The Recovery Theorem

Steve Ross<br>Franco Modigliani Professor of<br>Financial Economics<br>MIT

Revised
September 10, 2011

#### Abstract

We can only estimate the distribution of stock returns but we observe the distribution of risk neutral state prices. Risk neutral state prices are the product of risk aversion - the pricing kernel - and the natural probability distribution. The Recovery Theorem enables us to separate these and to determine the market's forecast of returns and the market's risk aversion from state prices alone. Among other things, this allows us to determine the pricing kernel, the market risk premium, the probability of a catastrophe, and to construct model free tests of the efficient market hypothesis.

I want to thank the participants in the UCLA Finance workshop for their insightful comments as well as Richard Roll, Hanno Lustig, Rick Antle, Andrew Jeffrey, Peter Carr, Kevin Atteson, Jessica Wachter, Ian Martin, Leonid Kogan, Torben Andersen, John Cochrane, Dimitris Papanikolaou, William Mullins, Jon Ingersoll, Jerry Hausman, Steve Leroy, and Phil Dybvig. All errors are my own.

Because financial markets price securities with payoffs extending out in time the hope that they can be used to forecast the future has long fascinated both scholars and practitioners. Nowhere has this been more apparent than with the studies of the term structure of interest rates with its enormous literature devoted to examining the predictive content of forward rates. But with the exception of foreign exchange and some futures markets, a similar line of research has not developed in other markets and, most notably, not in the equity markets.

While we have a rich market in equity options and a well-developed theory of how to use their prices to extract the martingale risk neutral probabilities (see Cox and Ross (1976a, 1976b)), there has been a theoretical hurdle to using them to make forecasts or, for that matter, to speak to issues in the natural world. Risk neutral returns are natural returns that have been 'risk adjusted'. In the risk neutral measure the expected return on all assets is the risk free rate because the risk neutral measure is the natural measure with the risk premium subtracted out. The risk premium is a function both of risk and of the market's risk aversion, and to use risk neutral prices to inform about real or natural probabilities we have to know the risk adjustment so we can add it back in. In models with a representative agent this is equivalent to knowing that agent's utility function and that is not directly observable. Instead, we infer it from fitting or 'calibrating' market models.

Furthermore, efforts to empirically measure the aversion to risk have led to more controversy than consensus. For example, measurements of the coefficient of aggregate risk aversion range from 2 or 3 to 500 depending on the model. The data are less helpful than we would like because we have a lengthy history in which U.S. stock returns seemed to have consistently outperformed fixed income returns - the equity premium puzzle (Prescott and Mehra [1985])- and that has given rise to a host of suspect proscriptions for the unwary investor. These conundrums have led some to propose that finance has its equivalent to the dark matter cosmologists posit to explain the behavior of their models for the universe when observables don't seem to be sufficient. Our dark matter is the very low probability of a catastrophic event and the impact that changes in that perceived probability can have on asset prices (see, e.g., Barro [2006] and Weitzmann [2007]). Apparently, though, such events are not all that remote and five sigma events seem to occur with a frequency that belies their supposed low probability.

When we extract the risk neutral probabilities of such events from the prices of options on the S\&P 500, we find the risk neutral probability of, for example, a $25 \%$ drop in a month, to be higher than the probability calculated from historical stock returns. But, since the risk neutral probabilities are the natural probabilities adjusted for the risk premium, either the market forecasts a higher probability of a stock decline than occurred historically or the market requires a very high risk premium to insure against a decline. Without knowing which, it is impossible to separate the two out and find the market's forecast of the event probability.

Finding the market's forecast for returns is important for other reasons as well. The natural expected return of a strategy depends on the risk premium for that strategy and, consequently, it has long been argued that any tests of efficient market hypotheses are simultaneously, tests of a particular asset pricing model and of the efficient market hypothesis (Fama [1970]). But if we knew the kernel we could estimate how variable the risk premium is (see Ross [2005]), and a bound on the variability of the kernel would limit how predictable a model for returns could be and still not violate efficient markets. In other words, it would provide a model free test of the efficient markets hypothesis.

