ABSTRACT

GreatSPN is a tool that supports the design and the qualitative and quantitative analysis of Generalized Stochastic Petri Nets (GSPN) and of Stochastic Well-Formed Nets (SWN). The very first version of GreatSPN saw the light in the late eighties of last century: since then two main releases were developed and widely distributed to the research community: GreatSPN1.7 [12], and GreatSPN2.0 [7]. This paper reviews the main functionalities of GreatSPN2.0 and presents some recently added features that significantly enhance the efficacy of the tool.

1. INTRODUCTION

Generalized Stochastic Petri Nets (GSPN) [1] are Petri Nets that include timed and immediate transitions. Timed transitions have stochastic firing delays, while immediate transitions fire in zero time. Stochastic Well-Formed Nets [11] (SWN) are High Level Petri Nets (HLPN) where tokens can carry information and thus be distinguished (i.e. tokens are “colored” as opposed to traditional “black” tokens), and the events are represented by transition instances which are parameterized on the basis of a number of “color variables” associated with them. SWNs can have timed and immediate transitions, as in GSPNs. GreatSPN supports both GSPN and SWN-based performance evaluation either through discrete event simulation, or through the generation of a Markov chain representing the model behavior in time (if transition firing times are exponentially distributed). One of the characterizing aspect of GreatSPN is the analysis (reachability graph and Markov chain generation) of SWNs, that is based on particularly efficient algorithms that exploit symmetries to limit the state space explosion problem.

GreatSPN was initially developed at the Computer Science Department of the University of Torino, Italy; currently also the Computer Science Department of the University of Piemonte Orientale in Alessandria, Italy, is actively contributing to its maintenance, development and distribution.

The current distribution can be downloaded from the web page www.di.unito.it/~greatspn: it runs on Linux, So-

laris and MacOS X¹, and requires the Open Motif library for the graphical interface. It is also possible to download a VMware image including a Linux installation of the package, that can be run on any platform for which a VMware virtual machine exists (e.g. Windows). Recently, the porting towards 64 bits architectures has started. The package is available free of charge for academic institutions and non profit organizations.

In the following we present GreatSPN2.0 basic functionalities (Section 2) and some recently added features (that are also part of the current distribution): utilities for model construction and transformation in Section 3, and two modules for the efficient analysis of SWN models that are partially symmetric in Section 4.

A summary of the various interactions of GreatSPN with other Petri nets and non-Petri nets tools that have taken place over the years is presented in Section 5.

2. GREATSPN BASIC FEATURES

This section is an overview about the main features of the GreatSPN software distribution. Further details and technical aspects can be found in [7, 12, 17].

The GreatSPN software distribution is mainly composed of three groups of programs:

The Graphical User Interface: the GUI is developed above the Motif toolkit and besides the editing facilities allowing to draw a net and specify performance indexes, it allows to run the analysis modules (for structural properties, state space and performance indices computation) and show the results, to play the token game (GSPN only) and to perform an interactive simulation of timed and stochastic models (GSPN only). Figure 1 illustrates the GreatSPN’s GUI Main window and the Console window, which shows the output results coming from the execution of an analysis module (in the figure it is shown the output of the SRG computation module applied to an example SWN). The GUI has limited support for the structuration of models into submodels: it only allows to place the net elements on different *layers*; compositional model construction is supported by an external utility (*algebra*) described later. It is possible to export models in *eps* or *ps* graphic formats (the model pictures

¹For the moment only tested on version 10.4 and on PPC processor.

