

# THE RANDOM-CLUSTER MODEL

GEOFFREY GRIMMETT

ABSTRACT. The class of random-cluster models is a unification of a variety of stochastic processes of significance for probability and statistical physics, including percolation, Ising, and Potts models; in addition, their study has impact on the theory of certain random combinatorial structures, and of electrical networks. Much (but not all) of the physical theory of Ising/Potts models is best implemented in the context of the random-cluster representation. This systematic summary of random-cluster models includes accounts of the fundamental methods and inequalities, the uniqueness and specification of infinite-volume measures, the existence and nature of the phase transition, and the structure of the subcritical and supercritical phases. The theory for two-dimensional lattices is better developed than for three and more dimensions. There is a rich collection of open problems, including some of substantial significance for the general area of disordered systems, and these are highlighted when encountered. Amongst the major open questions, there is the problem of ascertaining the exact nature of the phase transition for general values of the cluster-weighting factor  $q$ , and the problem of proving that the critical random-cluster model in two dimensions, with  $1 \leq q \leq 4$ , converges when re-scaled to a stochastic Löwner evolution (SLE). Overall the emphasis is upon the random-cluster model for its own sake, rather than upon its applications to Ising and Potts systems.

## 1. Introduction

During a classical period, probabilists studied the behaviour of *independent* random variables. The emergent theory is rich, and is linked through theory and application to areas of pure/applied mathematics and to other sciences. It is however unable to answer important questions from a variety of sources concerning large families of *dependent* random variables. Dependence comes in many forms, and one of the targets of modern probability theory has been to derive robust techniques for studying it. The voice of statistical physics has been especially loud in the call for rigour in this general area. In a typical scenario, we are provided with an infinity of random variables, indexed by the vertices of some graph such as the cubic lattice, and which have some dependence structure governed by the geometry of the graph. Thus mathematicians and physicists have had further cause to relate probability and geometry. One major outcome of the synthesis of ideas from physics and probability is the theory of Gibbs states, [59], which is now established as a significant branch of probability theory.

A classic example of a Gibbs state is the (Lenz–)Ising model [89] for a ferromagnet. When formulated on the bounded region  $B$  of the square lattice  $\mathbb{L}^2$ , a random variable  $\sigma_x$  taking values  $-1$  and  $+1$  is assigned to each vertex  $x$  of  $B$ , and the probability of the configuration  $\sigma$  is proportional to  $\exp(-\beta H(\sigma))$ , where  $\beta > 0$  and the ‘energy’  $H(\sigma)$  is the negative of the sum of  $\sigma_x \sigma_y$  over all neighbouring pairs  $x, y$  of  $B$ . This ‘starter model’ has proved extraordinarily successful in generating beautiful and relevant mathematics, and has been useful and provocative in the mathematical theory of phase transitions and cooperative phenomena (see, for example, [50]).

There are many possible generalisations of the Ising model in which the  $\sigma_x$  may take a general number  $q$  of values, rather than  $q = 2$  only. One such generalisation, the so-called Potts model [126], has attracted especial interest amongst physicists, and has displayed a complex and varied structure; for example, when  $q$  is large, it enjoys a discontinuous phase transition, in contrast to the continuous transition

believed to take place for small  $q$ . Ising/Potts models are the first of three principal ingredients in the story of random-cluster models. Note that they are ‘vertex models’ in the sense that they involve random variables  $\sigma_x$  indexed by the vertices  $x$  of the underlying graph.

The ‘(bond) percolation model’ was inspired by problems of physical type, and emerged from the mathematics literature of the 1950s [29, 150]. In this model for a porous medium, each edge of a graph is declared ‘open’ (to the passage of fluid) with probability  $p$ , and ‘closed’ otherwise, different edges having independent states. The problem is to determine the typical large-scale properties of connected components of open edges, as the parameter  $p$  varies. Percolation theory is now a mature part of probability, at the core of the study of random media and interacting systems, and it is the second ingredient in the story of random-cluster models. Note that bond percolation is an ‘edge model’, in that the random variables are indexed by the set of edges of the underlying graph. [There is a variant termed ‘site percolation’ in which the vertices are open/closed at random rather than the edges.]

The third and final ingredient preceded the first two, and is the theory of electrical networks. Dating back at least to the 1847 paper [102] of Kirchhoff, this sets down a method for calculating macroscopic properties of an electrical network in terms of its local structure. In particular, it explains the relevance of counts of certain types of spanning trees of the graph. In the modern vernacular, an electrical network on a graph  $G$  may be studied via the properties of a ‘uniformly random spanning tree’ on  $G$  (see [16]).

These three ingredients seemed fairly distinct until Fortuin and Kasteleyn discovered, around 1970, [53, 54, 55, 94], that each features in a certain way within a family of probability measures of ‘edge models’, parameterised by two quantities,  $p \in [0, 1]$  and  $q \in (0, \infty)$ . [In actuality, electrical networks arise as a weak limit of such measures.] These models they termed ‘random-cluster models’, and they developed the basic theory — correlation inequalities and the like — in a series of papers published thereafter. The true power of random-cluster models as a mechanism for studying Ising/Potts models has emerged only gradually over the intervening thirty years.

We note in passing that the genesis of the random-cluster model lay in Kasteleyn’s observation that each of the three ingredients above satisfies certain series/parallel laws: any two edges in series (or parallel) may be replaced by a single edge in such a way that, if the interaction function is adapted accordingly, then the distributions of large-scale properties remain unchanged.

The family of random-cluster measures (that is, probability measures which govern random-cluster models) is not an extension of the Potts measures. The relationship is more sophisticated, and is such that *correlations* for Potts models correspond to *connections* in random-cluster models. Thus the *correlation structure* of a Potts model may be studied via the *stochastic geometry* of a corresponding random-cluster model. The intuition behind this geometrical study comes often from percolation, of which the random-cluster model is indeed an extension.

It turns out that, in many situations involving ferromagnetic Ising/Potts models, the best way forward is via the random-cluster model. As examples of this we mention the existence of discontinuous phase transitions [105], exact computations

in two dimensions [14], the verification of the Wulff construction for Ising droplets [36], and the Dobrushin theory of interfaces and non-translation-invariant measures [62]. As a major exception to the mantra ‘everything worth doing for Ising/Potts is done best via random-cluster’, we remind the reader of the so-called random-current expansion for the Ising model, wielded with effect in [1, 2, 5] and elsewhere. The random-current method appears to be Ising-specific, and has enabled a deep analysis of the Ising model unparalleled in more general Potts systems. (See Section 5.3.)

The primary target of this review is to summarise and promote the theory of random-cluster models for its own sake. In doing so, we encounter many results having direct impact on Ising/Potts systems, but we shall not stress such connections. Some of the theory has been discovered several times by apparently independent teams; whilst making a serious attempt to list key references, we apologise for unwitting omissions of which there will certainly be a few. The large number of references to work of the author is attributable in part to the fact that he is acquainted with these contributions.

It is a lesson in humility to return to the original Fortuin–Kasteleyn papers [53, 55], and especially [54], where so much of the basic theory was first presented. These authors may not have followed the slickest of routes, but they understood rather well the object of their study. Amongst the many papers of general significance since, we highlight: [4], which brought the topic back to the fore; [47], where the coupling between Potts and random-cluster models was so beautifully managed; [69], where the random-cluster model was studied systematically on infinite grids; [81], which links the theory to several other problems of interest in statistical mechanics; and [61], where random-cluster models are placed in the perspective of stochastic geometry as a tool for studying phase transitions.

This review is restricted mostly to core material for random-cluster models on the nearest-neighbour cubic lattice in a general number  $d$  of dimensions. Only in passing do we mention such subjects as extensions to long-range systems [4], mean-field behaviour in high dimensions [99], and mixing properties [7]. Neither do we stress the impact that graphical methods of the random-cluster type have had on a variety of other disordered systems, such as the Ashkin–Teller model [12, 81, 122, 132, 148], the Widom–Rowlinson model [39, 40, 60, 81, 146], or on methods for simulating disordered physical systems [41, 42, 141, 149].

Random-cluster methods may be adapted to systems with random interactions [3, 72, 81], and even to non-ferromagnetic systems of Edwards–Anderson spin-glass type [46, 117, 118] where, for example, they have been used to prove that, for a given set  $\{J_e\}$  of positive or negative interactions, uniqueness of the infinite-volume Gibbs measure for the ferromagnetic system having interactions  $\{|J_e|\}$  implies uniqueness for the original system.

Amongst earlier papers on random-cluster models, the following include a degree of review material: [4, 23, 61, 66, 81, 113].

Notwithstanding the fairly mature theory which has evolved, there remain many open problems including some of substantial significance for the general area. Many of these are marked in the text with the acronym **OP**.

## 2. Potts and random-cluster processes

We write  $\mu(f)$  for the expectation of a random variable  $f$  under a probability measure  $\mu$ .

### 2.1 RANDOM-CLUSTER MEASURES

Let  $G = (V, E)$  be a finite graph. An edge  $e$  having endvertices  $x$  and  $y$  is written as  $e = \langle x, y \rangle$ . A random-cluster measure on  $G$  is a member of a certain class of probability measures on the set of subsets of the edge set  $E$ . We take as state space the set  $\Omega = \{0, 1\}^E$ , members of which are vectors  $\omega = (\omega(e) : e \in E)$ . We speak of the edge  $e$  as being *open* (in  $\omega$ ) if  $\omega(e) = 1$ , and as being *closed* if  $\omega(e) = 0$ . For  $\omega \in \Omega$ , let  $\eta(\omega) = \{e \in E : \omega(e) = 1\}$  denote the set of open edges, and let  $k(\omega)$  be the number of connected components (or ‘open clusters’) of the graph  $(V, \eta(\omega))$ . Note that  $k(\omega)$  includes a count of isolated vertices, that is, of vertices incident to no open edge. We assign to  $\Omega$  the  $\sigma$ -field  $\mathcal{F}$  of all its subsets.

A *random-cluster measure* on  $G$  has two parameters satisfying  $0 \leq p \leq 1$  and  $q > 0$ , and is the measure  $\phi_{p,q}$  on the measurable pair  $(\Omega, \mathcal{F})$  given by

$$\phi_{p,q}(\omega) = \frac{1}{Z} \left\{ \prod_{e \in E} p^{\omega(e)} (1-p)^{1-\omega(e)} \right\} q^{k(\omega)}, \quad \omega \in \Omega,$$

where the ‘partition function’, or ‘normalising constant’,  $Z$  is given by

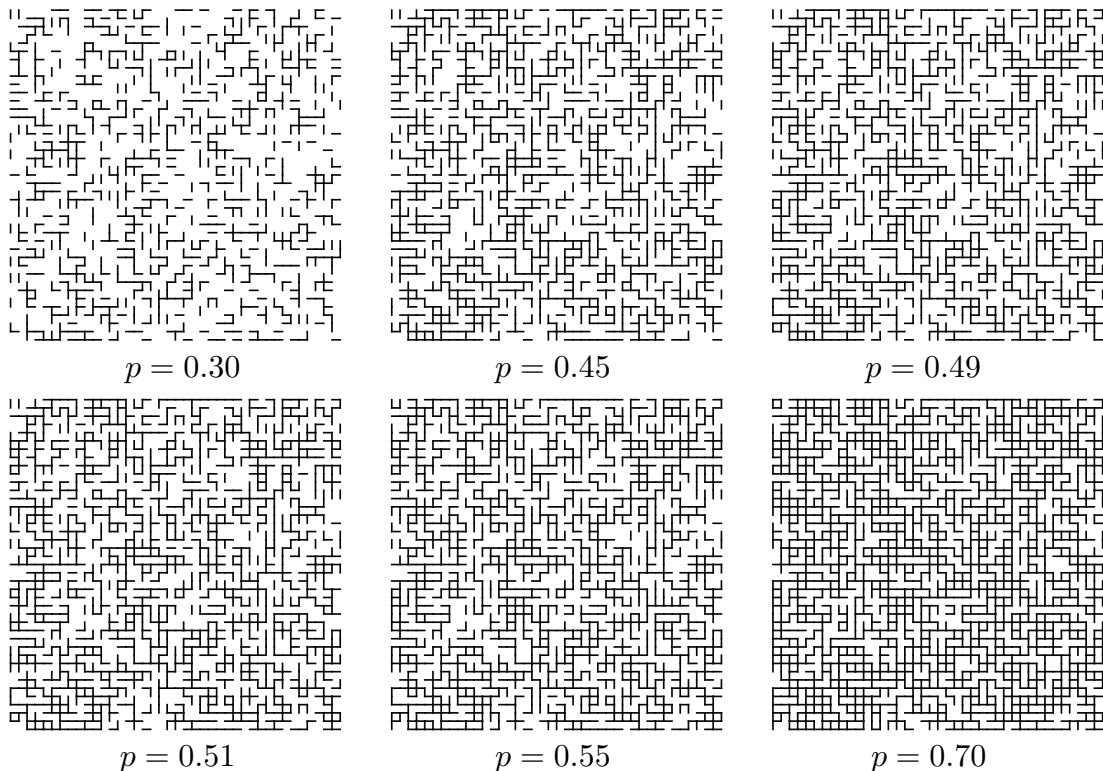

$$Z = \sum_{\omega \in \Omega} \left\{ \prod_{e \in E} p^{\omega(e)} (1-p)^{1-\omega(e)} \right\} q^{k(\omega)}.$$

This measure differs from product measure only through the inclusion of the term  $q^{k(\omega)}$ . Note the difference between the cases  $q \leq 1$  and  $q \geq 1$ : the former favours fewer clusters, whereas the latter favours many clusters. When  $q = 1$ , edges are open/closed independently of one another. This very special case has been studied in detail under the titles *percolation* and *random graphs*; see [25, 71, 90]. Perhaps the most important values of  $q$  are the integers, since the random-cluster model with  $q \in \{2, 3, \dots\}$  corresponds, in a way sketched in the next two sections, to the Potts model with  $q$  local states. The bulk of this review is devoted to the theory of random-cluster measures when  $q \geq 1$ . The case  $q < 1$  seems to be harder mathematically and less important physically. There is some interest in the limit as  $q \downarrow 0$ ; see Sections 2.4 and 3.6.

We shall sometimes write  $\phi_{G,p,q}$  for  $\phi_{p,q}$ , when the choice of graph  $G$  is to be stressed. Samples from random-cluster measures on  $\mathbb{Z}^2$  are presented in Figure 2.1.

### 2.2 ISING AND POTTS MODELS

In a famous experiment, a piece of iron is exposed to a magnetic field. The field is increased from zero to a maximum, and then diminishes to zero. If the temperature is sufficiently low, the iron retains some ‘residual magnetisation’, otherwise it does not. There is a critical temperature for this phenomenon, often called the *Curie point*. The famous (Lenz–)Ising model for such ferromagnetism, [89], may be summarised as follows. One supposes that particles are positioned at the points of

*Figure 2.1.* Samples from the random-cluster measure with  $q = 1$  on the box  $[0, 40]^2$  of the square lattice. We have set  $q = 1$  for ease of programming, the measure being of product form in this case. The critical value is  $p_c(1) = \frac{1}{2}$ . Samples with more general values of  $q$  may be obtained by the method of ‘coupling from the past’, as described in Section 8.2.

some lattice in Euclidean space. Each particle may be in either of two states, representing the physical states of ‘spin up’ and ‘spin down’. Spin-values are chosen at random according to a certain probability measure, known as a *Gibbs state*, which is governed by interactions between neighbouring particles. This measure may be described as follows.

Let  $G = (V, E)$  be a finite graph. We think of each vertex  $v \in V$  as being occupied by a particle having a random spin. Since spins are assumed to come in two basic types, we take as sample space the set  $\Sigma = \{-1, +1\}^V$ . The appropriate probability mass function  $\lambda_{\beta, J, h}$  on  $\Sigma$  has three parameters satisfying  $0 \leq \beta, J < \infty$  and  $h \in \mathbb{R}$ , and is given by

$$\lambda_{\beta, J, h}(\sigma) = \frac{1}{Z_I} e^{-\beta H(\sigma)}, \quad \sigma \in \Sigma,$$

where the partition function  $Z_I$  and the ‘Hamiltonian’  $H : \Sigma \rightarrow \mathbb{R}$  are given by

$$Z_I = \sum_{\sigma \in \Sigma} e^{-\beta H(\sigma)}, \quad H(\sigma) = - \sum_{e = \langle x, y \rangle \in E} J \sigma_x \sigma_y - h \sum_{x \in V} \sigma_x.$$

The physical interpretation of  $\beta$  is as the reciprocal  $1/T$  of temperature, of  $J$  as the strength of interaction between neighbours, and of  $h$  as the external field. For

reasons of simplicity, we shall consider only the case of zero external field, and we assume henceforth that  $h = 0$ . Each edge has equal interaction strength  $J$  in the above formulation. Since  $\beta$  and  $J$  occur only as a product  $\beta J$ , the measure  $\lambda_{\beta, J, 0}$  has effectively only a single parameter. In a more complicated measure not studied here, different edges  $e$  are permitted to have different interaction strengths  $J_e$ .