A related issue is the inability to find the current market forecast of the expected return on equities. Unable to read this off of prices as we do with forward rates, we are left to using historical returns and resorting to opinion polls of economists and investors asking them to reveal their estimated risk premiums. It certainly doesn't seem that we can derive the risk premium directly from option prices because by pricing one asset the derivative - in terms of another, the underlying, the elusive risk premium doesn't appear in the resulting formula.

But, in fact, all is not quite so hopeless. While quite different, our results are in the spirit of Dybvig and Rogers [1997], who showed that if stock returns follow a recombining tree (or diffusion) then from observing an agent's portfolio choice along a single path we can reconstruct the agent's utility function. We borrow their nomenclature and call our results recovery theorems as well. Section I presents the basic analytic framework tying the state price density to the kernel and the natural density. Section II derives the Recovery Theorem which allows us to estimate the natural probability of asset returns and the market's risk aversion, the kernel, from the state price transition process alone. Section III derives a second recovery theorem, the Multinomial Recovery Theorem, which offers an alternative route for recovering the natural distribution for binomial and multinomial processes. Section IV examines the application of these results to some examples and some extensions. Section V estimates the state price densities at different horizons from the S\&P 500 option prices on a randomly chosen recent date, April 27, 2011, estimates the state price transition matrix and applies the Recovery Theorem to derive the kernel and the natural probability distribution. We compare the model's estimate of the natural probability with the histogram of historical stock returns. In particular, we shed some light on the dark matter of economics by highlighting the difference between the odds of a catastrophe as derived from observed state prices with that obtained from historical data. The analysis of Section V is meant to be illustrative and is far from the much needed empirical analysis, but it provides the first estimate of the natural density of stock returns. Section VI derives a model free test of efficient market hypotheses. Section VII concludes and summarizes the paper and points to some future research directions.

## Section I: The Basic Framework

Consider a one period world with asset payoffs $\mathrm{x}(\theta)$ at time T, contingent on the realization of a state of nature, $\theta \varepsilon \Omega$. From the Fundamental Theorem of Asset Pricing (see Dybvig and Ross [1987, 2003]), no arbitrage ('NA') implies the existence of positive state space prices, i.e., Arrow Debreu contingent claims prices, $p(\theta)$ (or allowing for lumpy states, the distribution function, $P(\theta)$ ), paying $\$ 1$ in state $\theta$ and nothing in any other states. If the market is complete, then these state prices are unique. The current value of the asset is given by

$$
\begin{equation*}
p=\int x(\theta) d P(\theta) \tag{1}
\end{equation*}
$$

Since the sum of the contingent claims prices is the current value of a dollar for sure in the future, letting $r$ denote the riskless rate we can rewrite this in the familiar forms

$$
\begin{gathered}
p=\int x(\theta) d P(\theta) \\
=\left(\int d P(\theta)\right) \int x(\theta) \frac{d P(\theta)}{\int d P(\theta)} \equiv e^{-r T} \int x(\theta) d \pi^{*}(\theta) \equiv e^{-r T} E^{*}[x(\theta)] \\
=E[x(\theta) \varphi(\theta)]
\end{gathered}
$$

where an asterisk denotes the expectation in the martingale measure and where the pricing kernel, i.e., the state price/probability $\varphi(\theta)$ is the Radon-Nikodym derivative of $\mathrm{P}(\theta)$ with respect to the natural measure which we will denote as $\mathrm{F}(\theta)$. With continuous distributions, $\varphi(\theta)=p(\theta) / f(\theta)$ where $f(\theta)$ is the natural probability. The risk neutral probabilities, are given by $\pi^{*}(\theta)=p(\theta) / \int p(\theta)=e^{r T} p(\theta)$. Notice, that the interest rate, $r$, could be dependent on the current state, a possibility we will allow below.

Let x denote the current state and y a state one period forward. We assume that this is a full description of the state of nature including the stock price itself and other information that is pertinent to the future evolution of the stock market index, thus the stock price can be written as $S(x)$. From the forward equation for the martingale probabilities

$$
\begin{equation*}
Q(x, y, T)=\int Q(x, z, t) d Q(z, y, T-t) \tag{3}
\end{equation*}
$$

where $\mathrm{Q}(\mathrm{x}, \mathrm{y}, \tau)$ is the forward probability transition function for going from state x to state $y$ in $\tau$ periods and where the integration is over the intermediate state at time $\mathrm{t}, \mathrm{z}$. Notice that we have made the transition a function independent of calendar time and a function only of the time interval.

