentary on this exchange, concludes that Simpson made some progress on the problem, recognizing, for example, that the solution should pass through the point $(\bar{x}, \bar{y})$ and one data point. Boscovich provided a geometric solution, but the problem does not seem to have been fully resolved in print until the publication of Laplace (1789), who recognized (see Stigler, 1986) that one could obtain the slope estimate $\widehat{\beta}$ by computing a weighted median of the candidate slopes $s_i = (y_i - \bar{y})/(x_i - \bar{x})$, $i = 1, 2, \ldots, n$. More explicitly, let $s_{(i)}$ denote the ordered s_i's and let $w_{(i)}$ be the associated weights, $w_i = |x_i - \bar{x}|$, ordered according to the s_i's. Then $\widehat{\beta} = s_{(m)}$, where

$$m = \min\left\{ j \,\Big|\, \sum_{i=1}^{j} |w_{(i)}| \geq \sum_{i=1}^{n} \frac{|w_{(i)}|}{2} \right\}.$$

With the advent of least squares at the end of the 18th century, Boscovich's prototype ℓ_1-estimator faded into obscurity. It was revived more than a century later by Edgeworth (1887), who, like Laplace earlier, argued that it could deliver better estimates when the required "corrections" did not happen to follow the Gaussian law. Subsequently, Edgeworth (1888) discarded Boscovich's second constraint that the residuals sum to zero, and proposed to minimize the sum of absolute residuals with respect to both intercept and slope parameters, calling this his "double median" method. He noted that this approach could be extended, in principle, to a "plural median" method. A geometric algorithm was given for the bivariate case, and a discussion of conditions under which such median methods were preferable to least-squares methods was also provided. Unfortunately, the geometric approach to computing Edgeworth's new median regression estimator was rather awkward, requiring, as he admitted, "the attention of a mathematician, and in the case of many unknowns some power of hypergeometrical conception" (Edgeworth, 1888, page 190).

Only with the emergence of the simplex algorithm for linear programming in the late 1940s did ℓ_1-methods become practical on a large scale. Papers by Charnes, Cooper and Ferguson (1955), Wagner (1959) and others provided a foundation for modern implementations, such as Barrodale and Roberts (1974) and Bartels and Conn (1980). See Bloomfield and Steiger (1983) for an extensive discussion of the algorithmic development of ℓ_1-methods, including some very interesting empirical comparisons of the performance of several competing algorithms.

The simplex approach to solving the general ℓ_1-regression problem

$$\min_{b \in \Re^p} \sum_{i=1}^{n} |y_i - x_i' b| \tag{2.1}$$

relies on the reformulation as the linear program

$$\min\{e'u + e'v \mid y = Xb + u - v,\ (u, v) \in \Re^{2n}_+\}. \tag{2.2}$$

Here e denotes an n-vector of ones. This problem has the dual formulation

$$\max\{y'd \mid X'd = 0,\ d \in [-1, 1]^n\}, \tag{2.3}$$

or, equivalently, setting $a = d + (1/2)e$,

$$\max\left\{ y'a \;\middle|\; X'a = \frac{1}{2}X'e,\ a \in [0,1]^n \right\}. \tag{2.4}$$

A p-element subset of $\mathcal{N} = \{1, 2, \ldots, n\}$ will be denoted by h, and $X(h)$, $y(h)$ will denote the submatrix and subvector of X, y with the corresponding rows and elements identified by h. Recognizing that solutions of (2.1) may be characterized as planes which pass through precisely $p = \dim(b)$ observations, or as convex combinations of such "basic" solutions, we can begin with any such solution, which we may write as

$$b(h) = X(h)^{-1}y(h). \tag{2.5}$$

We may regard any such "basic" primal solution as an extreme point of the polyhedral convex constraint set. A natural algorithmic strategy is then to move to the adjacent vertex of the constraint set in the direction of steepest descent. This transition involves two stages: the first chooses a descent direction by considering the removal of each of the current basic observations and computing the gradient in the resulting direction; then, having selected the direction of steepest descent and thus an observation to be removed from the currently active "basic" set, we must find the maximal step length in the chosen direction by searching over the remaining $n - p$ available observations for a new element to introduce into the "basic" set. Each of these transitions involves an elementary "simplex pivot" matrix operation to update the current basis. The iteration continues in this manner until no direction is found, at which point the current $b(h)$ can be declared optimal.

The simplex algorithm offers an extremely efficient approach to computing ℓ_1-type estimators for many applications, yielding, as we shall see below, timings that are quite competitive with least squares on problems of moderate size. See Shamir (1993) for a survey of the extensive literature on the computational complexity of the simplex method. However, the performance of simplex on large problems is somewhat less satisfactory. Problems of sample size 50,000 may require as much as 50 times the computational effort of least squares to compute a median regression, ℓ_1, estimate. Recent implementations of simplex, notably those of Bixby and collaborators (see, e.g., Bixby's discussion of Lustig, Marsden and Shanno, 1994), primarily address efficient treatment of sparsity, and preprocessing to eliminate strictly dominated constraints, and therefore do not seem to be promising from the point of view of statistical applications. We begin our search for more efficient methods for large problems by looking in the most obvious place: the literature on interior point algorithms for linear programming, which have dramatically improved upon simplex for a broad class of problems.

3. INTERIOR POINT METHODS FOR CANONICAL LP'S

Although prior work in the Soviet literature offered theoretical support for the idea that linear programs could be solved in polynomial time, Karmarkar (1984) constituted a watershed in thinking about linear programming both by making a more cogent theoretical argument and by offering direct evidence for the first time that interior point methods were demonstrably faster in specific, large, practical problems.

The close connection between the interior point approach of Karmarkar (1984) and earlier work on barrier methods for constrained optimization, notably Fiacco and McCormick (1968), was observed by Gill et al. (1986) and others and has led to what may be called without much fear of exaggeration a paradigm shift in the theory and practice of linear and nonlinear programming. Remarkably, some of the fundamental ideas required for this shift appeared already in the 1950s in a sequence of Oslo working papers by the economist Ragnar Frisch. This work is summarized in Frisch (1956). We will sketch the main outlines of the approach, with the understanding that further details may be found in the excellent expository papers of Wright (1992), Lustig, Marsden and Shanno (1994) and the references cited there.

Consider the canonical linear program

$$\min\{c'x \mid Ax = b,\ x \geq 0\}, \tag{3.1}$$

and associate with this problem the following logarithmic barrier (potential-function) reformulation:

$$\min\{B(x, \mu) \mid Ax = b\}, \tag{3.2}$$

where

$$B(x, \mu) = c'x - \mu \sum \log x_k.$$

In effect, (3.2) replaces the inequality constraints in (3.1) by the penalty term of the log barrier. Solving (3.2) with a sequence of parameters μ such that $\mu \to 0$ we obtain in the limit a solution to the original problem (3.1). This approach was elaborated in Fiacco and McCormick (1968) for general constrained optimization, but was revived as a linear programming tool only after its close connection to the approach of Karmarkar (1984) was pointed out by Gill et al. (1986). The use of the logarithmic potential function seems to have been introduced by

Frisch (1956), who described it in the following vivid terms:

> My method is altogether different than simplex. In this method we work systematically from the interior of the admissible region and employ a logarithmic potential as a guide—a sort of radar—in order to avoid crossing the boundary.

Suppose that we have an initial feasible point x_0 for (3.1), and consider solving (3.2) by the classical Newton method. Writing the gradient and Hessian of B with respect to x as

$$\nabla B = c - \mu X^{-1} e,$$
$$\nabla^2 B = \mu X^{-2},$$

where $X = \text{diag}(x)$ and e denotes an n-vector of 1's, we have at each step the Newton problem

$$\min_p \left\{ c'p - \mu p' X^{-1} e + \tfrac{1}{2}\mu p' X^{-2} p \mid Ap = 0 \right\}. \tag{3.3}$$

Solving this problem and moving from x_0 in the resulting direction p toward the boundary of the constraint set maintains feasibility and is easily seen to improve the objective function. The first-order conditions for this problem may be written as

$$\mu X^{-2} p + c - \mu X^{-1} e = A'y, \tag{3.4}$$

$$Ap = 0, \tag{3.5}$$

where y denotes an m-vector of Lagrange multipliers. Solving for y explicitly, by multiplying through in the first equation by AX^2 and using the constraint to eliminate p, we have

$$AX^2 A'y = AX^2 c - \mu AXe. \tag{3.6}$$

These normal equations may be recognized as generated from the linear least squares problem

$$\min_y \| XA'y - Xc - \mu e \|_2^2. \tag{3.7}$$

Solving for y, computing the Newton direction p from (3.4) and taking a step in the Newton direction toward the boundary constitute the essential features of the primal log barrier method. A special case of this approach is the affine scaling algorithm in which we take $\mu = 0$ at each step in (3.6), an approach anticipated by Dikin (1967) and studied by Vanderbei, Meketon and Freedman (1986) and numerous subsequent authors.

Recognizing that similar methods may be applied to the primal and dual formulations simultaneously, recent theory and implementation of interior point methods for linear programming have focused on attacking both formulations. The dual problem corresponding to (3.1) may be written as

$$\max \{ b'y \mid A'y + z = c,\ z \geq 0 \}. \tag{3.8}$$

Optimality in the primal implies

$$c - \mu X^{-1} e = A'y, \tag{3.9}$$

so setting $z = \mu X^{-1} e$ we have the system

$$\begin{aligned} Ax &= b, \quad x > 0, \\ A'y + z &= c, \quad z > 0, \\ Xz &= \mu e. \end{aligned} \tag{3.10}$$

Solutions $[x(\mu), y(\mu), z(\mu)]$ of these equations constitute the central path of solutions to the logarithmic barrier problem, which approach the classical complementary slackness condition $x'z = 0$, as $\mu \to 0$, while maintaining primal and dual feasibility along the path.