As pointed out by Baxter, [14], the Ising model permits an infinity of generalisations. Of these, the extension to so-called ‘Potts models’ has proved especially fruitful. Whereas the Ising model permits only two possible spin-values at each vertex, the Potts model [126] permits a general number  $q \in \{2, 3, \dots\}$ , and is given as follows.

Let  $q$  be an integer satisfying  $q \geq 2$ , and take as sample space  $\Sigma = \{1, 2, \dots, q\}^V$ . Thus each vertex of  $G$  may be in any of  $q$  states. The relevant probability measure is now given by

$$\pi_{\beta, J, q}(\sigma) = \frac{1}{Z_P} e^{-\beta H'(\sigma)}, \quad \sigma \in \Sigma,$$

where  $Z_P$  is the appropriate normalising constant,

$$H'(\sigma) = - \sum_{e=\langle x, y \rangle} J \delta_{\sigma_x, \sigma_y},$$

and  $\delta_{u, v}$  is the Kronecker delta. When  $q = 2$ , we have that  $\delta_{\sigma_x, \sigma_y} = \frac{1}{2}(1 + \sigma_x \sigma_y)$ . It is now easy to see in this case that the ensuing Potts model is simply the Ising model with an adjusted value of  $J$ .

### 2.3 RANDOM-CLUSTER AND ISING–POTTS COUPLED

It was Fortuin and Kasteleyn [53, 54, 55, 94] who discovered that Potts models may be recast as random-cluster models, and furthermore that the relationship between the two systems facilitates an extended study of phase transitions in Potts models. Their methods were essentially combinatorial. In the more modern game, we construct the two systems on a common probability space, and then observe their relationship through their realisations. There may in principle be many ways to do this, but the standard coupling reported in [47] is of special value.

Let  $q \in \{2, 3, \dots\}$ ,  $0 \leq p \leq 1$ , and let  $G = (V, E)$  be a finite graph, as before. We consider the product sample space  $\Sigma \times \Omega$  where  $\Sigma = \{1, 2, \dots, q\}^V$  and  $\Omega = \{0, 1\}^E$  as above. We now define a probability mass function  $\mu$  on  $\Sigma \times \Omega$  by

$$\mu(\sigma, \omega) \propto \prod_{e \in E} \left\{ (1-p) \delta_{\omega(e), 0} + p \delta_{\omega(e), 1} \delta_e(\sigma) \right\}, \quad (\sigma, \omega) \in \Sigma \times \Omega,$$

where  $\delta_e(\sigma) = \delta_{\sigma_x, \sigma_y}$  for  $e = \langle x, y \rangle \in E$ . Elementary calculations reveal the following facts.

- (a) *Marginal on  $\Sigma$ .* The marginal measure  $\mu_1(\sigma) = \sum_{\omega \in \Omega} \mu(\sigma, \omega)$  is given by

$$\mu_1(\sigma) \propto \exp \left\{ \beta \sum_e J \delta_e(\sigma) \right\}$$

where  $p = 1 - e^{-\beta J}$ . This is the Potts measure.

(b) *Marginal on  $\Omega$ .* The second marginal of  $\mu$  is

$$\mu_2(\omega) = \sum_{\sigma \in \Sigma} \mu(\sigma, \omega) \propto \left\{ \prod_e p^{\omega(e)} (1-p)^{1-\omega(e)} \right\} q^{k(\omega)}.$$

This is the random-cluster measure.

(c) *The conditional measures.* Given  $\omega$ , the conditional measure on  $\Sigma$  is obtained by putting (uniformly) random spins on entire clusters of  $\omega$  (of which there are  $k(\omega)$ ). These spins are constant on given clusters, and are independent between clusters. Given  $\sigma$ , the conditional measure on  $\Omega$  is obtained by setting  $\omega(e) = 0$  if  $\delta_e(\sigma) = 0$ , and otherwise  $\omega(e) = 1$  with probability  $p$  (independently of other edges).

In conclusion, the measure  $\mu$  is a coupling of a Potts measure  $\pi_{\beta, J, q}$  on  $V$ , together with the random-cluster measure  $\phi_{p, q}$  on  $\Omega$ . The parameters of these measures are related by the equation  $p = 1 - e^{-\beta J}$ . Since  $0 \leq p \leq 1$ , this is possible only if  $\beta J \geq 0$ .

This special coupling may be used in a particularly simple way to show that correlations in Potts models correspond to open connections in random-cluster models. When extended to infinite graphs, this implies as discussed in Section 4 that the phase transition of a Potts model corresponds to the creation of an infinite open cluster in the random-cluster model. Thus arguments of stochastic geometry, and particularly those developed for the percolation model, may be harnessed directly in order to understand the correlation structure of the Potts system. The basic step is as follows.

We write  $\{x \leftrightarrow y\}$  for the set of all  $\omega \in \Omega$  for which there exists an open path joining vertex  $x$  to vertex  $y$ . The complement of the event  $\{x \leftrightarrow y\}$  is denoted  $\{x \nleftrightarrow y\}$ .

The ‘two-point correlation function’ of the Potts measure  $\pi_{\beta, J, q}$  on the finite graph  $G = (V, E)$  is defined to be the function  $\tau_{\beta, J, q}$  given by

$$\tau_{\beta, J, q}(x, y) = \pi_{\beta, J, q}(\sigma_x = \sigma_y) - \frac{1}{q}, \quad x, y \in V.$$

The term  $q^{-1}$  is the probability that two independent and uniformly distributed spins are equal. The ‘two-point connectivity function’ of the random-cluster measure  $\phi_{p, q}$  is defined as the function  $\phi_{p, q}(x \leftrightarrow y)$  for  $x, y \in V$ , that is, the probability that  $x$  and  $y$  are joined by a path of open edges. It turns out that these ‘two-point functions’ are (except for a constant factor) the same.

**Theorem 2.1 (Correlation/connection) [94].** *If  $q \in \{2, 3, \dots\}$  and  $p = 1 - e^{-\beta J}$  satisfies  $0 \leq p \leq 1$ , then*

$$\tau_{\beta, J, q}(x, y) = (1 - q^{-1})\phi_{p, q}(x \leftrightarrow y), \quad x, y \in V.$$

*Proof.* The indicator function of an event  $A$  is denoted  $1_A$ . We have that

$$\begin{aligned}\tau_{\beta,J,q}(x,y) &= \sum_{\sigma,\omega} \left\{ 1_{\{\sigma_x=\sigma_y\}}(\sigma) - q^{-1} \right\} \mu(\sigma,\omega) \\ &= \sum_{\omega} \phi_{p,q}(\omega) \sum_{\sigma} \mu(\sigma \mid \omega) \left\{ 1_{\{\sigma_x=\sigma_y\}}(\sigma) - q^{-1} \right\} \\ &= \sum_{\omega} \phi_{p,q}(\omega) \left\{ (1 - q^{-1}) 1_{\{x \leftrightarrow y\}}(\omega) + 0 \cdot 1_{\{x \nleftrightarrow y\}}(\omega) \right\} \\ &= (1 - q^{-1}) \phi_{p,q}(x \leftrightarrow y),\end{aligned}$$

where  $\mu$  is the above coupling of the Potts and random-cluster measures.  $\square$

The theorem may be generalised as follows. Suppose we are studying the Potts model, and are interested in some ‘observable’  $f : \Sigma \rightarrow \mathbb{R}$ . The mean value of  $f(\sigma)$  satisfies

$$\begin{aligned}\pi_{\beta,J,q}(f) &= \sum_{\sigma} f(\sigma) \pi_{\beta,J,q}(\sigma) = \sum_{\sigma,\omega} f(\sigma) \mu(\sigma,\omega) \\ &= \sum_{\omega} F(\omega) \phi_{p,q}(\omega) = \phi_{p,q}(F)\end{aligned}$$

where  $F : \Omega \rightarrow \mathbb{R}$  is given by

$$F(\omega) = \mu(f \mid \omega) = \sum_{\sigma} f(\sigma) \mu(\sigma \mid \omega).$$

The above theorem is obtained in the case  $f(\sigma) = \delta_{\sigma_x,\sigma_y} - q^{-1}$ , where  $x, y \in V$ .

The Potts models considered above have zero external field. Some complications arise when an external field is added; see the discussions in [8, 23].

#### 2.4 THE LIMIT AS $q \downarrow 0$

Let  $G = (V, E)$  be a finite connected graph, and let  $\phi_{p,q}$  be the random-cluster measure on the associated sample space  $\Omega = \{0, 1\}^E$ . We consider first the weak limit of  $\phi_{p,q}$  as  $q \downarrow 0$  for fixed  $p \in (0, 1)$ . This limit may be ascertained by observing that the dominant terms in the partition function

$$Z(p, q) = \sum_{\omega \in \Omega} p^{|\eta(\omega)|} (1-p)^{|E \setminus \eta(\omega)|} q^{k(\omega)}$$

are those for which  $k(\omega)$  is a minimum, that is, those with  $k(\omega) = 1$ . It follows that  $\lim_{q \downarrow 0} \phi_{p,q}$  is precisely the product measure  $\phi_{p,1}$  (that is, percolation with intensity  $p$ ) conditioned on the resulting graph  $(V, \eta(\omega))$  being connected. A more interesting limit arises if we allow  $p$  to converge to 0 with  $q$ , as follows.

The random-cluster model originated in a systematic study by Fortuin and Kasteleyn of systems of a certain type which satisfy certain parallel and series laws. Electrical networks are the best known such systems — two parallel (respectively, series) connections of resistances  $r_1$  and  $r_2$  may be replaced by a single connection

with resistance  $(r_1^{-1} + r_2^{-1})^{-1}$  (respectively,  $r_1 + r_2$ ). Fortuin and Kasteleyn [55] realised that the electrical-network theory of a graph  $G$  is related to the limit as  $q \downarrow 0$  of the random-cluster model on  $G$ . Their argument may be expanded as follows.

Suppose  $p = p_q$  is related to  $q$  in such a way that  $p \rightarrow 0$  and  $q/p \rightarrow 0$  as  $q \rightarrow 0$ . We may write  $Z(p, q)$  as

$$Z(p, q) = (1-p)^{|E|} \sum_{\omega \in \Omega} \left( \frac{p}{1-p} \right)^{|\eta(\omega)| + k(\omega)} \left( \frac{q(1-p)}{p} \right)^{k(\omega)}.$$

Note that  $p/(1-p) \rightarrow 0$  and  $q(1-p)/p \rightarrow 0$  as  $q \rightarrow 0$ . Now  $k(\omega) \geq 1$  and  $|\eta(\omega)| + k(\omega) \geq |V|$  for all  $\omega \in \Omega$ ; these two inequalities are satisfied simultaneously with equality if and only if  $\eta(\omega)$  is a spanning tree of  $G$ . It follows that, in the limit as  $q \rightarrow 0$ , the ‘mass’ is concentrated on such configurations, and it is easily seen that the limit mass is uniformly distributed. That is,  $\lim_{q \downarrow 0} \phi_{p,q}$  is a probability measure which selects, uniformly at random, a spanning tree of  $G$ ; in other words, the limit measure is  $\phi_{\frac{1}{2}, 1}$  conditioned on the resulting graph being a spanning tree.

The link to the theory of electrical networks is now provided by Kirchhoff’s theorem [102], which expresses effective resistances in terms of counts of spanning trees. See also [79].

The theory of random spanning trees is beautiful in its own right (see [16]), and is linked in an important way to the emerging field of stochastic growth processes of ‘stochastic Löwner evolution’ (SLE) type (see [111, 130]), to which we return in Section 6.4. Another limit emerges if  $p = q$  and  $q \downarrow 0$ , namely uniform measure on the set of forests of  $G$ . More generally, take  $p = \alpha q$  where  $\alpha \in (0, \infty)$  is constant, and take the limit as  $q \downarrow 0$ . The limit measure is the percolation measure  $\phi_{\beta, 1}$  conditioned on the non-existence of open circuits, where  $\beta = \alpha/(1 + \alpha)$ . If  $p/q \rightarrow 0$  as  $p, q \rightarrow 0$ , the limit measure is concentrated on the empty set of edges.

## 2.5 RANK-GENERATING FUNCTIONS

The partition functions of Potts and random-cluster measures are particular evaluations of rank-generating functions, defined as follows. The *rank-generating function* of the simple graph  $G = (V, E)$  is the function

$$W_G(u, v) = \sum_{E' \subseteq E} u^{r(G')} v^{c(G')}, \quad u, v \in \mathbb{R},$$

where  $r(G') = |V| - k(G')$  is the *rank* of the graph  $G' = (V, E')$ , and  $c(G') = |E'| - |V| + k(G')$  is its *co-rank*; here,  $k(G')$  denotes the number of components of the graph  $G'$ . The rank-generating function has various useful properties, and occurs in several contexts in graph theory; see [20, 142]. It crops up in other forms also. For example, the function

$$T_G(u, v) = (u-1)^{|V|-1} W_G((u-1)^{-1}, v-1)$$

is known as the *dichromatic* (or *Tutte*) *polynomial*, [142]. The partition function  $Z = Z_G$  of the random-cluster measure on  $G$  with parameters  $p, q$  is easily seen to satisfy

$$Z_G = q^{|V|} (1-p)^{|E|} W_G \left( \frac{p}{q(1-p)}, \frac{p}{1-p} \right),$$

a relationship which provides a link with other classical quantities associated with a graph. See [20, 21, 53, 144] also.

### 3. Infinite-volume random-cluster measures

It is in the infinite-volume limit that random-cluster measures exhibit phase transitions. There are two ways of constructing random-cluster measures on infinite graphs, namely by taking weak limits as a finite domain approaches the infinite system, and by studying measures on the infinite graph having the ‘correct’ conditional versions. Such matters are discussed in this section, which begins with a summary of certain valuable properties of random-cluster measures on finite graphs.

#### 3.1 STOCHASTIC ORDERING

The stochastic ordering of measures provides a technique fundamental to the study of random-cluster measures. Let  $G = (V, E)$  be a finite or countably infinite graph as above; let  $\Omega = \{0, 1\}^E$ , and let  $\mathcal{F}$  be the  $\sigma$ -field of  $\Omega$  generated by the finite-dimensional cylinders. Note first that  $\Omega$  is a partially ordered set with partial order  $\omega_1 \leq \omega_2$  if  $\omega_1(e) \leq \omega_2(e)$  for all  $e$ . A random variable  $f : \Omega \rightarrow \mathbb{R}$  is called *increasing* if  $f(\omega_1) \leq f(\omega_2)$  whenever  $\omega_1 \leq \omega_2$ . An event  $A \in \mathcal{F}$  is called *increasing* if its indicator function  $1_A$  is increasing. The word ‘decreasing’ should be interpreted in the natural way. Given two probability measures  $\mu_1, \mu_2$  on  $\Omega$ , we write  $\mu_1 \leq_{\text{st}} \mu_2$ , and say that  $\mu_1$  is stochastically smaller than  $\mu_2$ , if  $\mu_1(f) \leq \mu_2(f)$  for all bounded increasing random variables  $f$  on  $\Omega$ .