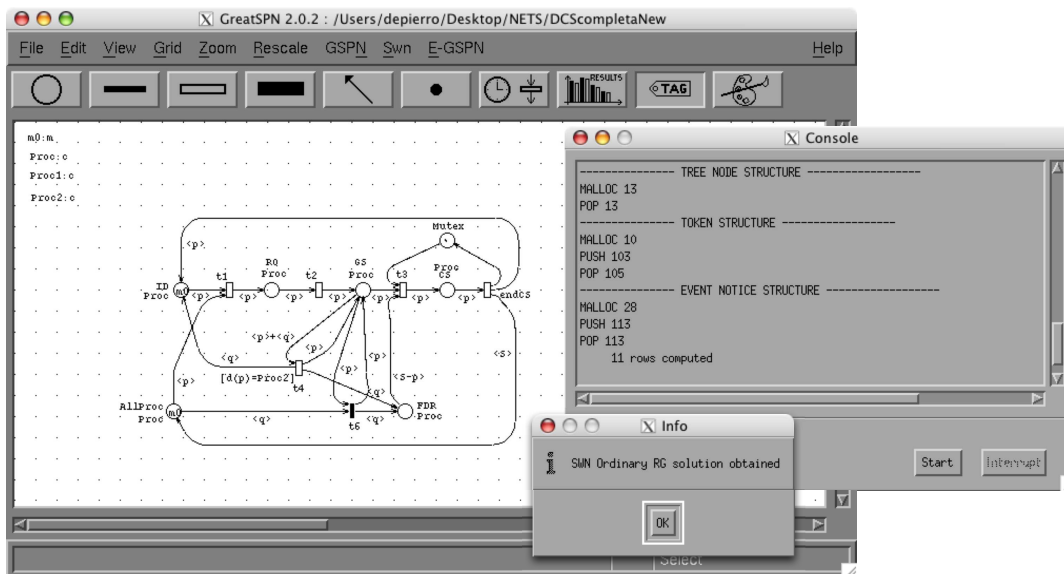

Figure 1: GreatSPN’s GUI: Main and Console windows

shown in this paper have been exported from GreatSPN).

The analysis modules: mainly implemented in C programming language, these programs run in their own address-space, separately from the GUI, although a GUI’s Console window allows to call them from within the graphical environment. The modules store the results of the analysis into files according to an internal format; several modules can cooperate (through intermediate result files) in order to compute a final result that requires several analysis steps;

Utilities: The GreatSPN distribution includes some utilities: **algebra**, for models composition, a tool for graphical visualization of the reachability graph (see Section 3) and a tool implemented in Java, **multisolve**, which allows to run multiple experiments of a given analysis module in a batch of runs varying some model parameters, the output results are saved into a file suitable for the generation of graphs through the **gnuplot** program. In addition a number of “exporters” that translate the GreatSPN model description files into the formats accepted by other analysis and drawing tools are also available: see Section 5 for the details.

The analysis modules provided by the distribution can be classified into structural analysis modules, state-space analysis modules, simulation modules and performance analysis modules based on the generation of a Markov chain (MC) and its numerical solution:

Structural analysis modules are available for GSPN models only (although it is possible to apply them to *unfolded* SWN models). Among them there are: the P and T semi-flows computation module; the structural boundness and unbounded transition sequences computation modules; the structural traps and deadlocks computation modules. Several other kinds of net structural properties (whose results are useful to speed up other analysis algorithms) can be computed such as mutual exclusion, confusion, implicit places, causal connection, structural conflict, Extended Conflict Sets (ECS). A structural performance bound analyser is also available, which requires **lpsolve** (lpsolve.sourceforge.net).

State-space analysis: for the uncolored formalisms an efficient state space generation module is available, i.e. the Reachability Graph (RG) generator and the Tangible RG (TRG) generator that build the set of reachable markings and the transitions connecting them. Moreover a separate module computes several properties of the model state space (e.g. liveness, strongly connectedness, etc.). For the SWNs, both ordinary RG computation and more efficient Symbolic RG generation modules are available;

Simulation: event-driven simulation modules are available for both supported formalisms. The simulator allows to compute steady state performance indices through the batch means method. For SWNs the simulation can be performed either using ordinary markings and transitions or symbolic ones. Moreover, SWN ordinary simulation allows for timed transitions general firing time distributions. For GSPNs an interactive version cooperating with the GUI is also available: it allows graphical animation of the model with movement of tokens, with step-by-step and automatic run, forward and backward time progression, real-time update of performance figures, arbitrary rescheduling of events.

Markov chain generation and analysis modules: from the TRG or SRG a MC can be automatically generated; both transient (based on a randomization technique) and steady-state numerical analysis modules are then provided, to derive performance indices from the MC.

3. UTILITIES

One important choice in the development of GreatSPN has been the introduction of an HLPN formalism, SWNs, together with a suite of efficient algorithms for their analysis: this has greatly facilitated the construction of complex models, in particular those representing several entities with homogeneous behavior, and the analysis of qualitative and quantitative properties of the represented systems.

However the possibility of using an HLPN formalism is not enough when the model is more naturally specified in terms of interacting components. For this reason a net composi-

tion tool called **algebra** has been introduced, with the aim of supporting a compositional model construction approach. The **algebra** tool is a command line one, able to compose two subnets by superposition on (labelled) places, or transitions or both. In this section we show **algebra** at work on a running example that will be used also throughout the paper for illustrating other GreatSPN tools and features.