If we now apply Newton's method to this system of equations, we obtain

$$\begin{pmatrix} Z & 0 & X \\ A & 0 & 0 \\ O & A' & I \end{pmatrix} \begin{pmatrix} p_x \\ p_y \\ p_z \end{pmatrix} = \begin{pmatrix} \mu e - Xz \\ b - Ax \\ c - A'y - z \end{pmatrix}, \tag{3.11}$$

which can be solved explicitly as

$$\begin{aligned} p_y &= (AZ^{-1}XA')^{-1} \\ &\quad \cdot \left[AZ^{-1}X(c - \mu X^{-1} e - A'y) + b - Ax \right], \\ p_x &= XZ^{-1}[A'p_y + \mu X^{-1} e - c + A'y], \\ p_z &= -A'p_y + c - A'y - z. \end{aligned} \tag{3.12}$$

Like the primal method, the real computational effort of computing this step is the Choleski factorization of the diagonally weighted matrix $AZ^{-1}XA'$. Note that the consequence of moving from a purely primal view of the problem to one that encompasses both the primal and dual is that $AX^{-2}A'$ has been replaced by $AZ^{-1}XA'$ and the right-hand side of the equation for the y-Newton step has altered somewhat. However, the computational effort is essentially identical. To complete the description of the primal-dual algorithm we would need to specify how far to go in the Newton direction p, how to adjust μ as the iterations proceed and how to stop.

In fact, the most prominent examples of implementations of the primal-dual log barrier approach now employ a variant due to Mehrotra (1992), which resolves all of these issues. We will briefly describe this variant in the next section in the context of a slightly more general class of linear programs which encompasses the ℓ_1-problem as well as the general linear quantile regression problem.

4. INTERIOR POINT METHODS FOR QUANTILE REGRESSION

Quantile regression, as introduced in Koenker and Bassett (1978), places asymmetric weight on positive and negative residuals, and solves the slightly modified ℓ_1-problem

$$\min_{b\in\Re^p} \sum_{i=1}^{n} \rho_\tau(y_i - x_i'b), \tag{4.1}$$

where $\rho_\tau(r) = r[\tau - I(r < 0)]$ for $\tau \in (0,1)$. This yields the modified linear program

$$\min\{\tau e'u + (1-\tau)e'v \mid y = Xb + u - v, \quad (u,v) \in \Re_+^{2n}\} \tag{4.2}$$

and dual formulations

$$\max\{y'd \mid X'd = 0,\ d \in [\tau - 1, \tau]^n\} \tag{4.3}$$

or, setting $a = d + 1 - \tau$,

$$\max\{y'a \mid X'a = (1-\tau)X'e,\ a \in [0,1]^n\}. \tag{4.4}$$

The dual formulation of the quantile regression problem fits nicely into the standard formulations of interior point methods for linear programs with bounded variables. The function $a(\tau)$ that maps $[0,1]$ to $[0,1]^n$ plays a crucial role in connecting the statistical theory of quantile regression to the classical theory of rank tests as described in Gutenbrunner and Jurečková (1992) and Gutenbrunner, Jurečková, Koenker and Portnoy (1993). See Koenker and d'Orey (1987, 1993) for a detailed description of modifications of the Barrodale–Roberts (Barrodale and Roberts, 1974) simplex algorithm for this problem.

Adding slack variables, s, satisfying the constraint $a + s = e$, we obtain the barrier function

$$B(a,s,\mu) = y'a + \mu \sum_{i=1}^{n} (\log a_i + \log s_i), \tag{4.5}$$

which should be maximized subject to the constraints $X'a = (1-\tau)X'e$ and $a + s = e$. The Newton step δ_a solving

$$\max\{y'\delta_a + \mu\delta_a'(A^{-1} - S^{-1})e - \tfrac{1}{2}\mu\delta_a'(A^{-2} + S^{-2})\delta_a\}, \tag{4.6}$$

subject to $X'\delta_a = 0$, satisfies

$$y + \mu(A^{-1} - S^{-1})e - \mu(A^{-2} + S^{-2})\delta_a = Xb \tag{4.7}$$

for some $b \in \Re^p$, and δ_a such that $X'\delta_a = 0$. As before, multiplying through by $X'(A^{-2}+S^{-2})^{-1}$ and using the constraint, we can solve explicitly for the vector b,

$$b = (X'WX)^{-1}X'W[y + \mu(A^{-1} - S^{-1})e], \tag{4.8}$$

where $W = (A^{-2} + S^{-2})^{-1}$. This is a form of the primal log barrier algorithm described above. Setting $\mu = 0$ in each step yields an affine scaling variant of the algorithm. We should stress again that the basic linear algebra of each iteration is essentially unchanged, only the form of the diagonal weighting matrix W has changed. We should also emphasize that there is nothing especially sacred about the explicit form of the barrier function used in (4.5). Indeed, one of the earliest proposed modifications of Karmarkar's original work was the affine scaling algorithm of Vanderbei, Meketon and Freedman (1986), which used, implicitly, $\mu\sum_{i=1}^{n}\log[\min(a_i, s_i)]$ in lieu of the additive specification.

Again, it is natural to ask if a primal–dual form of the algorithm could improve performance. In the bounded variables formulation we have the Lagrangian

$$\begin{aligned} &L(a,s,b,u,\mu) \\ &\quad = B(a,s,\mu) - b'(X'a - (1-\tau)X'e) \\ &\qquad - u'(a + s - e), \end{aligned} \tag{4.9}$$

and setting $v = \mu A^{-1}$ we have the first-order conditions, describing the central path (see Gonzaga, 1992),

$$\begin{aligned} X'a &= (1-\tau)X'e, \\ a + s &= e, \\ Xb + u - v &= y, \\ USe &= \mu e, \\ AVe &= \mu e, \end{aligned} \tag{4.10}$$

yielding the Newton step

$$\begin{aligned} \delta_b &= (X'WX)^{-1}[(1-\tau)X'e - X'a + X'W\xi(\mu)], \\ \delta_a &= W[X\delta_b + \xi(\mu)], \\ \delta_s &= -\delta_a, \\ \delta_u &= \mu A^{-1}e - Ue - A^{-1}U\delta_a, \\ \delta_v &= \mu S^{-1}e - Ve + S^{-1}V\delta_s, \end{aligned} \tag{4.11}$$

where $\xi(\mu) = y - Xb + \mu(S^{-1} - A^{-1})e$. The most successful implementations of this approach to date employ the predictor-corrector step of Mehrotra (1992), which is described in the context of bounded variables problems in Lustig, Marsden and Shanno (1992). A related earlier approach is described in Zhang (1992). In Mehrotra's approach we proceed somewhat differently. Rather than solving for the

Newton step (4.11) directly, we substitute the step directly into (4.10) to obtain

$$\begin{aligned} X'(a+\delta_a) &= (1-\tau)X'e, \\ (a+\delta_a)+(s+\delta_s) &= e, \\ X(b+\delta_b)+(u+\delta_u)-(v+\delta_v) &= y, \\ (U+\Delta_u)(S+\Delta_s) &= \mu e, \\ (A+\Delta_a)(V+\Delta_v) &= \mu e, \end{aligned} \tag{4.12}$$

where $\Delta_a, \Delta_v, \Delta_u, \Delta_s$ denote the diagonal matrices with diagonals $\delta_a, \delta_v, \delta_u, \delta_s$, respectively. As noted by Lustig, Marsden and Shanno, the primary difference between solving this system and the prior Newton step is the presence of the nonlinear terms $\Delta_u\Delta_s$, $\Delta_a\Delta_v$ in the last two equations. To approximate a solution to these equations, Mehrotra (1992) suggests first solving for an affine primal–dual direction by setting $\mu = 0$ in (4.11). Given this preliminary direction, we may then compute the step length using the following ratio test:

$$\begin{aligned} \widehat{\gamma}_P = \sigma \min\Bigg\{ &\min_j \left\{ -\frac{a_j}{\delta_{a_j}}, \delta_{a_j} \right\}, \\ &\min_j \left\{ -\frac{s_j}{\delta_{s_j}}, \delta_{s_j} \right\} \Bigg\}, \end{aligned} \tag{4.13}$$

$$\begin{aligned} \widehat{\gamma}_D = \sigma \min\Bigg\{ &\min_j \left\{ -\frac{u_j}{\delta_{u_j}}, \delta_{u_j} \right\}, \\ &\min_j \left\{ -\frac{v_j}{\delta_{v_j}}, \delta_{v_j} \right\} \Bigg\}, \end{aligned} \tag{4.14}$$

using scaling factor $\sigma = 0.99995$, as in Lustig, Marsden, and Shanno. Then, defining the function

$$\begin{aligned} \widehat{g}(\widehat{\gamma}_P, \widehat{\gamma}_D) = &(s+\widehat{\gamma}_P\delta_s)'(u+\widehat{\gamma}_D\delta_u) \\ &+ (a+\widehat{\gamma}_P\delta_a)'(v+\widehat{\gamma}_D\delta_v), \end{aligned} \tag{4.15}$$

the new μ is taken as

$$\mu = \left(\frac{\widehat{g}(\widehat{\gamma}_P, \widehat{\gamma}_D)}{\widehat{g}(0,0)} \right)^3 \frac{\widehat{g}(0,0)}{2n}. \tag{4.16}$$

To interpret (4.15) we may use the first three equations of (4.10) to write, for any primal–dual feasible point (u, v, s, a),

$$\begin{aligned} &\tau e'u + (1-\tau)e'v - \big[a-(1-\tau)e\big]'y \\ &\quad = u's + a'v. \end{aligned} \tag{4.17}$$

So the quantity $u's + a'v$ is equal to the duality gap, the difference between the primal and dual objective function values at (u, v, s, a), and $\widehat{g}(\widehat{\gamma}_P, \widehat{\gamma}_D)$ is the duality gap after the tentative affine scaling step. Note that the quantity $a-(1-\tau)e$ is simply the vector d appearing in the dual formulation (4.3). At a solution, classical duality theory implies that the duality gap vanishes; that is, the values of the primal and dual objective functions are equal and the complementary slackness condition $u's + a'v = 0$ holds. If, in addition to feasibility, (u, v, s, a) happened to lie on the central path, the last two equations of (4.10) would imply that

$$u's + a'v = 2\mu n.$$

Thus, the function $\widehat{g}$ in (4.15) may be seen as an attempt to adapt μ to the current iterate in such a way that, for any given value of the duality gap, μ is chosen to correspond to the point on the central path with that gap. By definition, $\widehat{g}(\widehat{\gamma}_P, \widehat{\gamma}_D)/\widehat{g}(0,0)$ is the ratio of the duality gap after the tentative affine-scaling step to the gap at the current iterate. If this ratio is small the proposed step is favorable and we should reduce μ further, anticipating that the recentering and nonlinearity adjustment of the modified step will yield further progress. If, on the other hand, $\widehat{g}(\widehat{\gamma}_P, \widehat{\gamma}_D)$ isn't much different from $\widehat{g}(0,0)$, the affine scaling direction is unfavorable, and further reduction in μ is ill-advised. Since leaving μ fixed in the iteration brings us back to the central path, such unfavorable steps are intended to enable better progress in subsequent steps by bringing the current iterate back to the vicinity of the central path. The rationale for the cubic adjustment in (4.16), which implements these heuristics, is based on the fact that the recentering of the Newton direction embodied in the terms $\mu A^{-1}e$ and $\mu S^{-1}e$ of (4.11) and (4.18) accommodates the $\mathcal{O}(\mu)$ term in the expansion of the duality gap function $\widehat{g}$ while the nonlinearity adjustment described below accommodates the $\mathcal{O}(\mu^2)$ effect of the $\delta_s\delta_u$ and $\delta_a\delta_v$ terms.