We return now to the case when  $G$  is a *finite* graph. Let  $\mu_1, \mu_2$  be probability measures on  $\Omega$ , and assume for the moment that the  $\mu_i$  are strictly positive in the sense that  $\mu_i(\omega) > 0$  for all  $\omega \in \Omega$ . An important sufficient condition for the inequality  $\mu_1 \leq_{\text{st}} \mu_2$  was found by Holley [88], namely that

$$\mu_1(\omega_1 \vee \omega_2)\mu_2(\omega_1 \wedge \omega_2) \geq \mu_1(\omega_1)\mu_2(\omega_2) \quad \text{for all } \omega_1, \omega_2 \in \Omega,$$

where  $\omega_1 \vee \omega_2$  and  $\omega_1 \wedge \omega_2$  are the maximum and minimum configurations given respectively as  $\max\{\omega_1(e), \omega_2(e)\}$  and  $\min\{\omega_1(e), \omega_2(e)\}$ , for  $e \in E$ . A probability measure  $\mu$  on  $\Omega$  is said to have the *FKG lattice property* if

$$\mu(\omega_1 \vee \omega_2)\mu(\omega_1 \wedge \omega_2) \geq \mu(\omega_1)\mu(\omega_2) \quad \text{for all } \omega_1, \omega_2 \in \Omega,$$

and it is a consequence of Holley’s argument that any strictly positive measure with the FKG lattice property satisfies the so-called FKG inequality. This amounts to the following for random-cluster measures.

**Theorem 3.1 (FKG inequality) [54, 56].** *Suppose that  $0 \leq p \leq 1$  and  $q \geq 1$ . If  $f$  and  $g$  are increasing functions on  $\Omega$ , then  $\phi_{p,q}(fg) \geq \phi_{p,q}(f)\phi_{p,q}(g)$ .*

Specialising to indicator functions, we obtain that

$$\phi_{p,q}(A \cap B) \geq \phi_{p,q}(A)\phi_{p,q}(B) \quad \text{for increasing events } A, B,$$

whenever  $q \geq 1$ . It is not difficult to see that the FKG inequality does not generally hold when  $0 < q < 1$ .

Holley’s theorem leads easily to the following comparison inequalities, which were first proved by Fortuin.

**Theorem 3.2 (Comparison inequalities)** [54]. *It is the case that*

$$\begin{aligned} \phi_{p',q'} &\leq \phi_{p,q} && \text{if } q' \geq q, q' \geq 1, \text{ and } p' \leq p, \\ \phi_{p',q'} &\geq \phi_{p,q} && \text{if } q' \geq q, q' \geq 1, \text{ and } \frac{p'}{q'(1-p')} \geq \frac{p}{q(1-p)}. \end{aligned}$$

### 3.2 A DIFFERENTIAL FORMULA

One way of estimating the probability of an event  $A$  is via an estimate of its derivative  $d\phi_{p,q}(A)/dp$ . When  $q = 1$ , there is a formula for this derivative which has proved very useful, and which is commonly attributed to Russo, see [13, 71, 131]. This formula may be generalised to random-cluster measures as follows. The proof is an exercise in the differentiation of summations.

**Theorem 3.3** [19]. *Let  $0 < p < 1$ ,  $q > 0$ , and let  $\phi_{p,q}$  be the corresponding random-cluster measure on a finite graph  $G = (V, E)$ . Then*

$$\frac{d}{dp} \phi_{p,q}(A) = \frac{1}{p(1-p)} \{ \phi_{p,q}(|\eta|1_A) - \phi_{p,q}(|\eta|) \phi_{p,q}(A) \}$$

for any event  $A$ , where  $|\eta| = |\eta(\omega)| = \sum_{e \in E} \omega(e)$  is the number of open edges of the configuration  $\omega$ .

### 3.3 CONDITIONAL PROBABILITIES

Whether or not an edge  $e$  is open depends on the configuration on  $E \setminus \{e\}$ , and a further important property of random-cluster measures summarises the nature of this dependence.

For  $e \in E$ , we denote by  $G \setminus e$  (respectively,  $G.e$ ) the graph obtained from  $G$  by deleting (respectively, contracting)  $e$ . We write  $\Omega_e = \{0, 1\}^{E \setminus \{e\}}$ ; for  $\omega \in \Omega$  we define  $\omega_e \in \Omega_e$  by  $\omega_e(f) = \omega(f)$  for  $f \neq e$ . For  $e = \langle x, y \rangle$ , we write  $K_e$  for the event that  $x$  and  $y$  are joined by an open path not using  $e$ .

**Theorem 3.4** [54]. *Let  $e \in E$ . We have that*

$$\phi_{G,p,q}(\omega \mid \omega(e) = j) = \begin{cases} \phi_{G \setminus e,p,q}(\omega_e) & \text{if } j = 0, \\ \phi_{G.e,p,q}(\omega_e) & \text{if } j = 1, \end{cases}$$

and

$$\phi_{G,p,q}(\omega(e) = 1 \mid \omega_e) = \begin{cases} p & \text{if } \omega_e \in K_e, \\ \frac{p}{p + (1-p)q} & \text{if } \omega_e \notin K_e. \end{cases}$$

That is to say, the effect of conditioning on the absence or presence of an edge  $e$  is to replace the measure  $\phi_{G,p,q}$  by the random-cluster measure on the respective graph  $G \setminus e$  or  $G.e$ . Secondly, the conditional probability that  $e$  is open, given the configuration elsewhere, depends only on whether or not  $K_e$  occurs, and is then given by the stated formula. The proof is elementary. The final equation of the

theorem leads to properties of random-cluster measures referred to elsewhere as ‘insertion tolerance’ and the ‘finite-energy property’.

### 3.4 INFINITE-VOLUME WEAK LIMITS

In studying random-cluster measures on infinite graphs, we restrict ourselves to the case of the hypercubic lattice in  $d$  dimensions, where  $d \geq 2$ ; similar observations are valid in greater generality. Let  $d \geq 2$ , and let  $\mathbb{Z}^d$  be the set of all  $d$ -vectors of integers; for  $x \in \mathbb{Z}^d$ , we normally write  $x = (x_1, x_2, \dots, x_d)$ . For  $x, y \in \mathbb{Z}^d$ , let

$$\|x - y\| = \sum_{i=1}^d |x_i - y_i|.$$

We place an edge  $\langle x, y \rangle$  between  $x$  and  $y$  if and only if  $\|x - y\| = 1$ ; the set of such edges is denoted by  $\mathbb{E}^d$ , and we write  $\mathbb{L}^d = (\mathbb{Z}^d, \mathbb{E}^d)$  for the ensuing lattice. For any subset  $S$  of  $\mathbb{Z}^d$ , we write  $\partial S$  for its boundary, that is,

$$\partial S = \{s \in S : \langle s, t \rangle \in \mathbb{E}^d \text{ for some } t \notin S\}.$$

Let  $\Omega = \{0, 1\}^{\mathbb{E}^d}$ , and let  $\mathcal{F}$  be the  $\sigma$ -field of subsets of  $\Omega$  generated by the finite-dimensional cylinders. The letter  $\Lambda$  is used to denote a finite box of  $\mathbb{Z}^d$ , which is to say that  $\Lambda = \prod_{i=1}^d [x_i, y_i]$  for some  $x, y \in \mathbb{Z}^d$ ; we interpret  $[x_i, y_i]$  as the set  $\{x_i, x_i + 1, x_i + 2, \dots, y_i\}$ . The set  $\Lambda$  generates a subgraph of  $\mathbb{L}^d$  having vertex set  $\Lambda$  and edge set  $\mathbb{E}_\Lambda$  containing all  $\langle x, y \rangle$  with  $x, y \in \Lambda$ .

We are interested in the ‘thermodynamic limit’ (as  $\Lambda \uparrow \mathbb{Z}^d$ ) of the random-cluster measure on the finite box  $\Lambda$ . In order to describe such weak limits, we shall need to introduce the notion of a ‘boundary condition’.

For  $\xi \in \Omega$ , we write  $\Omega_\Lambda^\xi$  for the (finite) subset of  $\Omega$  containing all configurations  $\omega$  satisfying  $\omega(e) = \xi(e)$  for  $e \in \mathbb{E}^d \setminus \mathbb{E}_\Lambda$ ; these are the configurations which ‘agree with  $\xi$  off  $\Lambda$ ’. For  $\xi \in \Omega$  and values of  $p, q$  satisfying  $0 \leq p \leq 1, q > 0$ , we define  $\phi_{\Lambda, p, q}^\xi$  to be the random-cluster measure on the finite graph  $(\Lambda, \mathbb{E}_\Lambda)$  ‘with boundary condition  $\xi$ ’; this is the equivalent of a ‘specification’ for Gibbs states. More precisely, let  $\phi_{\Lambda, p, q}^\xi$  be the probability measure on the pair  $(\Omega, \mathcal{F})$  given by

$$\phi_{\Lambda, p, q}^\xi(\omega) = \begin{cases} \frac{1}{Z_{\Lambda, p, q}^\xi} \left\{ \prod_{e \in \mathbb{E}_\Lambda} p^{\omega(e)} (1-p)^{1-\omega(e)} \right\} q^{k(\omega, \Lambda)} & \text{if } \omega \in \Omega_\Lambda^\xi, \\ 0 & \text{otherwise,} \end{cases}$$

where  $k(\omega, \Lambda)$  is the number of components of the graph  $(\mathbb{Z}^d, \eta(\omega))$  which intersect  $\Lambda$ , and where  $Z_{\Lambda, p, q}^\xi$  is the appropriate normalising constant

$$Z_{\Lambda, p, q}^\xi = \sum_{\omega \in \Omega_\Lambda^\xi} \left\{ \prod_{e \in \mathbb{E}_\Lambda} p^{\omega(e)} (1-p)^{1-\omega(e)} \right\} q^{k(\omega, \Lambda)}.$$

Note that  $\phi_{\Lambda, p, q}^\xi(\Omega_\Lambda^\xi) = 1$ .

**Definition 3.5.** Let  $0 \leq p \leq 1$  and  $q > 0$ . A probability measure  $\phi$  on  $(\Omega, \mathcal{F})$  is called a *limit random-cluster measure* with parameters  $p$  and  $q$  if there exist  $\xi \in \Omega$  and a sequence  $\mathbf{\Lambda} = (\Lambda_n : n \geq 1)$  of boxes satisfying  $\Lambda_n \rightarrow \mathbb{Z}^d$  as  $n \rightarrow \infty$  such that

$$\phi_{\Lambda_n, p, q}^\xi \Rightarrow \phi \quad \text{as } n \rightarrow \infty.$$

The set of all such measures  $\phi$  is denoted by  $\mathcal{W}_{p, q}$ , and the closed convex hull of  $\mathcal{W}_{p, q}$  is denoted  $\overline{\text{co } \mathcal{W}_{p, q}}$ .

In writing  $\Lambda_n \rightarrow \mathbb{Z}^d$  we mean that, for all  $m$ ,  $\Lambda_n \supseteq [-m, m]^d$  for all large  $n$ . The arrow ‘ $\Rightarrow$ ’ denotes weak convergence.

It might seem reasonable to define a limit random-cluster measure to be any weak limit of the form  $\lim_{n \rightarrow \infty} \phi_{\Lambda_n, p, q}^{\xi_n}$  for some sequence  $(\xi_n : n \geq 1)$  of members of  $\Omega$  and some sequence  $\mathbf{\Lambda} = (\Lambda_n : n \geq 1)$  of boxes satisfying  $\Lambda_n \rightarrow \mathbb{Z}^d$ . It may however be shown that this adds no extra generality to the class as defined above, [69]. The dependence of the limit measure  $\phi$  on the choice of sequence  $(\Lambda_n)$  can be subtle, especially when  $q < 1$  (**OP**).

It is standard that  $\mathcal{W}_{p, q} \neq \emptyset$  for all  $0 \leq p \leq 1$ ,  $q > 0$ , and one way of seeing this is as follows. The sample space  $\Omega$  is the product of discrete spaces, and is therefore compact. It follows that any class of probability measures on  $\Omega$  is tight, and hence relatively compact (see the account of Prohorov’s theorem in [22]), which is to say that any infinite sequence of probability measures contains a weakly convergent subsequence.

When does the limit  $\lim_{n \rightarrow \infty} \phi_{\Lambda_n, p, q}^\xi$  exist, and when does it depend on the choice of boundary condition  $\xi$ ? The FKG inequality provides a route to a partial answer to this important question. Suppose for the moment that  $q \geq 1$ . Two extremal boundary conditions of special importance are provided by the configurations 0 and 1, comprising ‘all edges closed’ and ‘all edges open’ respectively. One speaks of configurations in  $\Omega_\Lambda^0$  as having ‘free’ boundary conditions, and configurations in  $\Omega_\Lambda^1$  as having ‘wired’ boundary conditions.

**Theorem 3.6 (Thermodynamic limit)** [4, 27, 54, 66, 69]. *Suppose  $0 \leq p \leq 1$  and  $q \geq 1$ .*

(a) *Let  $\mathbf{\Lambda} = (\Lambda_n : n \geq 1)$  be a sequence of boxes satisfying  $\Lambda_n \rightarrow \mathbb{Z}^d$  as  $n \rightarrow \infty$ . The weak limits*

$$\phi_{p, q}^b = \lim_{n \rightarrow \infty} \phi_{\Lambda_n, p, q}^b, \quad \text{for } b = 0, 1,$$

*exist and are independent of the choice of  $\mathbf{\Lambda}$ .*

(b) *We have that each  $\phi_{p, q}^b$  is translation-invariant, and*

$$\phi_{p, q}^0 \leq_{\text{st}} \phi \leq_{\text{st}} \phi_{p, q}^1 \quad \text{for all } \phi \in \mathcal{W}_{p, q}.$$

(c) *For  $b = 0, 1$ , the measure  $\phi_{p, q}^b$  is ergodic, in that any translation-invariant random variable is  $\phi_{p, q}^b$ -a.s. constant.*

The FKG inequality underlies all parts of Theorem 3.6. The claim (c) of ergodicity has until recently been considered slightly subtle (see the discussion after the forthcoming Theorem 3.9) but an easy proof may be found in [113].

It follows from the inequality of part (b) that  $|\mathcal{W}_{p,q}| = 1$  if and only if  $\phi_{p,q}^0 = \phi_{p,q}^1$ . It is an important open problem to determine for which  $p, q$  this holds, and we shall return to this question in Section 5 (**OP**). For the moment, we note one sufficient condition for uniqueness, proved using a certain convexity property of the logarithm of a partition function  $Z$ .

**Theorem 3.7** [67, 69]. *Let  $q \geq 1$ . There exists a subset  $\mathcal{D}_q$  of  $[0, 1]$ , at most countably infinite in size, such that  $\phi_{p,q}^0 = \phi_{p,q}^1$ , and hence  $|\mathcal{W}_{p,q}| = 1$ , if  $p \notin \mathcal{D}_q$ .*

It is believed but not proved (**OP**) that: for any given  $q \geq 1$ ,  $\mathcal{D}_q$  either is empty or consists of a singleton (the critical point, to be defined in Section 4), the former occurring if and only if  $q$  is sufficiently small.

### 3.5 RANDOM-CLUSTER MEASURES ON INFINITE GRAPHS

One may define a class of measures on the infinite lattice without having recourse to weak limits. The following definition of a random-cluster measure is based upon the Dobrushin–Lanford–Ruelle (DLR) definition of a Gibbs state, [44, 59, 106]. It was introduced in [66, 67], and discussed further in [27, 69]. For any box  $\Lambda$ , we write  $\mathcal{T}_\Lambda$  for the  $\sigma$ -field generated by the set  $\{\omega(e) : e \in \mathbb{E}^d \setminus \mathbb{E}_\Lambda\}$  of states of edges having at least one endvertex outside  $\Lambda$ .

**Definition 3.8.** Let  $0 \leq p \leq 1$  and  $q > 0$ . A probability measure  $\phi$  on  $(\Omega, \mathcal{F})$  is called a *random-cluster measure* with parameters  $p$  and  $q$  if

$$\text{for all } A \in \mathcal{F} \text{ and all finite boxes } \Lambda, \quad \phi(A \mid \mathcal{T}_\Lambda)(\xi) = \phi_{\Lambda,p,q}^\xi(A) \quad \text{for } \phi\text{-a.e. } \xi.$$

The set of such measures is denoted  $\mathcal{R}_{p,q}$ .

The condition of this definition amounts to the following. Suppose we are given that the configuration off the finite box  $\Lambda$  is that of  $\xi$ . Then, for almost every  $\xi \in \Omega$ , the (conditional) measure on  $\Lambda$  is simply the random-cluster measure with boundary condition  $\xi$ . No further generality is gained by replacing the finite box  $\Lambda$  by a general finite subset of  $\mathbb{Z}^d$ .