Let us consider a system where several users can require a resource to be used in mutual exclusion: the SWN model in Fig. 2(a) represents such situation; in this model “colors” (in *Proc*) are used to distinguish the identity of token-customers (in this section we assume $Proc = \{Proc1, Proc2\}$): the inscriptions appearing on the arcs express the fact that the identity of the tokens is maintained while moving among places. Notice that at this abstract level of system representation, keeping track of such identity is not actually needed: this over-specification may have quite a significant impact on the analysis complexity; the use of SWN-specific analysis tools (namely the Symbolic Reachability Graph – SRG – construction algorithm), recognizing that the customers behave homogeneously and automatically abstracting out the irrelevant information, allows to alleviate the state space explosion problem. Let us now assume that the identities are necessary for the selection of the customer that has the right of getting exclusive use of the unique resource among the subset of customer who have issued a request (e.g. identities correspond to customer priorities). The submodel in Fig. 2(b) represents a mechanism for the selection of the highest priority candidate for accessing the resource: it mimics a distributed selection process where pairs of customers compare their priorities, and the highest priority eliminates the lower priority one from the race. This process continues until only one customer remains, which is the highest priority one that is hence assigned the resource. More in detail, place *AllProc* contains the identities of the processes that are allowed to submit a request (initially the whole set *Proc*); place *GSbis* represents the requests that have reached the scheduler: when it is marked no new requests are accepted any longer (all tokens still in place *AllProc* are moved to place *FDR* by immediate transition t_6), and the selection process starts. Transition t_4 performs the highest priority customer selection (the guard $d(p) = Proc2$ means that process p has highest priority: the request of process q losing the race is discarded and sent back to place *IDbis*, while p remains in *GSbis*); finally transition t_3 represents the assignment of the resource to the race winner (it can fire only when all process identities except the winner are in place *FDR*, what is expressed by function $\langle S - \#p \rangle$ on the arc). A new race can start only after the end of the resource usage by the current customer (firing of transition *endCS*, which restores the whole set of customer identities in place *AllProc* through function $\langle S \rangle$ on the arc, thus making it possible the arrival of new requests).

The two submodels of Figs. 2(a) and 2(b) can be composed to form a complete model by superposition over labeled places and transitions. In particular the places *ID* and *GS*, and the transitions t_1 , t_3 and *endCS* in the first model, have an associated label (appearing next to the node name, separated by a | symbol) that allows to match them with the corresponding places and transitions in the second model, hence **algebra** can be employed to glue the two submodels. The result produced by **algebra** (after a light rearrangement of arcs) is shown in Fig. 2(c) (described in de-

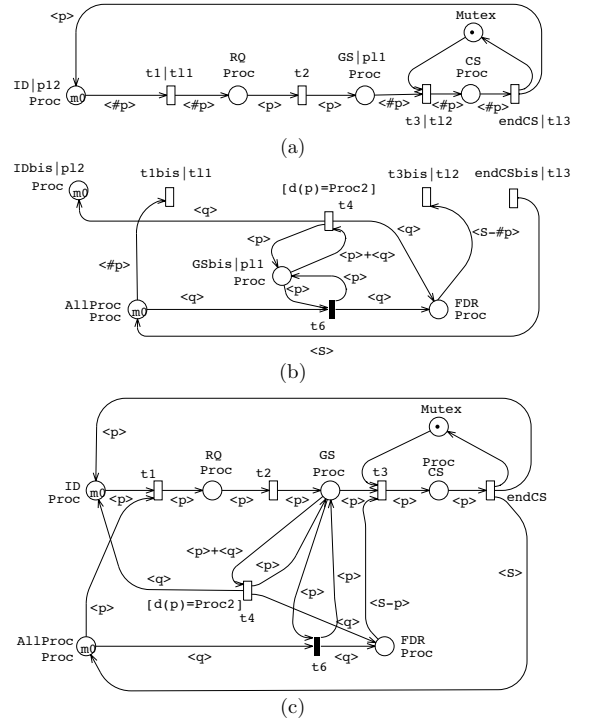

Figure 2: SWN submodel of a mutually exclusive access to a shared resource (a), a submodel for selection of the highest priority customer (b), and their composition (c)

tails in [6]). Much more complex composition situations are allowed, in particular several nodes in a submodel may contain the same label, moreover a node may be multi-labelled. Composition of $n > 2$ submodels can be achieved by a sequence of successive compositions of model pairs. For more details on the use of **algebra** see [9, 17].