We compute the following approximation to the solution of system (4.12) with this μ and the nonlinear terms $\Delta_s\Delta_u$ and $\Delta_a\Delta_v$ taken from the preliminary primal-dual affine direction:

$$\begin{aligned} \delta_b &= (X'WX)^{-1}\big[(1-\tau)X'e - X'a \\ &\qquad + X'W\xi(\mu)\big], \\ \delta_a &= W\big[X\delta_b + \xi(\mu)\big], \\ \delta_s &= -\delta_a, \\ \delta_u &= \mu A^{-1}e - Ue - A^{-1}U\delta_a + A^{-1}\Delta_s\Delta_u e, \\ \delta_v &= \mu S^{-1}e - Ve + S^{-1}V\delta_s + S^{-1}\Delta_a\Delta_v e. \end{aligned} \tag{4.18}$$

The iteration proceeds until the algorithm terminates when the duality gap $y'a - (1-\tau)e'Xb + e'v$ becomes smaller than a specified ε. Recall that the duality gap is zero at a solution, and thus this criterion offers a more direct indication of convergence than is usually available in iterative algorithms.

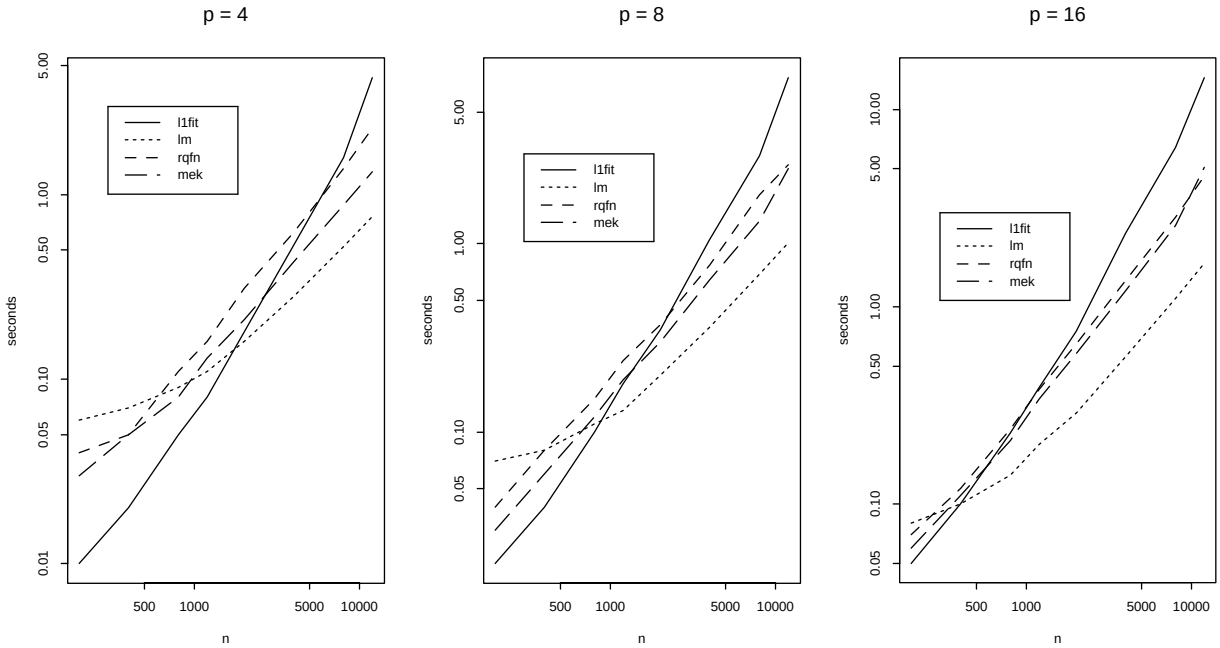

FIG. 2. *Timing comparison of three ℓ_1-algorithms for median regression*: *times are in seconds for the median of five replications for iid Gaussian data. The parametric dimension of the models is $p + 1$ with p indicated above each plot*; *p columns are generated randomly and an intercept parameter is appended to the resulting design. Timings were made at eight design points in n*: 200, 400, 800, 1,200, 2,000, 4,000, 8,000, 12,000. *The solid line represents the results for the simplex-based Barrodale–Roberts algorithm implemented in S-PLUS as* `l1fit`, *the* `rqfn` *dashed line represents a primal-dual interior point algorithm*, `mek` *uses an affine scaling form of the interior point approach and the dotted line represents least-squares timings based on* `lm(y~x)` *as a benchmark.*

Our expectations about satisfactory computational speed of regression estimators are inevitably strongly conditioned by our experience with least squares. In Figure 2 we illustrate the results of a small experiment to compare the computational speed of three ℓ_1-algorithms: the Barrodale–Roberts simplex algorithm (Barrodale and Roberts, 1974), which is employed in many contemporary statistical packages; Meketon's affine scaling algorithm; and our implementation of Mehrotra's (1992) predictor-corrector version of the primal–dual log barrier algorithm. The former is indicated in the figure as `mek` and the latter as `rqfn` for regression quantiles via Frisch–Newton. The two interior point algorithms were coded in Fortran employing Lapack (Anderson et al., 1995) subroutines for the requisite linear algebra. They were then incorporated as functions into S-PLUS and timings are based on the S-PLUS function `unix-time()`. The Barrodale–Roberts timings are based on the S-PLUS implementation `l1fit(x,y)`. For comparison we also illustrate timings for least-squares estimation based on S-PLUS function `lm(y~x)`.

Such comparisons are inevitably fraught with qualifications about programming style, system overhead and so on. We have chosen to address the comparison within the S-PLUS environment because (a) it is the computing environment in which we feel most comfortable, a view widely shared by the statistical research community, and (b) it offers a convenient means of incorporating new functions in lower-level languages, like Fortran and C, providing a reasonably transparent and efficient interface with the rest of the language. We have considerable experience with the Barrodale–Roberts (BR) Fortran code (Barrodale and Roberts, 1974) as implemented in S-PLUS for `l1fit`. This code also underlies the quantile regression routines described in Koenker and d'Orey (1987, 1993) and still represents the state of the art after more than 20 years. The S-PLUS function `l1fit` incurs a modest overhead getting problems into and out of BR's Fortran, but this overhead is quickly dwarfed by the time spent in the Fortran in large problems. Similarly, we have tried to write the interior point code to minimize the S-PLUS overhead, although some improvements are still possible in this respect.

Least-squares timings are also potentially controversial. The S-PLUS function `lm` as described by Chambers (1992) offers three method options: QR decomposition, Cholesky and singular-value decomposition. All of our comparisons are based on the

default choice of the QR method. Again there is a modest overhead involved in getting the problem descriptions into and the solutions out of the lower-level Lapack routines which underlie `lm`. We have run some very limited timing comparisons outside S-PLUS directly in Fortran to evaluate these overhead effects and our conclusion from this is that any distortions in relative performance due to overhead effects are slight.

We would stress that the code underlying the least-squares computations we report is the product of decades of refinement, while our interior point routines are still in their infancy. There is still considerable scope for improvement in the latter.

Several features of the figures are immediately striking. For small problems all the ℓ_1-algorithms perform impressively. They are all faster than the QR implementation of least squares which is generally employed in `lm`. For small problems the simplex implementation of Barrodale and Roberts is the clear winner, but its roughly quadratic (in sample size) growth over the illustrated range quickly dissipates its initial advantage. The interior point algorithms do considerably better than simplex at larger sample sizes, exhibiting roughly linear growth, as does least squares. Meketon's affine scaling algorithm performs slightly better than the primal–dual algorithm, which is somewhat surprising, but for larger p the difference is hardly noticeable.

Beyond the range of problem sizes illustrated here, the advantage of the interior point method over simplex grows exorbitant, fully justifying the initial enthusiasm with which Karmarkar (1984) was received. Nevertheless, there is still a significant gap between ℓ_1 and ℓ_2 performance in large samples. We explore this gap from the probabilistic viewpoint of computational complexity in the next section.

5. COMPUTATIONAL COMPLEXITY

In this section we investigate the computational complexity of the interior point algorithms for quantile regression described above. We should stress at the outset, however, that the probabilistic approach to complexity analysis adopted here is rather different than that employed in the rest of the interior point literature, where the focus on worst-case analysis has led to striking discrepancies between theoretical rates and observed computational experience. The probabilistic approach has the virtue that the derived rates are much sharper and consequently more consonant with observed performance. A similar gap between worst-case theory and average practice can be seen in the analysis of parametric linear programming via the simplex algorithm, where it is known that in certain problems with an n-by-p constraint matrix there can be as many as n^p distinct solutions. However, exploiting some special aspects of the quantile regression problem and employing a probabilistic approach, Portnoy (1991) was able to show that the number of distinct vertex solutions (in τ) is $\mathcal{O}_p(n \log n)$, a rate which provides excellent agreement with empirical experience.