Some information about the structure of  $\mathcal{R}_{p,q}$ , and its relationship to  $\mathcal{W}_{p,q}$ , is provided in [69]. For example, for all  $p, q$ ,  $\mathcal{R}_{p,q}$  is non-empty and convex. We have no proof that  $\mathcal{W}_{p,q} \subseteq \mathcal{R}_{p,q}$ , but we state one theorem in this direction. For  $\omega \in \Omega$ , let  $I(\omega)$  be the number of infinite open clusters of  $\omega$ . We say that a probability measure  $\phi$  on  $(\Omega, \mathcal{F})$  has the *0/1-infinite-cluster property* if  $\phi(I \in \{0, 1\}) = 1$ .

**Theorem 3.9** [69, 70, 73]. *Let  $0 \leq p \leq 1$  and  $q > 0$ . If  $\phi \in \overline{\text{co } \mathcal{W}_{p,q}}$  and  $\phi$  has the 0/1-infinite-cluster property, then  $\phi \in \mathcal{R}_{p,q}$ .*

Since, [30], any translation-invariant probability measure satisfying a finite-energy property (see the discussion after Theorem 3.4) necessarily has the 0/1-infinite-cluster property, we have that all translation-invariant members of  $\overline{\text{co } \mathcal{W}_{p,q}}$  lie in  $\mathcal{R}_{p,q}$ . Suppose for the moment that  $q \geq 1$ . By Theorem 3.6(b), the weak limits  $\phi_{p,q}^b$ ,  $b = 0, 1$ , are translation-invariant, and therefore they belong to  $\mathcal{R}_{p,q}$ . It is not difficult to see, by the FKG inequality, that

$$(*) \quad \phi_{p,q}^0 \leq_{\text{st}} \phi \leq_{\text{st}} \phi_{p,q}^1 \quad \text{for all } \phi \in \mathcal{R}_{p,q},$$

and it follows that  $|\mathcal{R}_{p,q}| = 1$  if and only if  $\phi_{p,q}^0 = \phi_{p,q}^1$ . The claim of ergodicity in Theorem 3.6(c) is one consequence of the extremality (\*) of the  $\phi_{p,q}^b$  within the class  $\mathcal{R}_{p,q}$  (see also [113, page 1113]).

It may be seen by an averaging argument, [69], that  $\overline{\text{co } \mathcal{W}_{p,q}}$  necessarily contains at least one translation-invariant measure, for all  $p \in [0, 1]$  and  $q \in (0, \infty)$ . Therefore,  $\mathcal{R}_{p,q}$  is non-empty for all  $p$  and  $q$ .

We note that Theorem 3.9, and particularly the 0/1-infinite-cluster property, is linked to the property of so-called ‘almost sure quasilocality’, a matter discussed in [121].

### 3.6 THE CASE $q < 1$

The FKG inequality, a keystone of many arguments when  $q \geq 1$ , is not valid when  $q < 1$ . Consequently, many fundamental questions are unanswered to date, and the theory of random-cluster models on a finite graph  $G = (V, E)$  remains obscure when  $q < 1$ . The intuition is that certain positive correlations should be replaced by negative correlations; however, the theory of negative correlation is more problematic than that of positive correlation (see [120]). We return to this point later in this subsection.

As referred to above, there is an existence proof of infinite-volume weak limits and random-cluster measures for all  $q > 0$ . On the other hand, no constructive proof is known of the existence of such measures when  $q < 1$  (**OP**). More specifically, the existence of the weak limits  $\lim_{\Lambda \uparrow \mathbb{Z}^d} \phi_{\Lambda,p,q}^b$ ,  $b = 0, 1$ , is not known when  $q < 1$ . The best that can be shown currently is that the two limits exist and are equal when  $p$  is either sufficiently small or sufficiently large, [73]. This may be achieved by comparison with percolation models having different values of  $p$ , very much as in [69] (the claim for small  $p$  may also be shown by the arguments of [49, 51]).

The theory of percolation gives a clue to a possible way forward. When  $q = 1$ , the FKG inequality is complemented by the so-called ‘disjoint-occurrence’ (or ‘BK’) inequality. This latter inequality is said to be valid for a measure  $\mu$  if  $\mu(A \circ B) \leq \mu(A)\mu(B)$  for all increasing events  $A, B$ , where  $A \circ B$  is the event that  $A$  and  $B$  occur disjointly (see [18, 71] for a discussion of this and the more general ‘Reimer inequality’ [129]). The disjoint-occurrence inequality has been established for classes of measures which are only slightly more general than product measures, and it is an interesting open question whether it is valid for a wider class of measures of importance (**OP**). It has been asked whether the disjoint-occurrence inequality could be valid for random-cluster measures with  $q < 1$  (**OP**). A positive answer would aid progress substantially towards an understanding of limit random-cluster measures.

We illustrate this discussion about disjoint-occurrence with the following test question (**OP**): is it generally the case that the random-cluster measure  $\phi_{p,q}$  on  $G$  satisfies

$$(*) \quad \phi_{p,q}(\text{edges } e \text{ and } f \text{ are open}) \leq \phi_{p,q}(e \text{ is open})\phi_{p,q}(f \text{ is open})$$

for  $e \neq f$  and  $q < 1$ ? (See [120].) This equation would be a very special instance of the disjoint-occurrence inequality. A further restriction arises if we take the limit

as  $q \downarrow 0$ ; recall the discussion of Section 2.4. This leads to certain open questions of a purely graph-theoretic type, which combinatorial theorists might elevate to the status of conjectures. The first such question is the following. Let  $K(e_1, e_2, \dots)$  be the number of subsets  $F$  of the edge set  $E$ , containing  $e_1, e_2, \dots$ , such that the graph  $(V, F)$  is connected. Is it the case that **(OP)**

$$(**) \quad K(e, f)K(\emptyset) \leq K(e)K(f) \quad \text{if } e \neq f?$$

(See [93].) In the second such question, we ask if the same inequality is valid with  $K(e_1, e_2, \dots)$  redefined as the number of subsets  $F$  containing  $e_1, e_2, \dots$  such that  $(V, F)$  is a forest **(OF)**. These two questions are dual to one another in the sense that the first holds for a planar graph  $G$  if and only if the second holds for its planar dual. Explicit computations have confirmed the forest conjecture for all graphs  $G$  having nine or fewer vertices, [78].

In the ‘intermediate regime’, with  $K(e_1, e_2, \dots)$  redefined as the number of spanning trees (that is, connected forests) of  $G$  containing  $e_1, e_2, \dots$ , the corresponding inequality is indeed valid. An extra ingredient in this case is the link to electrical networks, and particularly the variational principle known as the Thomson or Dirichlet principle (see [45]). Further results and references are provided in [16]. Substantially more is known for spanning trees, namely a general result concerning the ‘negative association’ of the uniform measure on the set of spanning trees of  $G$ , [48].

We note a more general version of conjecture (\*\*), namely

$$K_\alpha(e, f)K_\alpha(\emptyset) \leq K_\alpha(e)K_\alpha(f) \quad \text{for } e \neq f, \quad 0 < \alpha < \infty,$$

where

$$K_\alpha(e_1, e_2, \dots) = \sum_{\substack{F \subseteq E \\ F \supseteq \{e_1, e_2, \dots\} \\ (V, F) \text{ connected}}} \alpha^{|F|}.$$

This is equivalent to (\*) in the limit as  $q \downarrow 0$ , where  $\alpha = p/(1-p)$ .

By other means one may establish a certain non-trivial monotonicity when  $q < 1$ , but by a more complicated reasoning than before involving a property of convexity of the logarithm of the partition function. Namely, the mean number of open edges is non-decreasing in  $p$ , for  $0 < q < \infty$ , [69].

#### 4. Phase transition, the big picture

Phase transition in a Potts model corresponds to the creation of an infinite open cluster in the corresponding random-cluster model. There are rich predictions concerning the nature of such a phase transition, but these have been proved only in part. This section is a summary of the expected properties of the phase diagram for different dimensions  $d$  and cluster-weighting factors  $q$ . The corresponding rigorous theory is described in Sections 5 and 6.

##### 4.1 INFINITE OPEN CLUSTERS

We assume henceforth that  $q \geq 1$ , and we concentrate here on the extremal random-cluster measures  $\phi_{p,q}^0$  and  $\phi_{p,q}^1$ . The phase transition of a random-cluster measure is marked by the onset of an infinite open cluster. We write  $\{0 \leftrightarrow \infty\}$  for the event that the origin is the endvertex of some infinite open path, and we define the  $\phi_{p,q}^b$  percolation probability by

$$\theta^b(p, q) = \phi_{p,q}^b(0 \leftrightarrow \infty), \quad b = 0, 1.$$

It is almost immediate by a stochastic-ordering argument that  $\theta^b(p, q)$  is non-decreasing in  $p$ , and therefore

$$\theta^b(p, q) \begin{cases} = 0 & \text{if } p < p_c^b(q), \\ > 0 & \text{if } p > p_c^b(q), \end{cases} \quad b = 0, 1,$$

for critical points  $p_c^b(q)$  given by

$$p_c^b(q) = \sup\{p : \theta^b(p, q) = 0\}, \quad b = 0, 1.$$

It is an easy exercise to show that the number  $I$  of infinite open clusters satisfies:

$$\phi_{p,q}^b(I \geq 1) = \begin{cases} 0 & \text{if } \theta^b(p, q) = 0, \\ 1 & \text{if } \theta^b(p, q) > 0. \end{cases}$$

We shall see in Section 5.2 that any infinite open cluster is  $\phi_{p,q}^b$ -a.s. unique whenever it exists.

We have by Theorem 3.7 that  $\phi_{p,q}^0 = \phi_{p,q}^1$  for almost every  $p$ , whence  $\theta^0(p, q) = \theta^1(p, q)$  for almost every  $p$ , and therefore  $p_c^0(q) = p_c^1(q)$ . Henceforth we use the abbreviated notation  $p_c(q) = p_c^0(q) = p_c^1(q)$ , and we refer to  $p_c(q)$  as the *critical point* of the corresponding random-cluster measures. The non-triviality of  $p_c(q)$  may be proved by comparisons of random-cluster measures with product measures via Theorem 3.2. Recall the fact, [71, Chapter 1], that  $0 < p_c(1) < 1$  if  $d \geq 2$ .

**Theorem 4.1 [4].** *We have for  $q \geq 1$  that*

$$p_c(1) \leq p_c(q) \leq \frac{qp_c(1)}{1 + (q-1)p_c(1)}.$$

When  $q$  is an integer satisfying  $q \geq 2$ , the phase transition of the random-cluster model corresponds in a special way to that of the Potts model with the same value of  $q$ . An indicator of phase transition in the Potts model is the ‘magnetisation’, defined as follows. Consider a Potts measure  $\pi_\Lambda^1$  on  $\Lambda$  having parameters  $\beta, J, q$ , and with ‘1’ boundary conditions, which is to say that all vertices on the boundary  $\partial\Lambda$  are constrained to have spin value 1. Let  $\tau_\Lambda = \pi_\Lambda^1(\sigma_0 = 1) - q^{-1}$ , a quantity which represents the net effect of this boundary condition on the spin at the origin. The corresponding random-cluster measure  $\phi_\Lambda^1$  has parameters  $p = 1 - e^{-\beta J}$  and  $q$ , and has wired boundary condition. We apply Theorem 2.1 to the graph obtained from  $\Lambda$  by identifying all vertices in  $\partial\Lambda$ , and we find that

$$\tau_\Lambda = (1 - q^{-1})\phi_\Lambda^1(0 \leftrightarrow \partial\Lambda).$$

The limit function  $\tau = \lim_{\Lambda \uparrow \mathbb{Z}^d} \tau_\Lambda$  is called the magnetisation, it is a non-decreasing function of  $\beta J$  and satisfies

$$\tau \begin{cases} = 0 & \text{if } \beta J \text{ is small,} \\ > 0 & \text{otherwise.} \end{cases}$$

It is not hard to show, [4], that  $\phi_\Lambda^1(0 \leftrightarrow \partial\Lambda) \rightarrow \phi^1(0 \leftrightarrow \infty)$  as  $\Lambda \uparrow \mathbb{Z}^d$ , whence  $\tau = (1 - q^{-1})\theta^1(p, q)$  where  $p = 1 - e^{-\beta J}$ . Therefore there is long-range order in the Potts model (that is,  $\tau > 0$ ) if and only if the origin lies in an infinite open cluster with strictly positive  $\phi_{p,q}^1$ -probability. In particular,  $p_c(q) = 1 - e^{-\beta_c J}$  where  $\beta_c$  is the critical value of  $\beta$  for the Potts model in question.

#### 4.2 FIRST- AND SECOND-ORDER PHASE TRANSITION

There is a rich physical theory of phase transitions in percolation, Ising, and Potts models, some of which has been made rigorous in the context of the random-cluster model. There follows a broad sketch of the big picture, a full rigorous verification of which is far from complete. Rigorous mathematical progress is described in Section 5.

##### I. *The subcritical phase, $p < p_c(q)$ .*

It is standard, [4], that

$$\phi_{p,q}^0 = \phi_{p,q}^1 \quad \text{if } \theta^1(p, q) = 0,$$

implying that there exists a unique random-cluster measure whenever  $\theta^1(p, q) = 0$ . In particular,  $|\mathcal{W}_{p,q}| = |\mathcal{R}_{p,q}| = 1$  when  $0 \leq p < p_c(q)$ . Assume for the moment that  $p < p_c(q)$ , and denote the unique random-cluster measure by  $\phi_{p,q}$ . By the definition of the critical point, all open clusters are  $\phi_{p,q}$ -a.s. finite. It is believed that they have a tail which decays exponentially, in that there exist  $\gamma = \gamma(p, q) > 0$  and  $\eta = \eta(p, q) > 0$  such that

$$\phi_{p,q}(|C| = n) = e^{-\gamma n(1+o(1))}, \quad \phi_{p,q}(\text{rad}(C) = n) = e^{-\eta n(1+o(1))}, \quad \text{as } n \rightarrow \infty,$$

where  $C$  denotes the open cluster containing the origin, and its *radius*  $\text{rad}(C)$  is defined as  $\sup\{\|x\| : x \in C\}$ . Such exponential decay would be the starting point for a complete exploration of the subcritical phase. More detailed asymptotics should then emerge, including the Ornstein–Zernike decay of the connectivity functions:

$$\phi_{p,q}(0 \leftrightarrow e_n) \sim \frac{c(p, q)}{n^{(d-1)/2}} e^{-n/\xi(p, q)} \quad \text{as } n \rightarrow \infty,$$

where  $e_n = (n, 0, 0, \dots, 0)$  and  $\xi(p, q)$  is termed the ‘correlation length’.

##### II. *The supercritical phase, $p > p_c(q)$ .*

This phase is characterised by the existence of one or more infinite open clusters (exactly one, in fact, for translation-invariant measures at least, see Section 5.2). It is believed that, as in the subcritical phase, we have that  $\phi_{p,q}^0 = \phi_{p,q}^1$  when  $p > p_c(q)$ ; this remains unproven in general. Thus the first main problem is to prove that there is a unique random-cluster measure when  $p > p_c(q)$ .

The theory of percolation, [71], suggests a route towards understanding the geometry of the supercritical phase, namely by developing a rigorous block renormalisation argument. This should permit the use of theory developed when  $p$  is close to 1 in order to understand the model when  $p$  is close to  $p_c(q)$ . In particular, one expects an exponential estimate for the decay of the probabilities of long-range connections within finite open clusters, and a Wulff construction for the shape of such clusters.

III. *Near the critical point,  $p \simeq p_c(q)$ .*

The main open problem is to understand the way in which the nature of the phase transition depends on the value of  $q$ . It is believed that the transition is continuous and governed by critical exponents and scaling theory when  $q$  is small, and is discontinuous when  $q$  is large. Presumably there exists a threshold for  $q$  which separates the so-called ‘second-order’ (or continuous) transition from the so-called ‘first-order’ (or discontinuous) transition. More specifically, it is believed that there exists  $Q = Q(d)$  satisfying

$$Q(d) = \begin{cases} 4 & \text{if } d = 2, \\ 2 & \text{if } d \geq 6, \end{cases}$$

such that the following hold.