SWN analysis is supported by specific solvers. However any SWN can be automatically translated into an equivalent GSPN by means of an *unfolding* procedure. This allows to use analysis modules available for GSPNs only (e.g. the structural analysis ones) but can also be the first step towards the translation of a GSPN in other modeling languages for which analysis algorithms not supported by GreatSPN are available through other tools (e.g. this approach has been used to export models to PRISM [10], as detailed in Section 5). The GreatSPN package embeds an unfolding tool that can transform an SWN into a GSPN. Fig. 3 illustrates the result of the unfolding of the net in Fig. 2(c) when the set of colors *Proc* (customer identities) has cardinality two: colored places and transitions are replicated and properly connected on the basis of their color domain. The model in Fig. 3 is the direct result of the automatic unfolding: some parameters allow to control the layout of the resulting model.

A new feature, recently introduced in GreatSPN, is the possibility to display graphically the (S)RG of a GSPN/SWN model. The (S)RG visualisation is performed in two steps and it is based on Graphviz (www.graphviz.org), an open source graph visualisation software, that includes several graph layout programs (e.g. dot, neato, twopi, ...).

The RG graphical representation for the model in Fig. 2(c)

Figure 3: Unfolding the net in Fig.2(c) ($|Proc| = 2$)

Figure 4: Graphical representation of the RG of the SWN model in Fig. 2(c)

is shown in Fig 4. This result is achieved in two steps: first the RG generation module for SWNs is run with a specific option so that an additional `.dot` result file is generated, this file is then parsed by the `dot` tool which generates the corresponding graph in a graphic format such as GIF, PNG, SVG or PostScript. The nodes in the graph are labeled with a short name: the complete marking description is stored in a separate textual file. Vanishing and tangible markings as well as immediate and timed transition firings are represented in different colors (grey and black, respectively) to ease their identification.

4. NEW SOLUTION MODULES FOR SWN

The well-known *state space explosion* problem of complex systems can be contrasted in several ways, among them there are techniques based on the construction of a reduced graph equivalent to the RG w.r.t. some set of properties. In the context of (S)WNs, a symmetry based method can be applied, which builds the Symbolic Reachability Graph (SRG): each SRG node corresponds to a set of states leading to an equivalent behavior. On the SRG one can study the reachability problem, temporal logic problems (whenever the atomic propositions of the formula are symmetrical), but also the performance of the modeled system, solving the lumped MC isomorphic to the SRG.

This approach has some limitations when the symmetric behavior of the modeled system has some exceptions: from an application point of view, it may happen that the (token) identities lead to asymmetric behaviors, e.g. in the context

of distributed algorithms identities can be used to break deadlock situations. Symmetry-based methods are not able to efficiently handle these *partial symmetries*, hence some strategy is needed to be able to efficiently treat these situations. Two approaches have been developed to this purpose: the Extended SRG (ESRG) [6] and the Dynamic SRG (DSRG) [4], now distributed with GreatSPN [3].

The ESRG method: in this approach, an abstract state representation (called *Symmetric Representation*) is used which does not take the asymmetries into account, until some asymmetric transition becomes enabled, then a more refined marking representation (called *eventuality*) is used until the influence of the asymmetric firing is “absorbed” by a completely symmetric state.

In the SWN of Fig. 2(c) only transition t_4 is asymmetric, because of the guard $d(p) = Proc2$. Hence, the need to distinguish the elements of $Proc2$ from the other elements of color class $Proc$ arises only when transition t_4 is enabled.

The ESRG representation is based on *extended symbolic markings* (ESM); each ESM is characterized by a *symmetric representation* (SR) not taking into account the asymmetries, and possibly a set of *eventualities*, which refine the SR and take asymmetries into account: the eventualities are produced only when an asymmetrical transition is enabled in the ESM or when only a subset of the possible eventualities are reachable.

Whenever possible only SRs are maintained. In order to reduce the size of the ESRG it is also possible to discard the already generated eventualities of an ESM: this happens when the ESM becomes *saturated* (i.e. when all its eventualities have been reached) and all the asymmetric transitions fireable from them have been fired.

The DSRG method: in this approach, a system is modeled by use of two components: a completely symmetric SWN and a control automaton. In the symmetric SWN no references to particular identities are allowed, hence this SWN defines a superset of the behavior of the partially asymmetric system to be modeled.