For interior point methods the crux of the complexity argument rests on showing that at each iteration the algorithm reduces the duality gap by a proportion, say $\theta_n < 1$. Thus, after K iterations, an initial duality gap of Δ_0 has been reduced to $\theta_n^K \Delta_0$. Once the gap is sufficiently small (say, less than ε), there is only one vertex of the constraint set at which the duality gap can be smaller. This follows obviously from the fact that the vertices are discrete. Thus, the vertex with the smaller duality gap must be the optimal one, and this vertex may be identified by taking p simplex-type steps. This process, called purification in Gonzaga (1992, Lemma 4.7), requires in our notation p steps involving $\mathcal{O}(np^2)$ operations, or $\mathcal{O}(np^3)$ operations. Hence, the number of iterations K required to make $\theta_n^K \Delta_0 < \varepsilon$ is

$$K < \log(\Delta_0/\varepsilon)/(-\log \theta_n).$$

In the worst-case analysis of the interior point literature, ε is taken to be 2^{-L}, where L is the total number of binary bits required to encode the entire data of the problem. Thus, in our notation ε would be $\mathcal{O}(np)$. Further, the conventional worst-case analysis employs the bound $\theta_n < (1 - cn^{-1/2})$ and takes Δ_0 independent of n so the number of required iterations is $\mathcal{O}(\sqrt{n}L)$. Since each iteration requires a weighted least-squares solutions of $\mathcal{O}(np^2)$ operations, the complexity of the algorithm as a whole would be $\mathcal{O}(n^{5/2}p^3)$, apparently hopelessly disadvantageous relative to least squares. Fortunately, however, in the random problems for which quantile regression methods are designed, the ε bound on the duality gap at the second best vertex can be shown to be considerably larger, at least with probability tending to 1, than this worst-case value of 2^{-L}. Lemma A.1 provides the bound $\log \varepsilon = \mathcal{O}_p(p \log n)$ under mild conditions on the underlying regression model. This leads to a considerably more optimistic view of these methods for large problems.

Renegar (1988) and numerous subsequent authors have established the existence of a large class of interior point algorithms for solving linear programs which, starting from an initially feasible primal–dual point with duality gap Δ_0,

can achieve convergence to a prescribed accuracy ε in $\mathcal{O}(\sqrt{n}\log[\Delta_0/\varepsilon])$ iterations *in the worst case.* More recently, Sonnevend, Stoer, and Zhao (1991) have shown under somewhat stronger nondegeneracy conditions that this rate can be improved to $\mathcal{O}(n^a \log[\Delta_0/\varepsilon])$ with $a < 1/2$. We will call an algorithm which achieves this rate an n^a-algorithm. They give explicit conditions, which hold with probablity 1 if the the y's have a continuous density, for the case $a = 1/4$. The following result then follows immediately from Lemma A.1.

THEOREM 5.1. *Under the conditions of Lemma* A.1*, an n^a-algorithm for median regression converges in $\mathcal{O}_p(n^a p \log n)$ iterations. With $\mathcal{O}(np^2)$ operations required per iteration and $\mathcal{O}(np^3)$ operations required for the final "purification" process such an algorithm has complexity $\mathcal{O}_p(n^{1+a} p^3 \log n)$.*

Mizuno, Todd and Ye (1993) provide an alternative probabilistic approach to the existence of an n^a-algorithm, with $a < 1/2$, and provide a heuristic argument for $a = 1/4$. They also conjecture that n^a might be improvable to $\log n$, by a more refined probabilistic approach. This would improve the overall complexity in Theorem 5.1 to $\mathcal{O}_p(np^3 \log^2 n)$ and seems quite plausible in light of the empirical evidence reported below, and elsewhere in the interior point literature. In either case we are still faced with a theoretical gap between ℓ_1 and ℓ_2 performance that substantiates the empirical experience reported in the previous section. We now introduce a new form of preprocessing for ℓ_1-problems that has been successful in further narrowing this gap.

6. PREPROCESSING FOR QUANTILE REGRESSION

Many modern linear programming algorithms include an initial phase of preprocessing which seeks to reduce problem dimensions by identifying redundant variables and dominated constraints. See, for example, the discussion in Lustig, Marsden, and Shanno (1994, Section 8.2) and the remarks of the discussants. Bixby, in this discussion, reports reductions of 20–30% in the row and column dimensions of a sample of standard commercial test problems due to "aggressive implementation" of preprocessing. Standard preprocessing strategies for LP's are not, however, particularly well suited to the statistical applications which underlie quantile regression. In this section we describe some new preprocessing ideas designed explicitly for quantile regression, which can be used to reduce dramatically the effective sample sizes for these problems.

The basic idea underlying our preprocessing step rests on the following elementary observation. Consider the directional derivative of the median regression (ℓ_1) problem

$$\min_b \sum_{i=1}^n |y_i - x_i'b|,$$

which may be written in direction w as

$$g(b, w) = -\sum_{i=1}^n x_i'w \operatorname{sgn}^*\left(y_i - x_i'b, -x_i'w\right),$$

where

$$\operatorname{sgn}^*(u, v) = \begin{cases} \operatorname{sgn}(u), & \text{if } u \neq 0, \\ \operatorname{sgn}(v), & \text{if } u = 0. \end{cases}$$

Optimality may be characterized as a b^* such that $g(b^*, w) \geq 0$ for all $w \in \Re^p$. Suppose for the moment that we "knew" that a certain subset J_H of the observations $N = \{1, \ldots, n\}$ would fall above the optimal median plane and another subset J_L would fall below. Then consider the revised problem

$$\min_{b \in \Re^p} \sum_{i \in N \setminus J_L \cup J_H} |y_i - x_i'b| + |y_L - x_L'b| + |y_H - x_H'b|,$$

where $x_K = \sum_{i \in J_K} x_i$, for $K \in \{H, L\}$, and y_L, y_H can be chosen as arbitrarily small and large enough, respectively, to ensure that the corresponding residuals remain negative and positive. We will refer in what follows to these combined pseudo-observations as *globs*. The new problem, under our provisional hypothesis, has exactly the same gradient condition as the original one, and therefore the same solutions, but the revision has reduced effective sample size by $\#\{J_L, J_H\} - 2$, that is, by the number of observations in the globs.

How might we know J_L, J_H? Consider computing a preliminary estimate $\widehat{\beta}$ based on a subsample of m observations. Compute a simultaneous confidence band for $x_i'\beta$ based on this estimate for each $i \in N$. Under plausible sampling assumptions we will see that the length of each interval is proportional to $p/\sqrt{m}$, so if M denotes the number of y_i falling inside the band, $M = \mathcal{O}_p(np/\sqrt{m})$. Take J_L, J_H to be composed of the indices of the observations falling outside the band. So we may now create the "globbed" observations (y_K, x_K), $K \in \{L, H\}$, and reestimate based on $M + 2$ observations. Finally, we must check to verify that all the observations in J_H, J_L have the anticipated residual signs; if so, we are done; if not, we must repeat the process. If the coverage probability of the bands is P, presumably near 1, then the expected number of repetitions of this process is the expectation of a geometric random variable Z with expectation P^{-1}. We will call each repetition a cycle.

6.1 Implementation

In this subsection we will sketch some further details of the preprocessing strategy. We should emphasize that there are many aspects of the approach that deserve further research and refinement. In an effort to encourage others to contribute to this process we have made all of the code described below available at the website `http://www.econ.uiuc.edu/research/rqn/rqn.html`. We will refer in what follows to the Frisch–Newton quantile regression algorithm *with preprocessing* as `prqfn`.

The basic structure of the current `prqfn` algorithm looks like this:

```
k ← 0
l ← 0
m ← [2n^{2/3}]
while (k is small){
  k = k + 1
  solve for initial rq using first m observations
  compute confidence interval for this solution
  reorder globbed sample as first M observations
  while (l is small){
    l = l + 1
    solve for new rq using the globbed sample
    check residual signs of globbed observations
    if no bad signs: return optimal solution
    if only few bad: adjust globs, reorder sample,
            update M, continue
    if too many bad: increase m and break to
            outer loop
    }
}
```

The algorithm presumes that the data has undergone some initial randomization so the first m observations may be considered representative of the sample as a whole. In all of the experiments reported below we use the Mehrotra–Lustig–Marsden–Shanno primal–dual algorithm to compute the subsample solutions. For some "intermediately large" problems it would be preferable to use the simplex approach, but we postpone this refinement. Although the affine scaling algorithm of Meketon (1986) exhibited excellent performance on certain subsets of our early test problems, like those represented in Figure 2, we found its performance inconsistent in other tests. It was consequently abandoned in favor of the more reliable primal–dual formulation. This choice is quite consistent with the general development of the broader literature on interior point methods for linear programming, but probably also deserves further exploration.

6.2 Confidence Bands

The confidence bands used in our reported computational experiments are of the standard Scheffé type. Under iid error assumptions the covariance matrix of the initial solution is given by

$$V = \omega^2 (X'X)^{-1},$$

where $\omega^2 = \tau(1-\tau)/f^2[F^{-1}(\tau)]$; the reciprocal of the error density at the τth quantile is estimated using the Hall–Sheather bandwidth (Hall and Sheather, 1988) for Siddiqui's (1960) estimator. Quantiles of the residuals from the initial fit are computed using the Floyd–Rivest algorithm (Floyd and Rivest, 1975). We then pass through the entire sample computing the intervals

$$B_i = \left(x_i'\widehat{\beta} - \zeta||\widehat{V}^{1/2}x_i||,\ x_i'\widehat{\beta} + \zeta||\widehat{V}^{1/2}x_i||\right).$$

The parameter ζ is currently set, naively, at 2, but could, more generally, be set as $\zeta = (\Phi^{-1}(1-\alpha) + \sqrt{2p-1})/\sqrt{2} = \mathcal{O}(\sqrt{p})$ to achieve $(1-\alpha)$ coverage for the band, and thus assures that the number of cycles is geometric. Since, under the moment condition of Lemma A.1, if $p \to \infty$, the quantity $||\widehat{V}^{1/2}x_i||$ also behaves like the square root of a χ^2 random variable, the width of the confidence band is $\mathcal{O}_p(p/\sqrt{m})$.