(i) *Assume that  $q < Q$ .*

- For any  $p$ , there exists a unique random-cluster measure, denoted  $\phi_{p,q}$ . In particular  $\phi_{p_c(q),q}^0 = \phi_{p_c(q),q}^1$ .
- $\theta(p,q) = \phi_{p,q}(0 \leftrightarrow \infty)$  is a continuous function of  $p$ . There is no percolation at the critical point, in the sense that  $\theta(p_c(q), q) = 0$ .
- The edge-density  $h(p,q) = \phi_{p,q}(e \text{ is open})$ , viewed as a function of  $p$ , is continuous at the critical point  $p = p_c(q)$ . [The letter  $e$  denotes a typical edge of the lattice.]
- These functions and others have power-law singularities at  $p_c(q)$ , and the associated critical exponents satisfy the scaling relations (see [71, Chapter 9]).
- When  $d$  is large (how large depends on the value of  $q$ ), these critical exponents take on their ‘mean-field’ values, and depend no further on the value of  $d$ .
- There is no ‘mass gap’, in the sense that the correlation length  $\xi(p,q)$  satisfies  $\lim_{p \uparrow p_c(q)} \xi(p,q) = \infty$ .
- Universality reigns, in that the critical exponents depend on the number  $d$  of dimensions but not on the choice of lattice. For example, the exponents associated with the square lattice are expected to be the same as those for the triangular lattice.
- Assume  $d = 2$  and  $1 \leq q < 4$ . The process with  $p = p_c(q)$  converges as the lattice spacing shrinks to zero, the limit process when suitably defined being a stochastic Löwner evolution  $\text{SLE}_\kappa$  having parameter  $\kappa$  satisfying  $\cos(4\pi/\kappa) = -\frac{1}{2}\sqrt{q}$ ,  $\kappa \in (4, 8)$  (see Section 6.4 and [130]).

(ii) *Assume that  $q > Q$ .*

- There exists a unique random-cluster measure if and only if  $p \neq p_c(q)$ . When  $d = 2$  and  $p = p_c(q)$ , there are exactly two extremal members of  $\mathcal{R}_{p,q}$ , namely the free and the wired measures  $\phi_{p,q}^b$ ,  $b = 0, 1$ . When  $d \geq 3$  and  $p = p_c(q)$  there exist other extremal members of  $\mathcal{R}_{p,q}$  including a variety of non-translation-invariant measures.
- We have that  $\theta^0(p_c(q), q) = 0$  but  $\theta^1(p_c(q), q) > 0$ .
- The edge-density  $h(p, q)$  is a discontinuous function of  $p$  at the critical point  $p_c(q)$ .
- There is a ‘mass gap’ in the sense that the correlation length  $\xi(p, q)$  satisfies  $\lim_{p \uparrow p_c(q)} \xi(p, q) < \infty$ .

## 5. General results in $d (\geq 2)$ dimensions

The properties of the random-cluster model depend pivotally on whether the process is subcritical ( $p < p_c(q)$ ), supercritical ( $p > p_c(q)$ ), or critical ( $p \simeq p_c(q)$ ). We consider these situations in turn, in each case identifying major results and open problems. There is a bulk of information available for certain values of  $q$ , namely when  $q = 1, 2$  and  $q$  is sufficiently large. In addition, the case  $d = 2$  is special, and we shall return to this in Section 6. We assume throughout this section that  $q \geq 1$ .

Little is known in general about the numerical values of  $p_c(q)$ . For example, it is known that  $p_c(q)$  is Lipschitz-continuous and strictly increasing when  $d \geq 2$ , [68], and there is a striking conjecture (**OP**) that  $p_c(q) = \sqrt{q}/(1 + \sqrt{q})$  when  $d = 2$  (see Section 6.2). Some concrete inequalities involving the  $p_c(q)$  are implied by the comparison inequalities of Theorem 3.2.

### 5.1 THE SUBCRITICAL PHASE, $p < p_c(q)$

As remarked in Section 4.2, there is a unique random-cluster measure when  $p < p_c(q)$ , and we shall denote this by  $\phi_{p,q}$ .

The key theorem for understanding the subcritical phase of percolation states that long-range connections have exponentially decaying probabilities. Such a result is believed to hold for all random-cluster models with  $q \geq 1$ , but no proof has been found (**OP**) which is valid for all  $q \geq 1$  and all  $p < p_c(q)$ . The full result is known only when  $q = 1$ ,  $q = 2$ , or  $q$  is sufficiently large, and the three sets of arguments for these cases are somewhat different from one another. As for results valid for all  $q (\geq 1)$ , the best that is currently known is that the connectivity function decays exponentially for sufficiently small  $p$  (this follows by Theorem 3.2 and the corresponding  $q = 1$  result), and that it decays *exponentially* whenever it decays at a sufficient *polynomial* rate. We describe the last result next.

As a preliminary we introduce another definition of a critical point. Let  $B(n)$  be the cube  $[-n, n]^d$ . We write

$$Y(p, q) = \limsup_{n \rightarrow \infty} \left\{ n^{d-1} \phi_{p,q}(0 \leftrightarrow \partial B(n)) \right\}$$

and  $p_g(q) = \sup \{ p : Y(p, q) < \infty \}$ . Evidently  $0 < p_g(q) \leq p_c(q)$ , and it is believed that  $p_g(q) = p_c(q)$  for all  $q \geq 1$  (**OP**).

**Theorem 5.1 [76].** *Let  $q \geq 1$ ,  $d \geq 2$ , and  $0 \leq p < p_g(q)$ . There exists  $\gamma = \gamma(p, q)$  satisfying  $\gamma > 0$  such that*

$$\phi_{p,q}(0 \leftrightarrow \partial B(n)) \leq e^{-\gamma n} \quad \text{for all large } n.$$

The spirit of the theorem is close to that of Hammersley [84] and Simon–Lieb [112, 136] who proved exponential estimates when  $q = 1, 2$  subject to a hypothesis of finite susceptibility (that is, under the hypothesis that  $\sum_x \phi_{p,q}(0 \leftrightarrow x) < \infty$ ). The latter assumption is slightly stronger than the assumption of the above theorem when  $d = 2$ .

Connectivity functions are expected to decay exponentially with a correction term of power order. More specifically, it is expected as reported in Section 4.2 that

$$\phi_{p,q}(0 \leftrightarrow x) \sim \frac{c}{|x|^{(d-1)/2}} \exp(-|x|/\xi) \quad \text{as } |x| \rightarrow \infty,$$

for constants  $c(p, q)$  and  $\xi(p, q)$ , and for some suitable norm  $|\cdot|$  on  $\mathbb{Z}^d$ . Such ‘Ornstein–Zernike’ decay is a characteristic of many systems in their disordered phases. No proof is known (**OP**), except in the special cases when  $q = 1$  and  $q = 2$ , [32, 33]. In [9] may be found a weaker result which bounds the fluctuations by a power-law when  $d = 2$ , under the assumption that the function does indeed decay exponentially.

## 5.2 THE SUPERCRITICAL PHASE, $p > p_c(q)$

We assume as usual that  $q \geq 1$ , and we begin with a discussion of the number of infinite clusters. For  $\omega \in \Omega$ , let  $I(\omega)$  be the number of infinite open clusters. Suppose that  $\phi_{p,q}$  is a translation-invariant member of  $\mathcal{R}_{p,q}$ . If in addition  $\phi_{p,q}$  is ergodic, then, by a well known theorem of Burton and Keane [30],

$$\text{either } \phi_{p,q}(I = 0) = 1 \quad \text{or} \quad \phi_{p,q}(I = 1) = 1;$$

that is to say, the infinite open cluster is almost surely unique whenever it exists. It is noted in [30] that methods of ergodic decomposition enable the extension of such results to translation-invariant measures which are not necessarily ergodic. That is, under the assumption of translation-invariance alone,

$$\phi_{p,q}(I \in \{0, 1\}) = 1,$$

which is to say that translation-invariant random-cluster measures have the 0/1-infinite-cluster property. A further comment on the use of ergodic decomposition in this context is to be found in [31].

In two dimensions, the supercritical process is best studied via the subcritical process which arises as its graphical dual (see Section 6). There are two general approaches to the supercritical phase in a general number  $d (\geq 3)$  of dimensions. The less powerful is to derive results for large  $p$  by comparison with percolation, the theory of which is relatively complete. Without an extra ingredient, such an approach will not reveal the structure of the supercritical phase all the way down to the critical value  $p_c(q)$ . As an example, we present one theorem concerning the uniqueness of random-cluster measures.

**Theorem 5.2 [69].** *If  $d \geq 2$  and  $q \geq 1$ , there exists  $p' = p'(d, q) < 1$  such that  $\phi_{p,q}^0 = \phi_{p,q}^1$  whenever  $p > p'$ .*

It is an important open problem to prove that  $\phi_{p,q}^0 = \phi_{p,q}^1$  for all  $p > p_c(q)$ , or equivalently that there exists a unique random-cluster measure throughout the phase **(OP)**.

A more powerful approach, sometimes used in conjunction with the comparison argument summarised above, is the ‘block argument’ laid out in [36, 125]. One may think of block arguments as a form of rigorous renormalisation. One divides space into blocks, constructs events of an appropriate nature on such blocks, having large probabilities, and then allows these events to combine across space. There have been substantial successes using this technique, of which the most striking is the resolution, subject to certain side conditions, of the so-called Wulff construction for the asymptotic shape of large Ising droplets.

Rather than discussing the physical background of the Wulff construction, we mention instead its impact on random-cluster models. Let  $B(n) = [-n, n]^d$ , and consider the wired random-cluster measure  $\phi_{B(n),p,q}^1$  with  $p > p_c(q)$ . The larger is an open cluster, the more likely it is to be joined to the boundary  $\partial B(n)$ . Suppose that we condition on the event that there exists in  $B(n)$  an open cluster  $C$  which does not touch  $\partial B(n)$  and which has volume of the order of the volume  $n^d$  of the box. What can be said about the shape of  $C$ ? Since  $p > p_c(q)$ , there is little cost in having large *volume*, and the price is spent around its *boundary*. Indeed, the price may be expressed as a surface integral of an appropriate function termed ‘surface tension’. This ‘surface tension’ may be specified as the exponential rate of decay of a certain probability. The Wulff prediction for the shape of  $C$  is that, when re-scaled in the limit of large  $n$ , its shape converges to the solution of a certain variational problem, that is, the limit shape is obtained by minimising a certain surface integral subject to a condition on its volume.

No proof of this general picture for random-cluster models has appeared in the literature, although it is believed that the methods of [36, 37, 125] enable such a proof. The authors of [36] have instead concentrated on using random-cluster technology to solve the corresponding question for the asymptotic shape of large droplets in the Ising model. The outcome is an important ‘large deviation’ theorem which utilises block arguments and yields a full solution to the Ising problem whenever the corresponding random-cluster model (which has  $q = 2$ ) has parameter  $p$  satisfying  $p > \widehat{p}_c(2)$  and  $\phi_{p,2}^0 = \phi_{p,2}^1$ . Here,  $\widehat{p}_c(2)$  is the limit of a certain decreasing sequence of critical points defined on slabs in  $\mathbb{Z}^d$ , and is conjectured **(OP)** to be equal to the critical point  $p_c(2)$ . [Closely related results have been obtained in [24]. Fluctuations in droplet shape for *two-dimensional* random-cluster models have been studied in [10, 11].]

The ‘slab critical point’  $\widehat{p}_c(q)$  may be defined for any random-cluster model as follows. Fix  $q \geq 1$ , and let  $d \geq 3$ . Let  $S(n, L) = [-n, n]^{d-1} \times [-L, L]$ . Let  $\psi_{p,q}^{n,L}$  be the random-cluster measure on  $S(n, L)$  with parameters  $p, q$  (and with free boundary conditions). We denote by  $\Pi(p, L)$  the property that:

there exists  $\alpha > 0$  such that, for all  $x \in S(n, L)$  and all  $n, \psi_{p,q}^{n,L}(0 \leftrightarrow x) > \alpha$ .

It is not hard to see that  $\Pi(p, L) \Rightarrow \Pi(p', L')$  if  $p \leq p'$  and  $L \leq L'$ . It is thus natural to define the quantities

$$\widehat{p}_c(q, L) = \inf\{p : \Pi(p, L) \text{ occurs}\}, \quad \widehat{p}_c(q) = \lim_{L \rightarrow \infty} \widehat{p}_c(q, L),$$

and it is clear that  $\widehat{p}_c(q) \geq p_c(q)$ .

**Conjecture 5.3 [125].** *Let  $q \geq 1$  and  $d \geq 3$ . We have that  $\widehat{p}_c(q) = p_c(q)$ .*

Subject to a verification of this conjecture, and of a positive answer to the question of the uniqueness of random-cluster measures when  $p > p_c(q)$ , the block arguments of [36, 125] may be expected to result in a fairly complete picture of the supercritical phase of random-cluster models with  $q \geq 1$ ; see [37] also.

The case  $q = 1$  is special, percolation enjoys a spatial independence not shared with general random-cluster models. This additional property has been used in the formulation of a type of ‘dynamic renormalisation’, which has in turn yielded a proof that  $\widehat{p}_c(1) = p_c(1)$  for percolation in three or more dimensions, [71, Chapter 7, 74]. Such arguments do not to date have a random-cluster counterpart.

As a further application of a block argument we note the following bound, [125], for the tail of the size of the open cluster  $C$  at the origin,

$$\phi_{p,q}^b(|C| = n) \leq \exp(-\alpha n^{(d-1)/d}) \quad \text{for all } n,$$

for some  $\alpha = \alpha(p, q) > 0$ , and valid for  $d \geq 3$ ,  $b = 0, 1$ , and  $p$  sufficiently close to 1. The complementary inequality

$$\phi_{p,q}^b(|C| = n) \geq \exp(-\alpha' n^{(d-1)/d}) \quad \text{for all } n,$$

may be obtained for large  $p$  as done in the case of percolation, [71, Section 8.6].

### 5.3 NEAR THE CRITICAL POINT, $p \simeq p_c(q)$

Surprisingly little is known about random-cluster measures near the critical point, except in the cases  $q = 1, 2$  and  $q$  large. In each such case, there are special arguments which are apparently not suitable for generalisation. We summarise such results as follows.

#### I. Percolation, $q = 1$ .

There is a full theory of the subcritical and supercritical phases of percolation, [71]. The behaviour when  $p \simeq p_c(1)$  has been the subject of deep study, and many beautiful results are known. Nevertheless, the picture is incomplete. For example, it is believed but not proved that  $\theta(p_c(1), 1) = 0$  for all  $d \geq 2$ , but this is known only when  $d = 2$  (because of special properties of two dimensions explored for  $\mathbb{L}^2$  in Section 6) and when  $d$  is large ( $d \geq 19$  suffices) using a method termed the ‘lace expansion’. The lace expansion explains also the values of some critical exponents when  $d$  is large; see, for example, [85, 86].

Great progress has been made in recent years towards understanding the phase transition when  $d = 2$ . The idea is to work at the critical point  $p = p_c(1)$ , and to observe the process over an increasing sequence of regions of  $\mathbb{Z}^2$ . It is believed that

the process, re-scaled as the regions become larger, converges in a certain manner to a stochastic process generated in a prescribed way by a differential equation, known as a Löwner equation, which is driven in a certain way by a Brownian motion. Stochastic processes which arise in this way have been termed *stochastic Löwner evolutions* by Schramm, [135], and denoted  $\text{SLE}_\kappa$ , where  $\kappa$  is the variance parameter of the Brownian motion. It is believed that the space of stochastic Löwner evolutions is a canonical family of processes which arise as scaling limits of discrete processes such as critical percolation, critical random-cluster models with  $q \leq 4$ , self-avoiding walks, loop-erased random walk, and uniform spanning trees. Full proofs are not yet known (**OP**). We expand on this very important development in Section 6.4

## II. Ising model, $q = 2$ .

Integer values of  $q$  are special, and the value  $q = 2$  particularly so because of certain transformations which permit the passage to a model which might be termed a ‘Poisson graph’. Let  $G = (V, E)$  be a finite graph and let  $0 < \lambda < \infty$ . Suppose that  $\pi = \{\pi(e) : e \in E\}$  is a family of independent random variables each having the Poisson distribution with parameter  $\lambda$ . We now construct a random graph  $G_\pi = (V, E_\pi)$  having vertex set  $V$  and, for each  $e \in E$ , having exactly  $\pi(e)$  edges in parallel joining the endvertices of the edge  $e$  [the original edge  $e$  is itself removed]. We call  $G_\pi$  a *Poisson graph with intensity*  $\lambda$ , and write  $\mathbb{P}_\lambda$  and  $\mathbb{E}_\lambda$  for the appropriate probability measure and expectation operator.