The control automaton is an event-based automaton, used to reduce the symmetric SWN behavior to the actual one. This reduction is obtained by operating a synchronized product between the two components (in GreatSPN the automaton is specified in textual form through an additional file).

As an example, the system modeled by the SWN of Fig.2(c) would be modeled by a symmetric SWN, (without the guard $d(p) = Proc2$), and a control automaton with one state, l , and two arcs $l \xrightarrow{\neg t_4} l$ and $l \xrightarrow{t_4[p \in Proc2]} l$. Synchronizing the automaton with the SWN any transition $t_i \neq t_4$ enabled in the SWN are allowed to fire (synchronized with $\neg t_4$) while only those instances of t_4 with $p \in Proc2$ are allowed.

The DSRG is as a directed graph where each node is composed of a symbolic marking and a state of the control automaton. Based on the restrictions imposed by the control automaton each symbolic marking specifies its own degree of symmetry (represented by the so-called *local partition*, which partitions the identities keeping in the same subset those which in that state exhibit symmetric behavior). Contrary to the traditional SRG method, that is based on the unique global partition of the identities taking into account all potential asymmetries of the model (statically defined at the net level), the DSRG partition is dynamically adjusted during its construction.

With respect to the ESRG, where we have two possible

representations, the SR and the eventuality, in the DSRG many intermediate representations may exist, corresponding to abstraction levels in between the SR and the eventuality (and corresponding to sets of eventualities). One remarkable difference between the ESRG and the DSRG is that while the ESMs always represent disjoint subsets of eventualities, the DSRG nodes may have non null intersection.

The efficiency of the ESRG approach is measured by the number of SR (without eventualities) that are present in it. Since eventualities may be generated and then discarded when the ESM they belong to reaches *saturation*, this generates a *memory peak problem* (which can be relevant if saturation is reached late in the ESRG computation).

Also, the derivation of a (lumped) MC from the ESRG is not straightforward: in fact the final structure does not always satisfy the (strong/exact) lumpability condition (as the SRG does). Hence an algorithm, to compute the coarsest Refined ESRG (RESRG) that satisfies the exact or the strong lumpability condition, must be derived. In [6], an efficient algorithm, based on the Paige and Tarjan's partition refinement algorithm, is proposed. Also this refinement algorithm may suffer from a memory peak problem: to satisfy the desired lumpability condition (exact or strong), the refinement of some SRs into its eventualities may be required. The generated eventualities are kept in memory until the end of the computation. Hence the peak evolution depends on the number of SRs involved in such refinement. If there is a wide *domino-effect* then the peak could prevent the computation of the RESRG and the corresponding lumped MC. In the worst case the final RESRG is equal to the SRG.

By construction, the DSRG satisfies the exact lumpability condition. Hence, it does not need further refinement, and does not exhibit any memory peak problem. On the other hand, due to the non null intersection between its nodes, it may grow beyond the size of underlying ordinary RG.

A final remark is important: the type of performance measure of interest may have an impact on the state space reduction method that can be applied: the MC derived from the SRG satisfies both exact and strong lumpability, hence the probability of any individual ordinary marking can be derived from the probability of the symbolic markings. Also the DSRG method builds an aggregate MC satisfying the exact lumpability. The ESRG refinement step can be performed according to either the strong or the exact lumpability condition, however only in the latter case the probability of each ordinary marking can be computed.

To give a flavor of the space saving that can be achieved by exploiting the ESRG and DSRG methods, let us indicate some figures for the model of Fig. 2(c) for the case $|Proc| = 8$ (note that when $|Proc| > 2$ the guard of transition $t4$ must be adapted to check that the identity of p is greater than the identity of q) the SRG has 23.041 states, the ESRG has 74 SRs plus 5.281 final eventualities (and a peak of 5.796). The number of states of the RESRG w.r.t. strong lumpability is 74, however the number of refined states that are instantiated to achieve the final RESRG is 5.327; when refining the ESRG w.r.t. exact lumpability, the RESRG size is 547 with an intermediate peak of 6.343 states. Finally the DSRG size is 4.168 (in between the peak and the final RESRG size). In general, the degree of space saving can span several orders of magnitude, depending on the locality of the asymmetric behavior. Other figures illustrating the performance of the proposed methods can be found in [3, 4, 6].