Unfortunately, using the Scheffé bands requires $\mathcal{O}(np^2)$ operations, a computation of the same order as that required by least-squares estimation of the model. It seems reasonable, therefore, to consider alternatives. One possibility, suggested by the Studentized range, is to base intervals on the inequality

$$|x_i'\widehat{\beta}| \le \max_j \left\{ \frac{|\widehat{\beta}_j|}{s_j} \right\} \times \sum_{j=1}^{p} |x_{ij}|\, s_j, \tag{6.1}$$

where s_j is $\widehat{\omega}$ times the jth diagonal element of the $(X'X)^{-1}$ matrix, and $\widehat{\omega}$ is computed as for the Scheffé intervals. This approach provides conservative (although not "exact") confidence bands with width $c_q \sum_{j=1}^{p} |x_j|\, s_j$. Note that this requires only $\mathcal{O}(np)$ operations, thus providing an improved rate. Choice of the constant c_q is somewhat problematic, but some experimentation with simulated data showed that c_q could be taken conservatively to be approximately 1, and that the algorithm was remarkably independent of the precise value of c_q. For these bands the width is again $\mathcal{O}_p(p/\sqrt{m})$, as for the Scheffé bands. Although these $\mathcal{O}(np)$ confidence bands worked well in simulation experiments, and thus merit further study, the computational experience reported here is based entirely on the more traditional Scheffé bands.

After creating the globbed sample, we again solve the quantile regression problem, this time with the M observations of the globbed sample. Finally, we check the signs of the globbed observations. If they all agree with the signs predicted by the confidence band we may declare victory and return the optimal solution. If there are only a few incorrect signs, we have found it expedient to adjust the globs, reintroduce these observations into the new globbed sample and resolve. If there are too many incorrect signs, we return to the initial phase, increasing the initial sample size somewhat, and repeat the process. One or two repetitions of the inner (fixup) loop are not unusual; more than two cycles of the outer loop is highly unusual given current settings of the confidence band parameters.

6.3 Choosing m

The choice of the initial subsample size m and its implications for the complexity of an interior point algorithm for quantile regression *with preprocessing* is resolved by the next lemma.

THEOREM 6.1. *Under the conditions of Lemma* A.1*, for any nonrecursive quantile regression algorithm with complexity* $\mathcal{O}_p(n^\alpha p^\beta \log n)$*, for problems with dimension* (n, p)*, there exists a confidence band construction based on an initial subsample of size* m *with expected width* $\mathcal{O}_p(p/\sqrt{m})$*, and, consequently, the optimal initial subsample size is* $m^* = \mathcal{O}((np)^{2/3})$*. With this choice of* m^**,* M *is also* $\mathcal{O}((np)^{2/3})$*. Then, with* $\alpha = 1 + a$ *and* $\beta = 3$*, from Theorem 5.1, the overall complexity of the algorithm with preprocessing is, for any* n^a *underlying interior point algorithm,*

$$\mathcal{O}_p\big[(np)^{2(1+a)/3} p^3 \log n\big] + \mathcal{O}_p(np).$$

For $a < 1/2$*,* n *sufficiently large and* p *fixed, this complexity is dominated by the complexity of the confidence band computation, and is strictly smaller than the* $\mathcal{O}(np^2)$ *complexity of least squares.*

PROOF. Formally, we treat only the case of p fixed, but we have tried to indicate the role of p in the determination of the constants, where possible. Thus, for example, for $p \to \infty$, we have suggested above that the width of both the Scheffé bands and the Studentized range bands are $\mathcal{O}_p(p/\sqrt{m})$. For p fixed this condition is trivially satisfied. By independence we may conclude that the number of observations inside such a confidence band will be

$$M = \mathcal{O}_p\big(np/\sqrt{m}\big),$$

and minimizing, for any constant c,

$$m^\alpha p^\beta \log m + \big(cnp/\sqrt{m}\big)^\alpha p^\beta \log\big(cnp/\sqrt{m}\big) \tag{6.2}$$

yields

$$m^* = \mathcal{O}\big[(np)^{2/3}\big].$$

Substituting this m^* back into (6.2), Theorem 5.1 implies that we have complexity

$$\mathcal{O}\big[(np)^{2(1+a)/3} p^3 \log n\big],$$

for each cycle of the preprocessing. The number of cycles required is bounded in probability since it is a realization of a geometrically distributed random variable with a finite expectation. The complexity computation for the algorithm as a whole is completed by observing that the required residual checking is $\mathcal{O}(np)$ for each cycle, and employing the Studentized range confidence bands also requires $\mathcal{O}(np)$ operations per cycle. Thus the contribution of the confidence band construction and residual checking is precisely $\mathcal{O}_p(np)$, and for any $a < 1/2$ the complexity of the ℓ_1-algorithm is therefore dominated by this term for any fixed p and n sufficiently large. □

REMARKS. (1) Clearly these results above apply not only to median regression, but to quantile regression in general. (2) If the explicit rates in p of Theorem 6.1 hold for $p \to \infty$, and if the Mizuno–Todd–Ye conjecture that n^a can be improved to $\log n$ holds, then the complexity of the algorithm becomes

$$\mathcal{O}\big(n^{2/3} p^3 \log^2 n\big) + \mathcal{O}_p(np).$$

The contribution of the first term in this expression would then assure an improvement over least squares for n sufficiently large, provided $p = o(n^{1/5})$, a rate approaching the domain of nonparametric regression applications. (3) It is tempting to consider the recursive application of the preprocessing approach described above, and this can be effective in reducing the complexity of the solution of the initial subsample m problem, but it does not appear possible to make it effective in dealing with the globbed sample. This accounts for the qualifier "nonrecursive" in the statement of the theorem.

7. COMPUTATIONAL EXPERIENCE

In this section we provide some further evidence on the performance of our implementation of the algorithm on both simulated and real data. In Figure 3 we compare the performance of `l1fit` with the new `prqfn`, which combines the primal–dual algorithm with preprocessing. With the range of sample

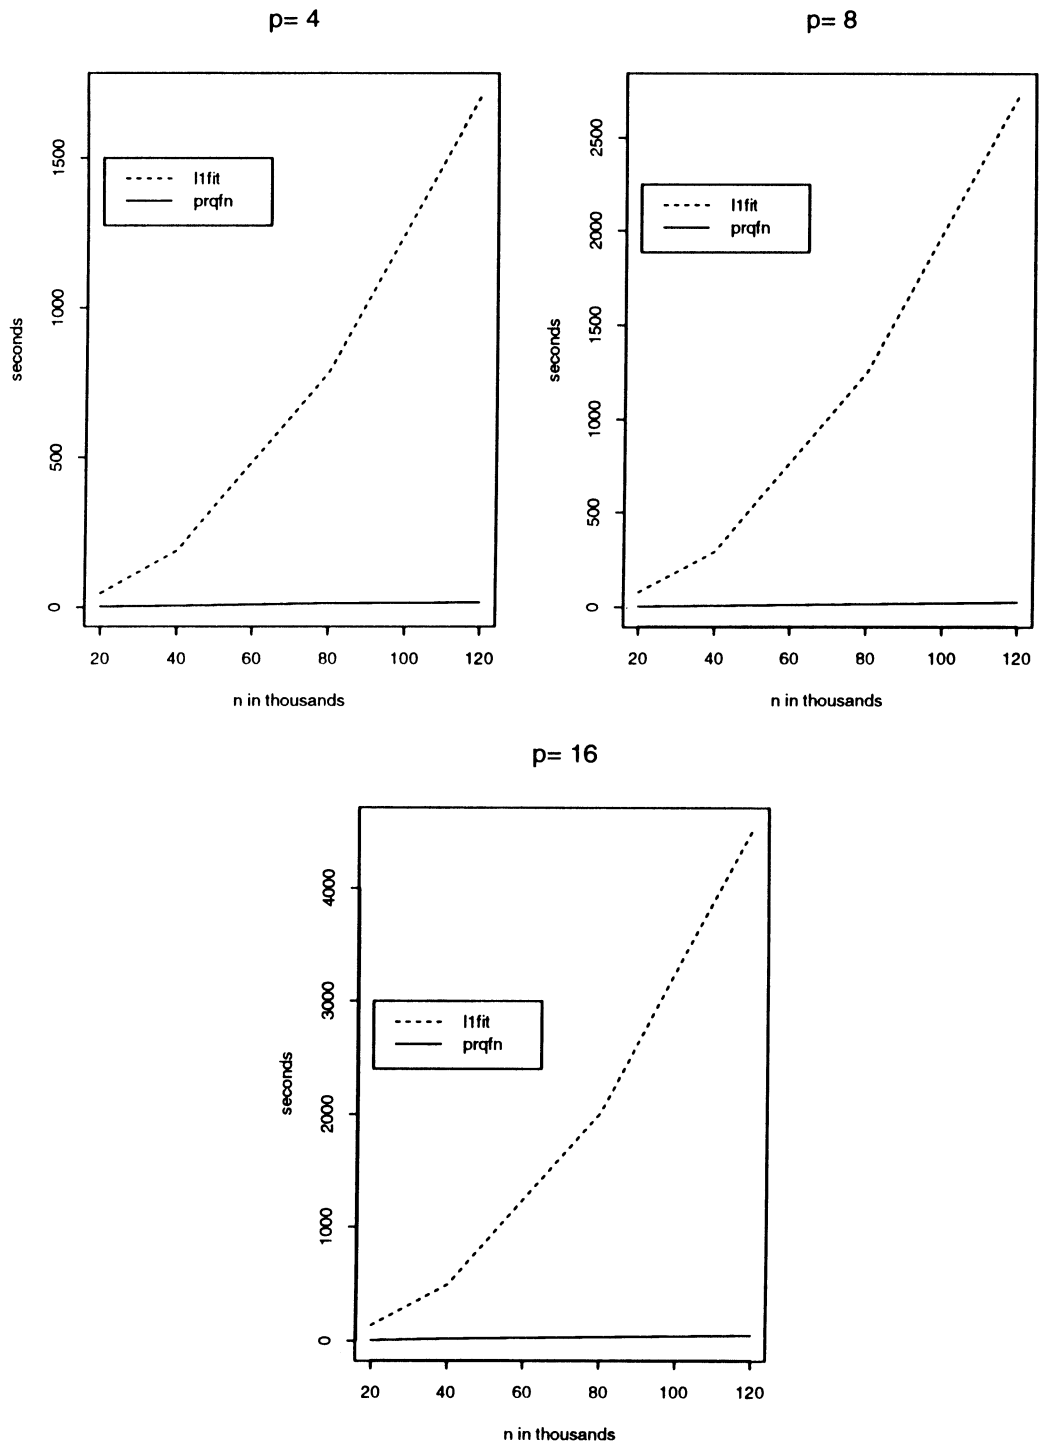

FIG. 3. *Timing comparison of two ℓ_1-algorithms for median regression: times are in seconds for the mean of five replications for iid Gaussian data. The parametric dimension of the models is $p+1$ with p indicated above each plot; p columns are generated randomly and an intercept parameter is appended to the resulting design. Timings were made at four design points in n: 20,000, 40,000, 80,000, 120,000. The dotted line represents the results for the simplex-based Barrodale–Roberts algorithm* `l1fit`, *which increases roughly quadratically in n. The solid line represents* `prqfn`, *the timings of the Frisch–Newton interior point algorithm, with preprocessing.*