We introduce next the concept of a flow on an oriented graph. Let  $q \in \{2, 3, \dots\}$  and let  $G' = (V', E')$  be a finite oriented graph. Let  $f : E' \rightarrow \{0, 1, 2, \dots, q-1\}$ . For  $x \in V'$ , the *total flow into*  $x$  is the sum of  $\pm f(e')$  over all edges  $e'$  incident to  $x$ , with  $+1$  when  $e'$  is oriented towards  $x$  and  $-1$  otherwise. The function  $f$  is called a *mod- $q$  flow* if the total flow into  $x$  is zero (modulo  $q$ ) for all  $x \in V'$ . The mod- $q$  flow  $f$  is called *non-zero* if  $f(e') \neq 0$  for every  $e' \in E'$ . We write  $F_q(G')$  for the number of non-zero mod- $q$  flows on  $G'$ . It is a remarkable fact, [142], that  $F_q(G')$  does not depend on the orientations of edges in  $E'$ , and thus one may define  $F_q(G')$  unambiguously for any *unoriented* graph  $G'$ .

We return now to the Poisson graph  $G_\pi$ . For  $x, y \in V$ ,  $x \neq y$ , we denote by  $G_\pi^{x,y}$  the graph obtained from  $G_\pi$  by adding an edge with endvertices  $x, y$ . [If  $x$  and  $y$  are already adjacent in  $G_\pi$ , we add exactly one further edge between them.] Connection probabilities and flows are related by the following theorem, which may be proved using properties of Tutte polynomials (see [142] and Section 2.5).

Let  $G = (V, E)$  be a finite graph, and write  $\phi_{G,p,q}$  for the random-cluster measure on  $G$  with parameters  $p, q$ .

**Theorem 5.4 [63, 73].** *Let  $q \in \{2, 3, \dots\}$  and  $0 \leq p = 1 - e^{-\lambda q} < 1$ . We have that*

$$(q-1)\phi_{G,p,q}(x \leftrightarrow y) = \frac{\mathbb{E}_\lambda(F_q(G_\pi^{x,y}))}{\mathbb{E}_\lambda(F_q(G_\pi))} \quad \text{for all } x, y \in V, x \neq y.$$

This formula takes on an especially simple form when  $q = 2$ , since non-zero mod-2 flows necessarily take only the value 1. It follows that, for any graph  $G'$ ,  $\mathbb{E}_\lambda(F_2(G'))$  equals the  $\mathbb{P}_\lambda$ -probability that the degree of every vertex of  $G'$  is even, [1]. Observations of this sort have led when  $q = 2$  to the so-called ‘random-current’

expansion for Ising models, thereby after some work [1, 2, 5] leading to proofs amongst other things of the following, expressed here in the language of random-cluster measures.

- (i) When  $q = 2$  and  $p < p_c(q)$ , we have exponential decay of the radius distribution,

$$\phi_{p,2}(\text{rad}(C) = n) \leq e^{-\eta n} \quad \text{for all } n,$$

where  $\eta = \eta(p) > 0$ ; exponential decay of the two-point connectivity function follows.

- (ii) When  $q = 2$  and  $d \neq 3$ , there is a unique random-cluster measure  $\phi_{p,2}$  for all  $p$ , in that  $|\mathcal{R}_{p,q}| = 1$ .
- (iii) The phase transition is continuous when  $q = 2$  and  $d \neq 3$ . In particular,  $\theta^0(p_c(2), 2) = \theta^1(p_c(2), 2) = 0$ , and the edge-density  $h(p, 2) = \phi_{p,2}(e \text{ is open})$  is a continuous function of  $p$  at the critical point  $p_c(2)$ .
- (iv) When  $d \geq 4$ , some (at least) critical exponents take their mean-field values, and depend no further on the value of  $d$ .

Note that the nature of the phase transition in three dimensions remains curiously undecided (**OP**).

### III. *The case of large $q$ .*

It is not known whether the phase transition is continuous for all small  $q$  (**OP**). The situation for large  $q$  is much better understood owing to a method known as Pirogov–Sinai theory [123, 124] which may be adapted in a convenient manner to random-cluster measures. The required computation, which may be found in [105], has its roots in an earlier paper [103] dealing with Potts models. A feature of such arguments is that they are valid ‘all the way to the critical point’ (rather than for ‘small  $p$ ’ or ‘large  $p$ ’ only), so long as  $q$  is sufficiently large. One obtains thereby a variety of conclusions including the following.

- (i) The edge-densities  $h^b(p, q) = \phi_{p,q}^b(e \text{ is open})$ ,  $b = 0, 1$ , are discontinuous functions of  $p$  at the critical point.
- (ii) The percolation probabilities satisfy  $\theta^0(p_c(q), q) = 0$ ,  $\theta^1(p_c(q), q) > 0$ .
- (iii) There is a multiplicity of random-cluster measures when  $p = p_c(q)$ , in that  $\phi_{p_c(q),q}^0 \neq \phi_{p_c(q),q}^1$ .
- (iv) If  $p < p_c(q)$ , there is exponential decay and a mass gap, in that the unique random-cluster measure satisfies

$$\phi_{p,q}(0 \leftrightarrow e_n) = e^{-(1+o(1))n/\xi} \quad \text{as } n \rightarrow \infty,$$

where  $e_n = (n, 0, 0, \dots, 0)$  and the correlation length  $\xi = \xi(p, q)$  is such that  $\lim_{p \uparrow p_c(q)} \xi(p, q) = \psi(q) < \infty$ .

- (v) If  $d = 3$  and  $p = p_c(q)$ , there exists a non-translation-invariant random-cluster measure, [38, 116].

It is not especially fruitful to seek numerical estimates on the required size  $Q(d)$  of  $q$  for the above conclusions to be valid. Such estimates may be computed, but turn out to be fairly distant from those anticipated, namely  $Q(2) = 4$ ,  $Q(d) = 2$  for  $d \geq 6$ .

The proofs of the above facts are rather complicated and will not be explained here. Proofs are much easier and not entirely dissimilar when  $d = 2$ , and a very short sketch of such a proof is provided in Section 6.3.

## 6. In two dimensions

The duality theory of planar graphs provides a technique for studying random-cluster models in two dimensions. We shall see in Section 6.1 that, for a dual pair  $(G, G^d)$  of planar graphs, the measures  $\phi_{G,p,q}$  and  $\phi_{G^d,p^d,q}$  are dual measures in a certain geometrical sense, where  $p, p^d$  are related by  $p^d/(1-p^d) = q(1-p)/p$ . Such a duality permits an analysis by which many results for  $\mathbb{L}^2$  may be derived. Of particular interest is the value of  $p$  for which  $p = p^d$ . This ‘self-dual point’ is easily found to be  $p = p_{\text{sd}}(q)$  where

$$p_{\text{sd}}(q) = \frac{\sqrt{q}}{1 + \sqrt{q}},$$

and it is conjectured that  $p_c(q) = p_{\text{sd}}(q)$  for  $q \geq 1$ .

### 6.1 GRAPHICAL DUALITY

Let  $G = (V, E)$  be a simple planar graph imbedded in  $\mathbb{R}^2$ . We obtain its dual graph  $G^d = (V^d, E^d)$  as follows (the roman letter ‘d’ denotes ‘dual’ rather than number of dimensions). We place a dual vertex within each face of  $G$ , including the infinite face of  $G$  if  $G$  is finite. For each  $e \in E$  we place a dual edge  $e^d = \langle x^d, y^d \rangle$  joining the two dual vertices lying in the two faces of  $G$  abutting  $e$ ; if these two faces are the same, then  $x^d = y^d$  and  $e^d$  is a loop. Thus  $E^d$  is in one–one correspondence to  $E$ . It is easy to see that the dual of  $\mathbb{L}^2$  is isomorphic to  $\mathbb{L}^2$ . What is the relevance of graphical duality to random-cluster measures on  $G$ ?

Suppose that  $G$  is finite. Any configuration  $\omega \in \Omega (= \{0, 1\}^E)$  gives rise to a dual configuration  $\omega^d$  lying in the space  $\Omega^d = \{0, 1\}^{E^d}$  defined by  $\omega^d(e^d) = 1 - \omega(e)$ . As before, to each configuration  $\omega^d$  corresponds the set  $\eta(\omega^d) = \{e^d \in E^d : \omega^d(e^d) = 1\}$  of its ‘open edges’. Let  $f(\omega)$  be the number of faces of the graph  $(V, \eta(\omega))$ , including the infinite face. By drawing a picture, one may easily be convinced (see Figure 6.1) that the faces of  $(V, \eta(\omega))$  are in one–one correspondence with the components of  $(V^d, \eta(\omega^d))$ , and therefore  $f(\omega) = k(\omega^d)$ , in the obvious notation. We shall make use of Euler’s formula (see [147]),

$$k(\omega) = |V| - |\eta(\omega)| + f(\omega) - 1, \quad \omega \in \Omega.$$

The random-cluster measure on  $G$  is given by

$$\phi_{G,p,q}(\omega) \propto \left( \frac{p}{1-p} \right)^{|\eta(\omega)|} q^{k(\omega)}, \quad \omega \in \Omega.$$

Using Euler’s formula and the equality  $f(\omega) = k(\omega^d)$ , we find that

$$\phi_{G,p,q}(\omega) = \phi_{G^d,p^d,q}(\omega^d) \quad \text{for } \omega \in \Omega,$$

Figure 6.1. A primal configuration  $\omega$  (with solid lines and vertices) and its dual configuration  $\omega^d$  (with dashed lines and hollow vertices). The arrows join the given vertices of the dual to a dual vertex in the infinite face. Note that each face of the primal graph (including the ‘infinite face’) corresponds to a unique component of the dual graph.

where the dual parameter  $p^d$  is given according to

$$\frac{p^d}{1 - p^d} = \frac{q(1 - p)}{p}.$$

The unique fixed point of the mapping  $p \mapsto p^d$  is given by  $p = p_{\text{sd}}(q)$  where  $p_{\text{sd}}(q) = \sqrt{q}/(1 + \sqrt{q})$ . We note at this point that

$$\phi_{G, p_{\text{sd}}(q), q}(\omega) \propto q^{\frac{1}{2}|\eta(\omega)| + k(\omega)} \propto q^{\frac{1}{2}(k(\omega^d) + k(\omega))},$$

by Euler’s formula. This representation of the random-cluster measure at the ‘self-dual point’  $p_{\text{sd}}(q)$  highlights the duality of measures.

Turning to the square lattice, let  $\Lambda_n = [0, n]^2$ , whose dual graph  $\Lambda_n^d$  may be obtained from  $[-1, n]^2 + (\frac{1}{2}, \frac{1}{2})$  by identifying all boundary vertices. By the above,

$$\phi_{\Lambda_n, p, q}^0(\omega) = \phi_{\Lambda_n^d, p^d, q}^1(\omega^d)$$

for configurations  $\omega$  on  $\Lambda_n$  (and with a small ‘fix’ on the boundary of  $\Lambda_n^d$ ). Letting  $n \rightarrow \infty$ , we obtain that  $\phi_{p, q}^0(A) = \phi_{p^d, q}^1(A^d)$  for all cylinder events  $A$ , where  $A^d = \{\omega^d : \omega \in A\}$ .

## 6.2 VALUE OF THE CRITICAL POINT

Consider the random-cluster process on the two-dimensional lattice  $\mathbb{L}^2 = (\mathbb{Z}^2, \mathbb{E}^2)$ , with parameters  $p$  and  $q$  satisfying  $q \geq 1$ . The following remarkable conjecture is widely believed (**OP**).

**Conjecture 6.1.** *Let  $q \geq 1$ . The critical value  $p_c(q)$  of  $\mathbb{L}^2$  is given by*

$$p_c(q) = \frac{\sqrt{q}}{1 + \sqrt{q}} \quad \text{for } q \geq 1.$$

This conjecture is known to hold when  $q = 1$ ,  $q = 2$ , and for  $q \geq 25.72$ . The  $q = 1$  case was answered by Kesten [97] in his famous proof that the critical probability of bond percolation on  $\mathbb{L}^2$  is  $\frac{1}{2}$ . For  $q = 2$ , the value of  $p_c(2)$  given above agrees with the celebrated calculation by Onsager [119] of the critical temperature of the Ising model on  $\mathbb{Z}^2$ , and is implied by probabilistic results in the modern vernacular of [2]. The formula for  $p_c(q)$  has been established rigorously in [104, 105] for sufficiently large (real) values of  $q$ , specifically  $q \geq 25.72$  (see also [70]).

Conjecture 6.1 arises in a natural manner from the observation that  $\mathbb{L}^2$  is a self-dual graph, and  $p = p_{\text{sd}}(q) = \sqrt{q}/(1 + \sqrt{q})$  is the self-dual point of a random-cluster measure on  $\mathbb{L}^2$  with parameters  $p, q$ .

Several other remarkable conjectures about the phase transition in  $\mathbb{L}^2$  may be found in the physics literature (see [14]), as consequences of ‘exact’ but non-rigorous arguments involving ice-type models. These include exact formulae for the asymptotic behaviour of the partition function  $\lim_{\Lambda \uparrow \mathbb{Z}^2} \{Z_{\Lambda, p, q}\}^{1/|\Lambda|}$ , and also for the edge-densities  $h^b(p_{\text{sd}}(q), q) = \phi_{p_{\text{sd}}(q), q}^b$  ( $e$  is open),  $b = 0, 1$ , at the self-dual point  $p_{\text{sd}}(q)$ .

Progress towards a rigorous verification of the conjecture may be summarised briefly as follows. Using an argument, [152], taken from percolation using the uniqueness of infinite open clusters, we obtain by duality that  $\theta^0(p_{\text{sd}}(q), q) = 0$  (see [69, 143]), whence the critical value of the square lattice satisfies  $p_c(q) \geq p_{\text{sd}}(q)$  for  $q \geq 1$ . The complementary inequality  $p_c(q) \leq p_{\text{sd}}(q)$  has eluded mathematicians despite progress by physicists, [87].

Suppose on the contrary that  $p_c(q) > p_{\text{sd}}(q)$ , so that  $p_c(q)^d < p_{\text{sd}}(q)$ . For  $p \in (p_c(q)^d, p_c(q))$  we have also that  $p^d \in (p_c(q)^d, p_c(q))$ . Therefore, for  $p \in (p_c(q)^d, p_c(q))$ , both primal and dual processes comprise, almost surely, the union of *finite* open clusters. This contradicts the intuitive picture, supported for  $p \neq p_c(q)$  by our knowledge of percolation, of finite clusters of one process floating in an infinite ocean of the other process.

Exact values for the critical points of the triangular and hexagonal lattices may be conjectured similarly, using graphical duality together with the star–triangle transformation, [14, 101].

Rigorous numerical upper bounds of impressive accuracy have been achieved for the square lattice and other two-dimensional lattices via an extension of the basic model to a larger class termed in [8] the ‘asymmetric random-cluster model’. The bound in question for  $\mathbb{L}^2$  is

$$p_c(q) \leq \frac{\sqrt{q}}{\sqrt{1 - q^{-1}} + \sqrt{q}}, \quad q \geq 1.$$

For example, when  $q = 10$ , we have that  $0.760 \leq p_c(10) \leq 0.769$ , to be compared with the conjecture that  $p_c(10) = \sqrt{10}/(1 + \sqrt{10}) \simeq 0.760$ . A valuable consequence of the comparison methods developed in [8] is the exponential decay of connectivity functions when  $q > 2$  and  $p$  is such that

$$p < p_{\text{sd}}(q - 1) = \frac{\sqrt{q - 1}}{1 + \sqrt{q - 1}}.$$

### 6.3 FIRST-ORDER PHASE TRANSITION

There is a special argument discovered first for Potts models, [104], which may be used to show first-order phase transition when  $q$  is sufficiently large.

Let  $a_n$  be the number of self-avoiding walks on  $\mathbb{L}^2$  beginning at the origin. It is standard, [114], that  $a_n^{1/n} \rightarrow \mu$  as  $n \rightarrow \infty$ , for some constant  $\mu$  called the *connective constant* of the lattice. Let  $Q = \left\{ \frac{1}{2}(\mu + \sqrt{\mu^2 - 4}) \right\}^4$ . We have that  $2.620 < \mu < 2.696$  (see [137]), whence  $21.61 < Q < 25.72$ . We set

$$\psi(q) = \frac{1}{24} \log \left\{ \frac{(1 + \sqrt{q})^4}{q\mu^4} \right\},$$

noting that  $\psi(q) > 0$  if and only if  $q > Q$ . We write  $B(n) = [-n, n]^2$ .