5. INTERACTION WITH OTHER TOOLS

We distinguish two main types of interactions of GreatSPN with other tools: (1) export of net models to a receiving tool, in order to use analysis techniques available in the receiving tool, (2) reuse of modules of GreatSPN (or part of them) by other tools.

Export to other tools. In its simplest form an export is a translation of the net description files (`.net` and `.def`) of GreatSPN onto the input files of the receiving tools, that might not necessarily be a Petri net tool.

For improved graphical manipulation of GSPN models, the `gspn2tgif` converter generates the `.obj` file format of TGIF (`bourbon.usc.edu:8001/tgif`); TGIF models are very convenient for inclusion in documents. An export to APNN (`www4.cs.uni-dortmund.de/APNN-TOOLBOX`), a GSPN tool, is also available (see [13]): if the GreatSPN net is split over layers, the translation maps layers on APNN partitions, so that the efficient Kronecker based Markovian solver of APNN can be used.

To allow GreatSPN users to check CSL [2] properties, two different translations are available. GSPN are translated [10] into PRISM (`www.prismmodelchecker.org`): the PRISM language is based on variables and actions, and a model is usually a set of modules that interacts on actions. The translation produces a single module, mapping places onto variables of equal name. The user can then check CSL properties in which the atomic propositions are expressions over the variables (that is to say over the places). PRISM does not support priorities among transitions and therefore only SPNs can be successfully translated. SWN have instead to undergo an unfolding step, as described in Section 3. CSL model checking of SWN can also be realized using a different approach [10]: the SWN underlying MC is generated first, together with a set of atomic proposition that hold true in each state; the chain and the properties are produced in a format accepted by the MRMC tool (`www.mrmc-tool.org`), that allows to check CSL properties of the MC.

Reuse inside other tools. We consider two different types of reuse, depending on whether a full module, usually a solver with its input and output files, is called by another tool, or whether it is a function, or a portion of it, that has been reused, usually totally embedded into the receiving tools code. Clearly the second option requires a deeper knowledge of the basic data structures of GreatSPN.

Examples of the first type are the tool PerfSWN [15] of the University of Savoie at Annecy for computing detailed performance indices of SWN nets based on the SRG analysis module and on SciLab (`www.scilab.org`), and the tool for computing bounds on Timed Petri Nets [8], that uses some of the modules for invariant computation and bounds computation of GreatSPN. Another extensive reuse of GreatSPN modules is what is done within the Draw-Net Modeling System [14], which supports a number of modeling formalisms, including the possibility of creating new formalism based on existing ones, and possibly mixing them. In Draw-Net whenever GSPN or SWN nets are involved, the GreatSPN solvers have been reused: among all of them we mention the possibility to compose SWN models at a graphical level exploiting the `algebra` module of GreatSPN.

We do not know how many cases of code reuse of GreatSPN actually exist (the source code of the tool has been distributed since the very beginning to non profit organizations). Two significant ones are due to a collaboration

with the researchers of the LIP6 laboratory of the University of Paris VI that have created and maintain CPN-AMI (move.lip6.fr/software/CPNAMI) and with the University of Savoie at Annecy. CPN-AMI includes a state space generation and analysis of SWN based on a very efficient symbolic (decision-diagram like) data structure [16] which has modified the GreatSPN functions for enabling and firing. The compSWN tool (an evolution of TenSWN [15]) developed at LISTIC, University of Savoie, uses modified SRG and associated MC computation algorithms, in order to combine symmetry based method and Kronecker algebra based techniques to SWN models comprising several submodels combined through synchronous or asynchronous composition: this is particularly useful when modeling component-based architectures.

Finally the tool for the analysis of Markov Decision Well-formed Nets (MDWN) [5], integrated in Draw-Net, uses algebra to compose the non deterministic and probabilistic subnets of a MDWN, and a modified version of the SRG module to derive a Markov Decision Process from a MDWN.

6. CONCLUSIONS

The GreatSPN package is a mature software tool for performance evaluation of GSPN and SWN models: the latest developments have been oriented towards the integration of some utilities to ease the models construction, and the development and implementation of new efficient analysis modules specifically oriented to the SWN high level formalism. The modular structure of the tool has favored the integration of some of its modules within other frameworks. Moreover several model translation tools have been developed to exploit other packages features. In several cases the SWN related functions have been reused in other tools: the production of a more accessible library to promote the reuse of such code is a medium term goal that the GreatSPN development team is pursuing within a collaboration with the MoVe group at LIP6, University of Paris VI.