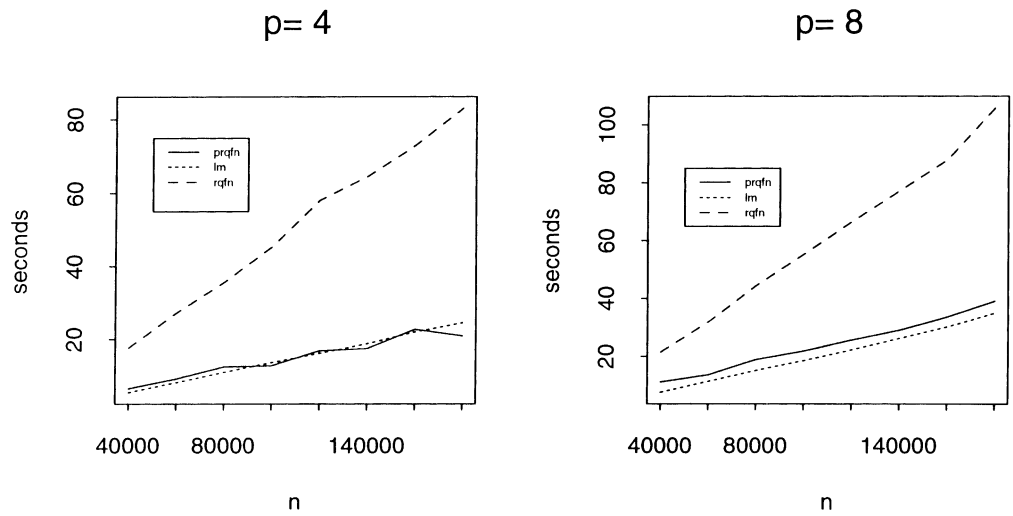

FIG. 4. *Timing comparison of two ℓ_1-algorithms for median regression: times are in seconds for the mean of* 10 *replications for iid Gaussian data. The parametric dimension of the models is $p+1$ with p indicated above each plot; p columns are generated randomly and an intercept parameter is appended to the resulting design. Timings were made at eight design points in n:* 40,000, 60,000, 80,000, 100,000, 120,000, 140,000, 160,000, 180,000. *The* `rqfn` *dashed line represents a primal-dual interior point algorithm;* `prqfn` *is* `rqfn` *with preprocessing; and the dotted line represents least-squares timings based on* `lm(y~x)` *as a benchmark.*

sizes 20,000–120,000, the clear superiority of `prqfn` is very striking. At $n = 20,000$, `prqfn` is faster than `l1fit` by a factor of about 10, and it is faster by a factor of 100 at $n = 120,000$. The quadratic growth in the `l1fit` timings is also quite apparent in this figure.

In Figure 4 we illustrate another small experiment to compare `rqfn` and `prqfn` with `lm` for n up to 180,000. Patience, or more accurately the lack thereof, however, does not permit us to include further comparisons with `l1fit`. Figure 4 displays the improvement provided by preprocessing and shows that `prqfn` is actually slightly faster than `lm` for $p = 4$ and quite close to least squares speed for $p = 8$ for this range of sample sizes. It may be noted that internal Fortran timings of `prqfn` have shown that most of the time is spent in the primal–dual routine `rqfn` for $n < 200,000$. The results of Sections 5 and 6 suggest that the greatest value of preprocessing appears when n is large enough that the time needed to create the globs and check residuals is comparable to that spent in `rqfn`.

Finally, we report some experience with a moderately large econometric application. This is a fairly typical wage equation as employed in the labor economics literature. See Buchinsky (1994, 1995) for a much more extensive discussion of related results. The data are from the 5% sample of the 1990 U.S. Census and consists of annual salary and related characteristics on 113,547 men from the state of Illinois who responded that they worked 40 or more weeks in the previous year and who worked on average 35 or more hours per week.

We seek to investigate the determinants of the logarithm of individuals' reported wage or salary income in 1989 based on their attained educational level, a quadratic labor market experience effect, and other characteristics. Results are reported for five distinct quantiles. Least-squares results for the same model appear in the final column of Table 1. The standard errors reported in parentheses were computed by the sparsity method described in Koenker (1994) using the Hall–Sheather bandwidth. There are a number of interesting findings. The experience profile of salaries is quite consistent across quantiles, with salary increasing with experience at a decreasing rate. There is a very moderate tendency toward more deceleration in salary growth with experience at the lower quantiles. The white–nonwhite salary gap is highest at the first quartile, with whites receiving a 17% premium over nonwhites with similar characteristics, but this appears to decline both in the lower tail and for higher quantiles. Marriage appears to entail an enormous premium at the lower quantiles, nearly a 30% premium at the fifth percentile, for example, but this premium declines somewhat as salary rises. The least squares results are quite consistent with the median regession results, but we should emphasize that the pattern of estimated quantile regression coefficients in the table as a whole is quite inconsistent with the classi-

cal iid-error linear model or, indeed, any of the conventional models accommodating some form of parametric heteroscedasticity.

In Table 2 we report the time (in seconds) required to produce the estimates in Table 1, using three alternative quantile regression algorithms. The time required for the least-squares estimates reported in the last column of Table 1 was 7.8 seconds, roughly comparable to the `prqfn` times. Again, the interior point approach with preprocessing as incorporated in `prqfn` is considerably quicker than the interior point algorithm applied to the full data set in `rqfn`. The simplex approach to computing quantile regression estimates is represented here by the modification of the Barrodale–Roberts (Barrodale and Roberts, 1974) algorithm described in Koenker and d'Orey (1987) and denoted by `rq` in the table. There is obviously a very substantial gain in moving away from the simplex approach to computation in large problems of this type.

8. CONCLUSIONS

There is a compelling general case for the superiority of interior point methods over traditional simplex methods for large linear programming problems, and for large quantile regression applications in particular. We have shown that preprocessing can effectively reduce the sample size dimension of quantile regression problems from n to $\mathcal{O}_p(n^{2/3})$, thereby enabling computational speed comparable to that of least squares for some large quantile regression problems. There are many possible refinements of the basic approach investigated here, but the message for that Gaussian hare who has been frolicking in the flowers, confident of victory, is clear. Laplace's old tortoise, despite the house he wears on his back to protect him from inclement statistical weather, has a few new tricks and the race is far from over.

TABLE 2
Timing comparisons for three methods in wage equation example: results are given in seconds for three different quantile regression algorithms described in the text

Method	$\tau = 0.05$	$\tau = 0.25$	$\tau = 0.5$	$\tau = 0.75$	$\tau = 0.95$
prwfn	9.92	9.78	19.91	7.68	8.64
rqfn	41.07	42.34	28.33	40.87	59.69
rq	565.97	2545.42	3907.42	3704.50	3410.49

APPENDIX

LEMMA A.1. *In the linear model* $Y_i = x_i'\beta + u_i$, $i = 1, \ldots, n$, *assume the following:*

(i) $\{(x_i, Y_i), i = 1, \ldots, n\}$ *are iid with a bounded continuous density in* $\Re^{p+1}$;

(ii) $E|x_{ij}|^p < \infty$ *and* $E|Y_i|^a < \infty$, *for some* $a > 0$.

Then the duality gap of the median regression estimator at the second best vertex exceeds $n^{-(p+5)}$ *with probability tending to 1 as* $n \to \infty$, *and the initial duality gap* Δ_0 *satisfies* $\log \Delta_0 = \mathcal{O}_p(\log n)$.

PROOF. Let $\hat{\beta}$ denote the optimal median regression solution based on the data $\{(x_i, Y_i),\ i = 1, \ldots, n\}$, and let $\hat{d}$ denote the corresponding dual solution. Consider the duality gap at another trial solution pair $(\tilde{\beta}, \tilde{d})$, which we can write

$$\begin{aligned} \Delta^* &= \sum_{i=1}^{n} |Y_i - x_i'\tilde{\beta}| - Y'\tilde{d} \\ &= \sum_{i=1}^{n} |Y_i - x_i'\tilde{\beta}| - \sum_{i=1}^{n} |Y_i - x_i'\hat{\beta}| \\ &\quad + Y'\hat{d} - Y'\tilde{d}, \end{aligned} \tag{A.1}$$

since the duality gap at $(\hat{\beta}, \hat{d})$ is zero. Now, as in Koenker and Bassett (1978), let $h = \{i_1, \ldots, i_p\}$ denote a subset of $N = \{1, 2, \ldots, n\}$ consisting of

p distinct indices. Define $X(h)$ to be the $p \times p$ matrix with rows $\{x_i'\colon i \in h\}$, define $Y(h)$ to be the vector with coordinates $\{Y_i\colon i \in h\}$ and let $\beta(h) = X^{-1}(h)Y(h)$. Now suppose $\hat{h}$ is the subset defining the optimal solution (i.e., $\hat{\beta} = \beta(\hat{h})$) and that $\tilde{h}$ represents the vertex of the constraint set (distinct from $\hat{h}$) for which $\tilde{\beta} = \beta(\tilde{h})$ is nearest to $\hat{\beta}$ in terms of the primal objective function.