**Theorem 6.2 [70, 104].** *If  $d = 2$  and  $q > Q$  then the following hold.*

- (a) *The critical point is given by  $p_c(q) = \sqrt{q}/(1 + \sqrt{q})$ .*
- (b) *We have that  $\theta^1(p_c(q), q) > 0$ .*
- (c) *For any  $\psi < \psi(q)$  and all large  $n$ ,  $\phi_{p_c(q), q}^0(0 \leftrightarrow \partial B(n)) \leq e^{-n\psi}$ . Hence, in particular,  $\theta^0(p_c(q), q) = 0$ .*

The idea of the proof is as follows. There is a partial order on circuits of  $\mathbb{L}^2$  given by  $\Gamma \leq \Gamma'$  if the bounded component of  $\mathbb{R}^2 \setminus \Gamma$  is a subset of the bounded component of  $\mathbb{R}^2 \setminus \Gamma'$ . We work at the self-dual point  $p = p_{sd}(q)$ , and with the box  $B(n)$  with wired boundary conditions. An ‘outer contour’ is defined to be a circuit  $\Gamma$  of the dual graph  $B(n)^d$  all of whose edges are open in the dual (that is, they traverse closed edges in the primal graph  $B(n)$ ), and which is maximal with this property. Using self-duality, one may show that

$$\phi_{B(n), p_{sd}(q), q}^1(\Gamma \text{ is an outer circuit}) \leq \frac{1}{q} \left( \frac{q}{(1 + \sqrt{q})^4} \right)^{|\Gamma|/4},$$

for any given circuit  $\Gamma$  of  $B(n)^d$ . Combined with a circuit-counting argument of Peierls-type involving the connective constant, this estimate implies after a little work the claims of Theorem 6.2. The idea of the proof appeared in [104] in the context of Potts models, and the random-cluster formulation may be found in [70].

We stress that corresponding conclusions may be obtained for general  $d$  ( $\geq 2$ ) when  $q$  is sufficiently large ( $q > Q(d)$  for suitable  $Q(d)$ ), as shown in [105] using so-called Pirogov–Sinai theory. Whereas, in the case  $d = 2$ , the above duality provides an especially simple proof, the proof for general  $d$  utilises nested sequences of surfaces of  $\mathbb{R}^d$  and requires a control of the effective boundary conditions within the surfaces.

### 6.4 SLE LIMIT WHEN $q \leq 4$

Many exact calculations are ‘known’ for critical processes in two dimensions, but the physical arguments involved have sometimes appeared in varying degrees magical or revelatory to mathematicians. The new technology of stochastic Löwner evolutions (SLE), discovered by Schramm [135] and mentioned in Section 5.3, threatens

to provide a rigorous underpinning of many such arguments in a manner most consonant with modern probability theory. Roughly speaking, the theory of SLE informs us of the correct weak limit of a critical process in the limit of large spatial scales, and in addition provides a mechanism for performing calculations for the limit process.

Let  $\mathbb{H} = (-\infty, \infty) \times (0, \infty)$  be the upper half-plane of  $\mathbb{R}^2$ , with closure  $\overline{\mathbb{H}}$ . We view  $\mathbb{H}$  and  $\overline{\mathbb{H}}$  as subsets of the complex plane. Consider the ordinary differential equation

$$\frac{d}{dt}g_t(z) = \frac{2}{g_t(z) - B_{\kappa t}}, \quad z \in \overline{\mathbb{H}} \setminus \{0\},$$

subject to the boundary condition  $g_0(z) = z$ , where  $t \in [0, \infty)$ ,  $\kappa$  is a positive constant, and  $(B_t : t \geq 0)$  is a standard Brownian motion. The solution exists when  $g_t(z)$  is bounded away from  $B_{\kappa t}$ . More specifically, for  $z \in \overline{\mathbb{H}}$ , let  $\tau_z$  be the infimum of all times  $\tau$  such that 0 is a limit point of  $g_s(z) - B_{\kappa s}$  in the limit as  $s \uparrow \tau$ . We let

$$H_t = \{z \in \mathbb{H} : \tau_z > t\}, \quad K_t = \{z \in \overline{\mathbb{H}} : \tau_z \leq t\},$$

so that  $H_t$  is open, and  $K_t$  is compact. It may now be seen that  $g_t$  is a conformal homeomorphism from  $H_t$  to  $\mathbb{H}$ .

We call  $(g_t : t \geq 0)$  a *stochastic Löwner evolution* (SLE) with parameter  $\kappa$ , written  $\text{SLE}_\kappa$ , and we call the  $K_t$  the *hulls* of the process. There is good reason to believe that the family  $K = (K_t : t \geq 0)$  provides the correct scaling limit of a variety of random spatial processes, the value of  $\kappa$  being chosen according to the process in question. General properties of  $\text{SLE}_\kappa$ , viewed as a function of  $\kappa$  have been studied in [130, 145], and a beautiful theory has emerged. For example, the hulls  $K$  form almost surely a simple path if and only if  $\kappa \leq 4$ . If  $\kappa > 8$ , then  $\text{SLE}_\kappa$  generates almost surely a space-filling curve.

Schramm [135] has identified the relevant value of  $\kappa$  for several different processes, and has indicated that percolation has scaling limit  $\text{SLE}_6$ , but full rigorous proofs are incomplete. In the case of percolation, Smirnov [138, 139] has proved the very remarkable result that, *for site percolation on the triangular lattice*, the scaling limit exists and is  $\text{SLE}_6$  (this last statement is illustrated and partly explained in Figure 6.2), but the existence of the limit is open for other lattices and for bond percolation.

It is possible to perform calculations on stochastic Löwner evolutions, and in particular to confirm, [110, 140], the values of many critical exponents associated with percolation (or, at least, site percolation on the triangular lattice). The consequences are in agreement with predictions of mathematical physicists previously considered near-miraculous (see [71], Chapter 9). In addition,  $\text{SLE}_6$  satisfies the appropriate version of Cardy's formula, [34, 107].

The technology of SLE is a major piece of contemporary mathematics which promises to explain phase transitions in an important class of two-dimensional disordered systems, and to help bridge the gap between probability theory and conformal field theory. It has already provided complete explanations of conjectures, by mathematicians and physicists, associated with two-dimensional Brownian motions and specifically their intersection exponents and fractionality of frontier, [108, 109].

*Figure 6.2.* Site percolation on the triangular lattice with  $p$  equal to the critical point  $\frac{1}{2}$ , and with a mixed boundary condition along the lower side. The interface traces the boundary between the white and the black clusters touching the boundary, and is termed the ‘exploration process’. In the limit of small lattice-spacing, the interface converges in a certain manner to the graph of a function which satisfies the Löwner differential equation driven by a Brownian motion with variance parameter  $\kappa = 6$ .

Extra work is needed in order to prove the validity of the limiting operation for other percolation models and random processes. In another remarkable recent paper [111], Lawler, Schramm, and Werner have verified the existence of the scaling limit for loop-erased random walk and for the uniform spanning tree Peano curve, and have shown them to be  $\text{SLE}_2$  and  $\text{SLE}_8$  respectively. It is believed that self-avoiding walk on  $\mathbb{L}^2$ , [114], has scaling limit  $\text{SLE}_{8/3}$ .

We turn now to the random-cluster model on  $\mathbb{L}^2$  with parameters  $p$  and  $q$ . For  $1 \leq q < 4$ , it is believed that the percolation probability  $\theta(p, q)$ , viewed as a function of  $p$ , is continuous at the critical point  $p_c(q)$  (**OP**), and furthermore that  $p_c(q) = \sqrt{q}/(1 + \sqrt{q})$ . It seems likely that, when re-scaled in the manner similar to that of percolation (illustrated in Figure 6.2), the exploration process of the model converges to a limit process of SLE type. It then remains only to specify the parameter  $\kappa$  of the limit in terms of  $q$ . It has been conjectured in [130] that  $\kappa$  satisfies  $\cos(4\pi/\kappa) = -\frac{1}{2}\sqrt{q}$ ,  $\kappa \in (4, 8)$ . This value is consistent with Smirnov’s theorem [139], and also with the finding of [111] that the scaling limit of the uniform spanning tree Peano curve is  $\text{SLE}_8$ , on recalling that the uniform spanning tree measure is obtainable as a limit of the random-cluster measure as  $p, q \downarrow 0$  (recall Section 2.4).

There are uncertainties over how this programme will develop. For a start, the theory of random-cluster models is not as complete as that of percolation and of

the uniform spanning tree. Secondly, the existence of spatial limits is currently known only in certain special cases. The programme is however ambitious and full of promise, and should ultimately yield a full picture of the critical behaviour — including values of exponents — of random-cluster models, and hence of Ising/Potts models, with  $q \leq 4$ .

## 7. On complete graphs and trees

While considerations of ‘real space–time’ support the study of such models on lattices such as  $\mathbb{L}^d$ , it has proved rewarding also to analyse the random-cluster model on certain other graphs including complete graphs and trees. It is the presence of circuits in the underlying graph which is the root cause of dependence between the states of edges, and for this reason it is the complete graph which provides an appropriate setting for what is termed ‘mean-field theory’, in which vertices ‘interact’ with *all* other vertices rather than with a selected subset of ‘neighbours’. Trees, on the other hand, contain no circuits, and their random-cluster theory is therefore sterile unless one introduces boundary conditions. [A different approach to mean-field theory has been studied in [99], namely on  $\mathbb{L}^d$  for large  $d$ .]

### 7.1 ON COMPLETE GRAPHS

The mean-field Potts model may be formulated as a Potts model on the complete graph  $K_n$ , being the graph with  $n$  labelled vertices every pair of which is joined by an edge. The study of such a process dates back at least to 1954, [100], and has been continued over the last fifty years [26, 99, 151]. The model is exactly soluble in the sense that quantities of interest may be calculated exactly and rigorously. It is therefore not surprising that the corresponding random-cluster models (for real  $q$ ) have ‘exact solutions’ also, [26].

Consider the random-cluster measure  $\psi_{n,\lambda,q} = \phi_{K_n,\lambda/n,q}$  on the complete graph  $K_n$ , having parameters  $p = \lambda/n$  and  $q$ ; this is the appropriate scaling to allow an interesting limit as  $n \rightarrow \infty$ . In the case  $q = 1$ , this measure is product measure, and therefore the ensuing graph is an Erdős–Rényi random graph [25, 90]. The overall picture for general values of  $q$  is rather richer than for the case  $q = 1$ , and many exact calculations may be performed rigorously. It turns out that the phase transition is of first-order if and only if  $q > 2$ , and the behaviour of the system depends on how  $\lambda$  compares with a ‘critical value’  $\lambda_c(q)$  taking the value

$$\lambda_c(q) = \begin{cases} q & \text{if } 0 < q \leq 2, \\ 2 \left( \frac{q-1}{q-2} \right) \log(q-1) & \text{if } q > 2. \end{cases}$$

From the detailed picture described in [26] the following information may be extracted. The given properties occur with  $\psi_{n,\lambda,q}$ -probability tending to 1 as  $n \rightarrow \infty$ .

I. *Subcritical case, when  $\lambda < \lambda_c(q)$ .*

The largest component of the graph is of order  $\log n$ .

II. *Supercritical case, when  $\lambda > \lambda_c(q)$ .*

Figure 7.1. The function  $\theta(\lambda, q)$  for the three cases  $q < 2$ ,  $q = 2$ ,  $q > 2$ .

There is a ‘giant component’ having order  $\theta(\lambda, q)n$  where  $\theta$  is defined to be the largest root of the equation

$$e^{\lambda\theta} = \frac{1 + (q-1)\theta}{1-\theta}.$$

III. *Critical case, when  $\lambda = \lambda_c(q)$ ,  $0 < q \leq 2$ .*

The largest component has order  $n^{2/3}$ .

IV. *Critical case, when  $\lambda = \lambda_c(q)$ ,  $q > 2$ .*

The largest component is either of order  $\log n$  or of order  $\theta(\lambda, q)n$ , where  $\theta$  is given as in case II above.

The dichotomy between first- and second-order phase transition is seen by studying the function  $\theta(\lambda, q)$ , sketched in Figure 7.1. When  $0 < q \leq 2$ , the function  $\theta(\lambda, q)$  descends continuously to 0 as  $\lambda \downarrow \lambda_c(q)$ . On the other hand, this limit is strictly positive when  $q > 2$ .

The above results are obtained via a relationship between the model for general  $q$  and the model for the special case  $q = 1$ . The latter system has been analysed extensively, [25, 90]. We illustrate the argument in the case  $q \geq 1$ ; a similar approach is valid when  $q < 1$ . Consider the open clusters  $C_1, C_2, \dots, C_m$  of a sample from the random-cluster measure  $\phi_{K_n, p, q}$ . We colour each such cluster *red* with probability  $\rho$ , and *white* otherwise, different clusters receiving independent colours. We delete all vertices in white clusters, and let  $H$  denote the remaining graph, comprising a certain random number  $N$  of vertices (from the red clusters) together with certain open edges joining pairs of them. It may be seen that, conditional on the value of  $N$ , the measure governing  $H$  is the random-cluster measure with parameters  $p$  and  $q\rho$ . We choose  $\rho = 1/q$  to obtain an Erdős–Rényi random graph on a *random* set of vertices. This is the observation which permits the full analysis to proceed.

One consequence of this study is an explicit identification of the exponential asymptotics of the partition function  $Z_{K_n, \lambda/n, q}$ , namely of the limit function

$$f(\lambda, q) = \lim_{n \rightarrow \infty} \left\{ \frac{1}{n} \log Z_{K_n, \lambda/n, q} \right\}.$$

This provides information via the Gärtner–Ellis theorem, [43], concerning the large-deviation theory of the number of clusters in such systems.

## 7.2 ON TREES AND NON-AMENABLE GRAPHS

Whereas physical considerations support the study of interacting systems on finite-dimensional lattices, mathematicians have been drawn also to the study of general graphs, thus enabling a clearer elucidation of the mathematical structure of such systems (see the discussion in [134]). A subject of special focus has been the class of graphs for which the ratio of surface to volume of finite boxes does not approach zero in the limit as the size of the box tends to infinity. A prime example of such a graph is an infinite regular tree with vertex degree at least three. We make the distinction more concrete as follows. Let  $G = (V, E)$  be an infinite connected graph with finite vertex degrees. For  $W \subseteq V$ , we define its *boundary*  $\partial W$  to be the set of all  $w \in W$  having some neighbour  $v$  not belonging to  $W$ . The countably infinite graph  $G$  is called *amenable* if its ‘Cheeger constant’

$$\kappa(G) = \inf \left\{ \frac{|\partial W|}{|W|} : W \subseteq V, 0 < |W| < \infty \right\}$$

satisfies  $\kappa(G) = 0$ ;  $G$  is called *non-amenable* if  $\kappa(G) > 0$ . It is easily seen that  $\mathbb{L}^d$  is amenable, whereas an infinite regular tree with degree at least three is non-amenable.

The role of amenability in probability theory has been evident since the work of Kesten [95, 96] concerning random walks on a general graph  $G$ . More relevant to this review are [17, 75], which consider the number of infinite clusters in the bond percolation model on  $G$ . Suppose  $G$  is a quasi-transitive graph (that is, its vertex set has only finitely many orbits under its automorphism group). Suppose in addition that  $G$  is amenable. Consider bond percolation on  $G$  with density  $p$ . It may be proved as in [30, 58] that the number  $I$  of infinite open clusters satisfies

$$\text{either } P_p(I = 0) = 1 \quad \text{or} \quad P_p(I = 1) = 1.$$

That is, if an infinite open cluster exists, then it is almost surely unique. Under similar assumptions on a non-amenable graph  $G$ , it is believed but not yet proved in full generality that there exists an interval of values of  $p$  for which  $P_p(I = \infty) = 1$ ; see, for example, the discussion in [113]. A corresponding question for random-cluster models is to ascertain for which graphs  $G$  and values of  $q$  there is non-uniqueness of random-cluster measures for an interval of values of  $p$ . [Recall Theorem 3.7, easily extended to more general amenable graphs, which states that, for  $q \geq 1$ , there is a unique random-cluster measure on  $\mathbb{L}^d$  for all except at most countably many values of  $p$ .] See [82, 92] and especially [134, Section 6.1] for recent accounts of this and associated questions, and [80] for an analysis of random-cluster measures on regular trees.