Note that $\tilde{h}$ is also a subset of size p and differs from $\hat{h}$ in exactly one element. Let i_1 be the (unique) index in $\hat{h} \cap \tilde{h}^c$, and let $i_2 \in \tilde{h} \cap \hat{h}^c$, where h^c denotes the complement of h. Let $\hat{r}_i$ and $\tilde{r}_i$ denote the respective ith residuals for $\hat{\beta}$ and $\tilde{\beta}$, and note the following: $\hat{r}_i = 0$ for $i \in \hat{h}$; $\tilde{r}_i = 0$ for $i \in \tilde{h}$; $\operatorname{sgn}(\hat{r}_i) = \operatorname{sgn}(\tilde{r}_i)$ for $i \notin \hat{h} \cup \tilde{h}$; and $\operatorname{sgn}(\hat{r}_{i_2}) = -\operatorname{sgn}(\tilde{r}_{i_1})$. Therefore, since the dual contribution to Δ^* is positive, we can write

$$\begin{aligned}
\Delta^* \geq \Delta_1^* &\equiv \sum_{i \notin h} |Y_i - x_i'\tilde{\beta}| - \sum_{i \notin \tilde{h}} |Y_i - x_i'\hat{\beta}| \\
&= \left(Y_{i_1} - x_{i_1}'\tilde{\beta}\right)\operatorname{sgn}(\tilde{r}_{i_1}) \\
&\quad - \left(Y_{i_2} - x_{i_2}'\hat{\beta}\right)\operatorname{sgn}(\hat{r}_{i_2}) \\
&\quad - \sum_{i \notin \hat{h} \cup \tilde{h}} x_i'\tilde{\beta}\,\operatorname{sgn}(\tilde{r}_i) + \sum_{i \notin \hat{h} \cup \tilde{h}} x_i'\hat{\beta}\,\operatorname{sgn}(\hat{r}_i) \\
&= \left(Y_{i_1} + Y_{i_2}\right)\operatorname{sgn}(\tilde{r}_{i_1}) \\
&\quad - \sum_{i \notin \tilde{h}} \operatorname{sgn}(\tilde{r}_i)\, x_i' X^{-1}(\tilde{h})Y(\tilde{h}) \\
&\quad + \sum_{i \notin \hat{h}} \operatorname{sgn}(\hat{r}_i)\, x_i' X^{-1}(\hat{h})Y(\hat{h}) \\
&\equiv \sum_{j=1}^{p+1} b_j\, Y_{i_j},
\end{aligned} \tag{A.2}$$

where, for $j = 2, \ldots, p$,

$$\begin{aligned}
b_1 &= \operatorname{sgn}(\tilde{r}_{i_1}) - \left(\sum_{i \notin \tilde{h}} \operatorname{sgn}(\tilde{r}_i)\, x_i' X^{-1}(\tilde{h})\right)_1 \\
b_2 &= \operatorname{sgn}(\tilde{r}_{i_1}) - \left(\sum_{i \notin \hat{h}} \operatorname{sgn}(\hat{r}_i)\, x_i' X^{-1}(\hat{h})\right)_1 \\
b_{j+1} &= \left(\sum_{i \notin \hat{h}} \operatorname{sgn}(\hat{r}_i)\, x_i' X^{-1}(\hat{h})\right)_j \\
&\quad - \left(\sum_{i \notin \tilde{h}} \operatorname{sgn}(\tilde{r}_i)\, x_i' X^{-1}(\tilde{h})\right)_j.
\end{aligned} \tag{A.3}$$

Now let $\mathscr{H}$ be the set of all pairs (h, h^*), where h and h^* are p-element subsets of indices that differ in exactly one element. Note that there are

$$\binom{n}{p+1}\binom{p+1}{2}$$

such pairs. For $(h, h^*) \in \mathscr{H}$, let $\Delta_1(h, h^*) = \sum_{j=1}^{p+1} b_j\, Y_{i_j}$, where $\{b_j\}$ are defined for arbitrary $(h, h^*) \in \mathscr{H}$ as in (A.3) and where $\{i_j\}$ ranges over $h \cup h^*$. Then, clearly,

$$\Delta_1^* \geq \inf\left\{\Delta_1(h, h^*)\colon (h, h^*) \in \mathscr{H}\right\}. \tag{A.4}$$

Now fix an arbitrary pair $(h,\ h^*) \in \mathscr{H}$,

$$\begin{aligned}
&\mathbf{P}\left\{|\Delta_1(h,\ h^*)| \leq \frac{1}{n^{p+5}}\right\} \\
&\quad \leq \mathbf{P}\left\{|b_j| \leq \frac{1}{n^3},\ \ j = 2, \ldots, p+1\right\} \\
&\quad\quad + \mathbf{P}\left\{\text{for some } j\colon |b_j| > \frac{1}{n^3}\right. \\
&\quad\quad\quad \left. \wedge \left|Y_{i_j} + \sum_{k \neq j} \frac{b_k}{b_j} Y_{i_k}\right| \leq \frac{1}{n^{p+2}}\right\} \\
&\quad \equiv P_A + P_B.
\end{aligned} \tag{A.5}$$

Now note that P_A is the probability that the vector whose coordinates are the "sum over $i \notin \hat{h}$" terms in $(b_2, \ldots, b_{p+1})$ (see (A.3)) lies in a specified cube with sides of length $2/n^3$ (centered at the other terms in b_j). That is, if $\mathscr{C}$ denotes the set of all cubes in $\Re^p$ with sides of length $2/n^3$, then

$$\begin{aligned}
P_A \leq \sup\Bigg\{\mathbf{P}\Bigg\{&\left(\sum_{i \notin h} \operatorname{sgn}(r_i)\, x_i'\right) \\
&\cdot X^{-1}(h) \in C\Bigg\}\colon C \in \mathscr{C}\Bigg\}
\end{aligned} \tag{A.6}$$

Now, multiplying the condition in P_A through by $X(h)$ and noting that the density of the sum in P_A is bounded by the density of a single x_i, (A.6) becomes

$$\begin{aligned}
P_A &\leq E_h a_0 \operatorname{Vol}(C) \det(X(h)) \leq a_1\left(\frac{2}{n^3}\right)^p \\
&\leq \frac{a_2}{n^{p+2}}
\end{aligned} \tag{A.7}$$

where a_0, a_1 and a_2 are constants, $\det(X(h))$ is bounded by the moment condition on $\{x_i\}$ and, for $p \geq 1$, $3p \geq p + 2$.

Similarly, P_B is bounded by

$$P_B \leq \sup_t\left\{\mathbf{P}\left\{Y_{i_j} \in [t, t + n^{-(p+2)}]\right\}\right\} \leq \frac{a_3}{n^{p+2}} \tag{A.8}$$

(where a_3 is a bound on the density of Y_i). Thus, from (A.5), (A.7) and (A.8),

$$\begin{aligned}
&\mathbf{P}\left\{|\Delta_1^*| \leq n^{-(p+5)}\right\} \\
&\quad \leq \binom{n}{p+1}\binom{p+1}{2}\frac{a_2 + a_3}{n^{p+2}} \to 0.
\end{aligned} \tag{A.9}$$

That is, $\Delta_1^* > n^{-(p+5)}$ with probability tending to 1.

Finally, taking the initial β and d to be 0, the initial duality gap is bounded by $\Delta_0 = \sum |Y_i|$. However, a simple Chebyschev-type inequality based on the moment condition ($E|Y_i|^a < +\infty$) yields

$$\mathbf{P}\left\{\sum_{i=1}^{n} |Y_i| \geq n^{1+2/a}\right\} \leq n\mathbf{P}\{|Y_1| \geq n^{2/a}\}$$

$$\leq \frac{n\,E|Y_1|^a}{n^{2a/a}} \to 0. \qquad \square$$

Comment

Ronald A. Thisted

1. INTRODUCTION

There are few papers on statistical computation that deserve to be described as "fabulous," but surely this is one. It contains a number of significant contributions, both to the practice of statistical computation and to the ways in which we think about the difficulty of computational problems that are relevant to data analysis. While absolute-error estimation is formally equivalent to linear programming, it is refreshing to see computational advances in this area that focus on specifically statistical applications, since those applications often have quite different features from a "typical" linear programming problem viewed form the operations research perspective. While the *mathematical* structure of quantile regression can be reduced to the same structure that is required to maximize profits for an airline given the constraints of equipment, crew, bookings and so on, the *practical* issues that arise in the two contexts are actually quite different. By concentrating on the statistical aspects, Portnoy and Koenker have produced real computational advances specific to the statistical problem of quantile regression.

This article also illustrates how valuable it can be to switch from a statistical point of view to a numerical analyst's point of view, and then back. In many ways, this interplay of statistical and computational approaches is reminiscent of the gains that integrating a dual problem with a primal algorithm can produce.

An important feature of this work is that it brings attention to the primal–dual formulation of the quantile regression problem, which has the useful feature that it provides a natural measure of convergence for the computation. The "duality gap," that is, the difference between the current value of the objective function being minimized in the primal problem and the value of the objective function being maximized by the dual problem, shrinks to zero at an optimal solution.

For considering the performance of algorithms in statistical contexts, the notion of average-case as opposed to worst-case performance is an appealing one. This contrasts with much work on algorithmic complexity investigations in computer science, which tend to focus on the latter rather than the for-

Ronald A. Thisted is Professor, Departments of Statistics, Health Studies, and Anesthesia and Critical Care, University of Chicago, Chicago, Illinois 60637 (e-mail: thisted@galton.uchicago.edu).

mer. Indeed, the notion of average-case performance of an algorithm that is, for instance, incorporated into a statistical package, is one that should be appealing to frequentists and Bayesians alike—albeit for different reasons.

In the remainder of my comments, I shall address this aspect of the paper in a bit more detail, and shall also propose some attractive lines for additional research.

2. AVERAGE-CASE VERSUS WORST-CASE PERFORMANCE

Floyd and Rivest's work on algorithms for computing quantiles (Floyd and Rivest, 1975) is the earliest example of which I am aware of using average-time performance of an algorithm to assess its computational complexity in a formal way. What has become clear is that if, in fact, average performance is of great practical importance, there are large gains in computing time which can be realized by using algorithms that occasionally may do worse than their "optimal" counterparts. The Floyd–Rivest selection algorithm is a good example.

The Floyd–Rivest idea for selecting an empirical quantile involves a preprocessing step. In this step, confidence intervals are calculated from a subset of the data, say the first m points in the data set, in order to (provisionally) exclude points from the computation which are quite unlikely to be near the quantile of interest. Occasionally the true quantile will fall outside the confidence interval, requiring the computation to backtrack after the error is recognized. Using this idea, however, requires that the first m data points constitute a random sample of the entire data. In the context of quantile regression (of which quantile selection is a very special case), this objective can be achieved by an initial randomization step (as the authors note).

By selecting a random m of n elements to occupy the first m data positions, the randomization step adds $\mathcal{O}(m) = \mathcal{O}(n^{2/3})$ to the computation, which of course does not affect the asymptotics presented in the paper—provides that only one pass through the data needs to be made. Unfortunately, very large data sets cannot always fit into random access memory, which increases both the computational and the data-management complexity of the problem.

Given the sloth to which the human (and the hare) both are wont, many implementors of the techniques described here will simply omit implementation of the randomization step. For this reason, it would be instructive to know what happens to `rqfn` when it is applied to a large data set in which the signed residuals obtained from the final fit are already sorted. This corresponds to the worst-case scenario for Floyd–Rivest, and in this unfavorable situation their algorithm performs quite badly. If this does cause problems for `rqfn`, just how "nonrandom" must the data be in order for an approach such as `rq` once again to become competitive?

Statistical decision theorists will recognize the discussion above as a variant on the minimax versus Bayesian decision framework. If the worst-case distribution of data point is a real (or even a likely) possibility, then the best algorithm is one which works well against this least-favorable (prior) distribution. On the other hand, if the data can be thought of as a random sample from a particular distribution, then the best algorithm is one which works well for most realizations from that (prior) distribution.

The gains to be made from the preprocessing step are impressive, but they are based on Gaussian, not Laplacian distributions. The empirical investigations described by the authors use data in which the errors are also Gaussian, guaranteeing the applicability of their asymptotics. It would be worthwhile to repeat the series of experiments reported here using two alternative data distributions with non-Gaussian shapes. First, a contaminated normal, for example,

$$(1-\alpha)N(0,1^2)+\alpha N(0,3^2)$$

might be expected to produce globs which are smaller than the Gaussian calculations would suggest. Second, a lognormal would introduce the treble features of failing to have moments, being highly asymmetric and actually being representative of some data sets which we might actually see (in economics, for instance). Tortoiselike plodding in this direction might be fruitful indeed in helping us to appreciate the limitations (or the robustness!) of the preprocessing included in the `prqfn` approach.

3. BATCH PROCESSING

Whenever I wish to calculate a quantile regression function for a data set, I am usually interested in obtaining *several quantiles at once*. Are there gains that can be achieved by performing the calculations simultaneously for several choices of π, instead of repeating the entire algorithm for each?

The most promising venue for exploring this question appears to be in the globbing phase of the preprocessing. If, for instance, we are interested in

$$\tau \in \{0.01, 0.10, 0.25, 0.50, 0.75, 0.95, 0.99\},$$

it would seem that I could first solve the $\tau = 0.01$ problem, and then automatically include all of data points whose residuals fell below the first percentile

in the lower glob for assessing the 99th percentile problem. I would then alternate between high and low choices for τ, perhaps decreasing m after every second iteration of this process.

4. CONCLUSION

The results presented here should provide impetus to revise the standard reference works in statistical computation (such as Kennedy and Gentle, 1980; Press, Flannery, Teukolsky and Vetterling, 1986; Thisted, 1988), several of which discuss the difficulties of L_1-methods. This paper also opens the door to potentially large areas of fruitful research in statistical computing. The authors are commended for accelerating the pace of this research by making their computer code available on the World Wide Web.

Comment

M. R. Osborne

This is an interesting and unusual paper stylishly written in a manner well-reflected in the title. I trust it finds a wide readership. The authors indicate that there is considerable opportunity for further application of their ideas.

The paper presents two main themes:

1. a case for the use of interior point methods instead of the more usual simplicial style of algorithm here identified with Barrodale and Roberts's LP-based algorithm as implemented in S-PLUS; other alternatives to the simplicial style methods have been championed recently (see Osborne and Watson, 1996);
2. an argument for "preconditioning" the calculation by tentatively classifying residuals predicted not to be zero in the final solution and aggregating their contribution to the necessary conditions; there is no reason why this step cannot be applied to methods other than interior point methods.

I have reservations about the case for the use of interior point methods, although not necessarily about the conclusions. These reservations are as follows:

1. Exponential worst case behavior of the simplex method is unusual. The examples I know can all be classified as very badly scaled. Quite a deal of work has gone into computing average case behavior, and this tends to give a very different picture. Given the general stochastic bias of the development here, it is a little surprising that this aspect is not referenced.
2. There is additional structure in the quantile problem over and above the generic LP. This comes from the special interval constrained form of the dual problem. This allows one simplex step to move off one bound constraint to its opposite bound, and this means that the new basic solution can be written down without further calculation. This pattern can occur in sequences of consecutive steps. This sequence is actually a linesearch step in other formulations (Osborne, 1985). It can be computed by the fast median algorithm of Bloomfield and Steiger, for example. The Barrodale–Roberts approach is equivalent to using a comparison sort in this context and seems already sufficient to explain the $O(n^2)$ behavior observed. Recently, Osborne and Watson (1996) have observed that the secant algorithm can be applied here and interpreted as an alternative to the usual median of three partitioning in the fast median computation. The improvement over Bloomfield and Steiger can be staggering in problems which arise in fitting a deterministic model in the presence of noise. For the record, the code distributed by Bartels, Conn and Sinclair used a heap sort in the linesearch implementation and was perhaps the first to improve on the $O(n^2)$ asymptotics. It would seem to be time that S-PLUS used a more modern implementation.
3. There is at least some folk law concerning the inferior performance of interior point methods when compared with simplex-style methods in postoptimality computations. However, this is the type of computation employed when study-

ing the behavior of regression quantiles as a function of the quantile parameter.

4. Primal-dual interior point methods have some question marks regarding their complete numerical stability when nonuniqueness or degeneracy occurs. That this potential trouble is on the cards is well documented in the original Basset and Koenker paper for the stackloss data set. The robustness possible with piecewise linear continuation methods is documented in my paper in *JIMA Numerical Analysis* of some years ago.

DISCLAIMER. Constraints of time and vagaries of the mail service have meant this discussion has to be prepared between Sydney and Singapore, and after an excellent dinner. Unintentionally, claims made may be stronger than would have been the case if a better vehicle than memory were available.

Rejoinder

Stephen Portnoy and Roger Koenker

We would like to begin by thanking the discussants for their encouraging comments as well as expressing our appreciation to the Editor, Paul Switzer, for organizing the discussion. We certainly share Ron Thisted's hope that this work may induce others to reevaluate the frequently lamented computational burden of ℓ_1-methods, and thereby gradually expand the domain of applicability for quantile regression and related methods.

There are many pathways left to explore. As Mike Osborne notes there are significant potential improvements possible in the simplex approach. It is indeed remarkable that the algorithm by Barrodale and Roberts is still the vehicle of choice among most statistically minded tortoises 25 years after its appearance. Our preprocessing strategy provides a very effective way of speeding up the simplex approach as well. In fact, it was only after we found this approach unsatisfactory for very large n and p that we began to explore interior point alternatives to simplex.

Both discussants comment on the importance of effective postoptimality analysis. In several earlier papers we have emphasized the value of estimation and inference methods based on the entire primal and dual quantile regression processes. As we have noted these processes can be computed with $\mathcal{O}_p(n \log n)$ simplex steps, starting from any initially optimal basic solution. However, in large problems it may suffice to compute the process $\hat{\beta}(\tau)$ or its dual counterpart on some prespecified grid. In such cases, it seems reasonable to explore interior point strategies for moving from one τ to the next, in effect, tunneling back through the interior rather than traversing from one vertex to another on the exterior of the constraint set. For n large this may be significantly quicker. As Osborne notes, there have been some doubts raised about interior point methods for postoptimality analysis. However, recent work, notably Monteiro and Mehrotra (1996), appears more promising. Thisted's suggestions for adapting our preprocessing approach for postoptimality analysis are worth pursuing since the quantile regression solution at any given τ is clearly informative about other solutions at nearby τ.

Following Thisted's comments, some experimentation was done to explore the consequences of nonnormal distributions. We considered Cauchy response and design variables—a setting where the random mechanism underlying globbing may be expected to fail, and also lognormal distributions. Approximate ratios of timings to those for normal cases appear in Table 1. Cauchy disturbances appear to degrade performance somewhat for large n and modest p, but asymmetry has negligible effect. Other informal experimentation indicates little effect for distributions less extreme than Cauchy, although a more systematic study of the adaptive choice of the tuning constants of the algorithm may have some value in improving performance for Cauchy-like samples.

Mike Osborne raises the question of the effect of degeneracy on the performance of the algorithm. Be-

TABLE 1
Ratios of timings to those for normal samples

	Cauchy		**Lognormal**	
	$n = 100{,}000$	$n = 50{,}000$	$n = 100{,}000$	$n = 50{,}000$
$p = 8$	1.34	1.07	1.09	1.01
$p = 4$	1.75	0.82	1.05	0.89

cause degeneracy is a serious potential problem for exterior point methods, there has been considerable attention devoted to it in the interior point literature. Güler, den Hertog, Ross and Terlaky (1993) provide an excellent survey of this topic. Since primal and dual degeneracy involve extreme points (vertices) of the primal and dual constraint sets, respectively, there is reason to believe that interior point methods may be less sensitive to degeneracy than simplex. This has been our experience in some limited experiments, but further investigation is definitely warranted.

Thinking about degeneracy leads naturally, in the theology of linear programming at least, to the subject of purification. Under degeneracy most interior point methods converge to a point on the relative interior of the solution set, thus apparently complicating any attempt to "purify" an interior point solution by finding a nearby vertex solution. Whether effective purification strategies can be devised to combine interior and exterior point approaches remains a subject of intense research interest and may eventually yield further hope for the Laplacian tortoise.