## 8. Time-evolutions of random-cluster models

Let  $\mu$  be a probability measure on a space  $(\Omega, \mathcal{F})$ . We may study stochastic processes taking values in  $\Omega$  which converge weakly to  $\mu$  in the limit of large times. There are a multiplicity of reasons for and benefits in studying time-evolutions.

First, physical systems generally have dynamics as well as equilibria. Secondly, new questions of interest arise, such as that of the estimation of a relaxation time. Thirdly, the dynamics thus introduced can yield a new technique for studying the limit measure  $\mu$ .

When studying a physical system, it is often acceptable to restrict oneself to dynamics which are reversible in time. In Section 8.1, we describe a natural reversible dynamic for a random-cluster model, akin to the Glauber dynamics of the Ising model. This dynamic permits an extension which couples together the random-cluster measures on a given graph as  $p$  and  $q$  range over their possible values.

The problem commonly arises in statistics, computer science, and statistical physics of how to obtain a sample from a system governed by a probability measure with complex structure. In Section 8.2 we summarise the Propp–Wilson ‘coupling from the past’ approach, [128], to this problem in the context of the random-cluster measure.

Since Potts models may be obtained from random-cluster models, there is an interplay between the dynamics for these two systems. A famous instance of this relationship is the so-called Swendsen–Wang dynamic [141], which is described in Section 8.3.

We assume throughout this section that  $G = (V, E)$  is a finite connected graph, and that  $\phi_{p,q}$  is the random-cluster measure on  $\Omega = \{0, 1\}^E$  with  $0 < p < 1$  and  $q > 0$ .

### 8.1 REVERSIBLE DYNAMICS

We shall consider transitions from a configuration  $\omega$  to configurations which differ from  $\omega$  on one edge only. Thus we introduce the following notation. For  $\omega \in \Omega$  and  $e \in E$ , let  $\omega^e$  and  $\omega_e$  be the configurations obtained by ‘switching  $e$  on’ and ‘switching  $e$  off’, respectively, that is

$$\omega^e(f) = \begin{cases} 1 & \text{if } f = e, \\ \omega(f) & \text{if } f \neq e, \end{cases} \quad \omega_e(f) = \begin{cases} 0 & \text{if } f = e, \\ \omega(f) & \text{if } f \neq e. \end{cases}$$

Let  $(X_t : t \geq 0)$  be a Markov chain, [77], on the state space  $\Omega$  with generator  $Q = \{q_{\omega, \omega'} : \omega, \omega' \in \Omega\}$  satisfying

$$q_{\omega_e, \omega^e} = p, \quad q_{\omega^e, \omega_e} = (1 - p)q^{D(e, \omega_e)}, \quad \text{for } \omega \in \Omega, e \in E,$$

where  $D(e, \xi)$  is the indicator function of the event that the endpoints of  $e$  are joined by no open path of  $\xi$ . This specifies the rate at which single edges are acquired or lost. We set  $q_{\omega, \xi} = 0$  if  $\omega$  and  $\xi$  differ on two or more edges, and we choose the diagonal elements  $q_{\omega, \omega}$  in such a way that  $Q$ , when viewed as a matrix, has row sums zero, that is,

$$q_{\omega, \omega} = - \sum_{\xi: \xi \neq \omega} q_{\omega, \xi}.$$

It is elementary that the ‘detailed balance equations’

$$\phi_{p,q}(\omega)q_{\omega, \omega'} = \phi_{p,q}(\omega')q_{\omega', \omega}, \quad \omega, \omega' \in \Omega,$$

hold, whence  $X$  is reversible with respect to  $\phi_{p,q}$ . It follows by the irreducibility of the chain that  $X_t \Rightarrow \phi_{p,q}$  as  $t \rightarrow \infty$  (where ‘ $\Rightarrow$ ’ denotes weak convergence). There are of course many Markov chains with generators satisfying the above detailed balance equations, the important quantity is the ratio  $q_{\omega,\omega'}/q_{\omega',\omega}$ .

Two extensions of this dynamical structure which have proved useful are as follows. The evolution may be specified in terms of a ‘graphical representation’ constructed via a family of independent Poisson processes. This allows a natural coupling of the measures  $\phi_{p,q}$  for different  $p$  and  $q$ . Such couplings are monotone in  $p$  when  $q \geq 1$ . One may similarly couple the unconditional measure  $\phi_{p,q}(\cdot)$  and the conditioned measure  $\phi_{p,q}(\cdot | A)$ . Such couplings permit probabilistic interpretations of differences of the form  $\phi_{p',q}(B | A) - \phi_{p,q}(B)$  when  $q \geq 1$ ,  $p \leq p'$ , and  $A$  and  $B$  are increasing, and this can be useful in particular calculations (see [19, 68, 69]).

We turn now to the thermodynamic limit, and the question of the structure of a Markovian random-cluster process on an infinite connected graph. In the case  $q \geq 1$ , the above couplings are monotone in the choice of the underlying graph  $G$ . Therefore there exist ‘limit dynamics’ as  $G$  passes through an increasing sequence of finite graphs. Boundary conditions may be introduced, and one may obtain thereby a certain Markov process  $\zeta = (\zeta_t : t \geq 0)$  on the state space  $[0, 1]^{\mathbb{E}}$ , where  $\mathbb{E}$  is the limiting (infinite) edge set. This process, which does not generally have the Feller property, generates a pair of ‘level-set processes’ taking values in  $\{0, 1\}^{\mathbb{E}}$ , defined for  $0 \leq p \leq 1$  by

$$\zeta_t^{p,-}(e) = 1_{\{\zeta_t(e) > 1-p\}}, \quad \zeta_t^{p,+}(e) = 1_{\{\zeta_t(e) \geq 1-p\}}, \quad e \in \mathbb{E},$$

where, as before,  $1_A$  denotes the indicator function of an event  $A$ . These two processes are Markovian and are reversible with respect to the infinite-volume free and wired random-cluster measures, respectively. See [69].

Note that the generator of the Markov chain given above depends on the random variable  $D(e, \omega_e)$ , and that this random variable is a ‘non-local’ function of the configuration  $\omega$  in the sense that there is no absolute bound on the distance from  $e$  of edges whose states may be relevant to its value. It is this feature of non-locality which leads to interesting complications linked in part to the 0/1-infinite-cluster property introduced before Theorem 3.9. Further discussion may be found in [69, 121].

## 8.2 COUPLING FROM THE PAST

In running Monte Carlo experiments, one requires the ability to sample from the probability measure  $\phi_{p,q}$ . The Markov chain  $X_t$  of Section 8.1 certainly converges weakly to  $\phi_{p,q}$  as  $t \rightarrow \infty$ , but this is not as good as having in the hand a sample with the *exact* distribution. Random-cluster measures are well suited to the Propp–Wilson approach to sampling termed ‘coupling from the past’, [128], and we sketch this here. Some illustrations may be found in [91].

First we provide ourselves with a discrete-time reversible Markov chain  $(Z_n : n \geq 0)$  on the state space  $\Omega$  having invariant measure  $\phi_{p,q}$ . The so-called *heat-bath algorithm* provides a suitable example of such a chain, and proceeds as follows. At each stage, we pick a random edge  $e$ , chosen uniformly from  $E$  and independently of all earlier choices, and we make  $e$  open with the correct conditional probability,

given the configuration on the other edges. The corresponding transition matrix is given by  $\Pi = \{\pi_{\omega, \omega'} : \omega, \omega' \in \Omega\}$  where

$$\pi_{\omega_e, \omega^e} = \frac{1}{|E|} \cdot \frac{\phi_{p,q}(\omega^e)}{\phi_{p,q}(\omega^e) + \phi_{p,q}(\omega_e)},$$

$$\pi_{\omega^e, \omega_e} = \frac{1}{|E|} \cdot \frac{\phi_{p,q}(\omega_e)}{\phi_{p,q}(\omega^e) + \phi_{p,q}(\omega_e)}.$$

A neat way to do this is as follows. Suppose that  $Z_n = \omega$ . Let  $e_n$  be a random edge of  $E$ , and let  $U_n$  be uniformly distributed on the interval  $[0, 1]$ , these variables being chosen independently of all earlier choices. We obtain  $Z_{n+1}$  from  $\omega$  by retaining the states of all edges except possibly that of  $e_n$ . We set

$$Z_{n+1}(e_n) = 0 \quad \text{if and only if} \quad U_n \leq \frac{\phi_{p,q}(\omega_e)}{\phi_{p,q}(\omega^e) + \phi_{p,q}(\omega_e)}.$$

Thus the evolution of the chain is determined by the sequences  $e_n, U_n$ , and the initial state  $Z_0$ . One may make this construction explicit by writing  $Z_{n+1} = \psi(Z_n, e_n, U_n)$  ( $= \psi(\omega, e_n, U_n)$ ) for some function  $\psi : \Omega \times E \times [0, 1] \rightarrow \Omega$ . It is easily seen by the Holley condition of Section 3.1 that, if  $q \geq 1$ , and for every  $e$  and  $u$ , the function  $\psi(\cdot, e, u)$  is non-decreasing in its first argument. It follows that the coupling is ‘monotone’ in the sense that, if  $\omega \leq \omega'$ , then the chain starting at  $\omega$  lies at all times beneath the chain starting at  $\omega'$  (using the partial order on  $\Omega$ ).

We let  $W = (W(\omega) : \omega \in \Omega)$  be a vector of random variables such that  $W(\omega)$  has the distribution of  $Z_1$  conditional on  $Z_0 = \omega$ . Following the scheme described above, we may take  $W(\omega) = \psi(\omega, e, U)$  where  $e$  and  $U$  are chosen at random. Let  $W_{-m}, m \geq 1$ , be independent random vectors distributed as  $W$ , that is,  $W_{-m}(\cdot) = \psi(\cdot, e_m, U_m)$  where the set  $\{(e_m, U_m) : m \geq 1\}$  comprises independent pairs of independent random variables, each  $e_i$  being uniform on  $E$ , and each  $U_i$  being uniform on  $[0, 1]$ . We now construct a sequence  $Y_{-n}, n \geq 1$ , of random maps from  $\Omega$  to  $\Omega$  by the following inductive procedure. First, for  $\omega \in \Omega$ , we set  $Y_{-1}(\omega) = W_{-1}(\omega)$ . Having found  $Y_{-1}, Y_{-2}, \dots, Y_{-m}$ , we define  $Y_{-m-1}(\omega) = Y_{-m}(W_{-m-1}(\omega))$ . That is,  $Y_{-m-1}(\omega)$  is obtained from  $\omega$  by passing in one step to  $W_{-m-1}(\omega)$ , and then applying  $Y_{-m}$  to this new state. The exact dependence structure of this scheme is an important ingredient of what follows.

We stop this process at the earliest time  $m$  at which ‘coalescence has occurred’, that is, at the moment  $M$  given by  $M = \min\{m : Y_{-m}(\cdot) \text{ is the constant function}\}$ . It is a theorem, [128], that  $M$  is  $\phi_{p,q}$ -a.s. finite and, for any  $\omega$ , the random output  $Y_{-M}(\omega)$  is governed exactly by the probability measure  $\phi_{p,q}$ .

This procedure looks unwieldy, since  $\Omega$  is typically rather large, but the reality is simpler when  $q \geq 1$ . By the monotonicity of the above coupling when  $q \geq 1$ , it suffices to follow the trajectories of the ‘smallest’ and ‘largest’ configurations, namely those beginning, respectively, with every edge closed and with every edge open. The processes starting at intermediate configurations remain sandwiched between the extremal processes, for all times  $t$ . Thus one may define  $M$  by  $M = \min\{m : Y_{-m}(0) = Y_{-m}(1)\}$ , where 0 and 1 denote the vectors of zeros and ones as before.

## 8.3 SWENDSEN–WANG DYNAMICS

It is a major target of statistical physics to understand the time-evolution of disordered systems, and a prime example lies in the study of the Ising model. A multiplicity of types of dynamics have been proposed. The majority of these share a quality of ‘locality’ in the sense that the evolution involves changes to the states of vertices in close proximity to one another, perhaps single spin-flips, or spin-exchanges. The state space is generally large, of size  $2^N$  where  $N$  is the number of vertices, and the Hamiltonian has complicated structure. When subjected to ‘local dynamics’, the process may approach equilibrium very slowly (see [115, 133] for accounts of recent work of relevance). ‘Non-local dynamics’, on the other hand, have the potential to approach equilibrium faster, since they permit large jumps around the state space, relatively unconstrained by neighbourly relations. The random-cluster model has played a role in the development of a simple but attractive such system, namely that proposed by Swendsen and Wang [141] and described as follows for the Potts model with  $q$  states.

As usual,  $G = (V, E)$  is a finite graph, typically a large box in  $\mathbb{Z}^d$ , and  $\Sigma = \{1, 2, \dots, q\}^V$  is the state space of a Potts model on  $G$ . We write  $\Omega = \{0, 1\}^E$ . Suppose that, at some time  $n$ , we have obtained a configuration  $\sigma_n \in \Sigma$ . We construct  $\sigma_{n+1}$  as follows. Let  $p = 1 - e^{-\beta J}$  where  $0 < \beta J < \infty$ .

I. We let  $\omega_n \in \Omega$  be given as follows. For  $e = \langle x, y \rangle \in E$ ,

$$\begin{aligned} &\text{if } \sigma_n(x) \neq \sigma_n(y), \text{ let } \omega_n(e) = 0, \\ &\text{if } \sigma_n(x) = \sigma_n(y), \text{ let } \omega_n(e) = \begin{cases} 1 & \text{with probability } p, \\ 0 & \text{otherwise,} \end{cases} \end{aligned}$$

different edges receiving independent states. The edge configuration  $\omega_n$  is carried forward to the next stage.

II. To each cluster  $C$  of the graph  $(V, \eta(\omega_n))$  we assign an integer chosen uniformly at random from the set  $\{1, 2, \dots, q\}$ , different clusters receiving independent labels. We let  $\sigma_{n+1}(x)$  be the value thus assigned to the cluster containing the vertex  $x$ .

It may be checked that the Markov chain  $(\sigma_n : n \geq 0)$  has as unique invariant measure the Potts measure on  $\Sigma$  with parameters  $\beta$  and  $J$ . (Recall paragraph (c) of Section 2.3.)

The Swendsen–Wang algorithm leads to samples which generally converge to equilibrium faster than those defined via local dynamics. This is especially evident in the ‘high  $\beta$ ’ (or ‘low temperature’) phase, for the following reason. Consider for example the simulation of an Ising model on a finite box with free boundary conditions, and suppose that the initial state is  $+1$  at all vertices. If  $\beta$  is large, then local dynamics result in samples which remain close to the ‘+ phase’ for a very long time. Only after a long wait will the process achieve an average magnetisation close to 0. Swendsen–Wang dynamics, on the other hand, can achieve large jumps in average magnetisation even in a single step, since the spin allocated to a given large cluster of the corresponding random-cluster model is equally likely to be either of the two possibilities. A rigorous analysis of rates of convergence is however

incomplete. It turns out that, *at* the critical point, Swendsen–Wang dynamics approach equilibrium only slowly, [28]. A further discussion is available in [61].

Algorithms of Swendsen–Wang type have been described for other statistical mechanical models having graphical representations of random-cluster-type; see [41, 42]. Related work may be found in [149].

**Acknowledgements.** GRG recalls John Hammersley passing to him in 1971 a copy of Fortuin’s thesis [52] in which much of the basic theory is developed. Piet Kasteleyn kindly filled out the origins of random-cluster models in two letters addressed to GRG in November 1992. The author acknowledges the opportunity given by the Landau Center of the Hebrew University, Jerusalem, to deliver a course of lectures on the random-cluster model during July 2001. Harry Kesten kindly criticised a draft of the work. Thanks are due to Malwina Łuczak for her contributions to discussions on certain topics in this paper, and to Ágoston Pisztora for reading and commenting on parts of it. The further suggestions of Christian Borgs, Olle Häggström, Russell Lyons, Roberto Schonmann, Oded Schramm, and Alan Sokal have been appreciated. The paper was completed during a programme at the Isaac Newton Institute (Cambridge).