This is a very general framework and allows for many interpretations. For example, the state could be composed of parameters that describe the motion of the process, e.g., the volatility of returns, v , as well as the current stock price, S , i.e., $\mathrm{x}=$ ( $S, v$ ). If the distribution of martingale returns is determined only by the volatility, then a transition could be written as a move from $x=(S, v)$ to $y=(S(1+R), z)$ where $R$ is the rate of return and

$$
\begin{equation*}
Q(x, y, t)=Q((S, v),(S(1+R), z), t) \tag{4}
\end{equation*}
$$

To simplify notation we will use state prices rather than the martingale probabilities so that we won't have to be continually correcting for the interest factor. Defining the state price matrix as the matrix of contingent forward prices, i.e., the price of an Arrow Debreu claim for a future payoffs in state y conditional on the current state x

$$
\begin{equation*}
p(x, y, t, T) \equiv e^{-r_{x}(T-t)} Q(x, y, t, T) \tag{5}
\end{equation*}
$$

and, assuming a time homogeneous process, period by period we have,

$$
\begin{equation*}
p(x, y)=e^{-r_{x}} Q(x, y) \tag{6}
\end{equation*}
$$

The state price matrix is the matrix of Notice that the risk free rate is allowed to be state dependent. This is appropriate and if we were to fix it across states we will see below that the model would degenerate.

Letting f denote the natural (time homogeneous) transition density, the kernel in this framework is defined as the price per unit of probability,

$$
\begin{equation*}
\varphi(x, y)=\frac{p(x, y)}{f(x, y)} \tag{7}
\end{equation*}
$$

Specializing this to an intertemporal model with additively time separable preferences and a constant discount factor, $\delta$, and letting c denote consumption at time $t$ as a function of the state, the kernel can be written as

$$
\begin{equation*}
\varphi(x, y)=\frac{p(x, y)}{f(x, y)}=\frac{\delta U^{\prime}(c(y))}{U^{\prime}(c(x))} \tag{8}
\end{equation*}
$$

Since this equation is simply the first order condition for the optimum for a representative agent,

$$
\begin{equation*}
\max _{\{c(x), c(y)\}}\left\{U(c(x))+\delta \int U(c(y)) f(x, y) d y\right\} \tag{9}
\end{equation*}
$$

s.t.

$$
c(x)+\int c(y) p(x, y) d y=w
$$

equation (8) for the kernel is the equilibrium solution for an economy with complete markets in which, for example, consumption is exogenous and prices are defined by the first order condition for the optimum. In a multiperiod model with complete markets and state independent intertemporally additive separable utility, there is a unique representative agent utility function that satisfies the above optimum condition and determines the kernel as a function of aggregate consumption (see Dybvig and Ross [1987, 2003]). Notice, too, that we don't have state dependent utility; the pricing kernel depends only on the marginal rate of substitution between future and the current consumption. The existence of such a representative agent will be a maintained assumption of our analysis below.

Rewriting (8) as,

$$
\begin{equation*}
U^{\prime}(c(x)) p(x, y)=\delta U^{\prime}(c(y)) f(x, y) \tag{10}
\end{equation*}
$$

and assuming that the market is complete and that we observe the state price transition function, $p(x, y)$, the objective is to solve this system to recover the three sets of unknowns, the natural probability transition function, $\mathrm{f}(\mathrm{x}, \mathrm{y})$, and the kernel, $\varphi(\mathrm{x}, \mathrm{y})$, and the included discount rate, $\delta$.

The literature on this problem is extensive and offers a variety of approaches. For example, Ait Sahalia and Lo [2000] combine state prices derived from option prices with estimates of the natural distribution to determine the kernel. Bollerslev and Tederov [2008] use high frequency data to estimate the premium for jump risk in a jump-diffusion model and, implicitly, the kernel. Jackwerth and Rubinstein [1996] and Jackwerth [2000] use implied binomial trees to represent the stochastic process. Bliss and Panigirtzoglou [2004] assume a functional form for the kernel from the constant relative and absolute risk aversion class and estimate the elasticity parameter by comparing the predictions of this form with historical data. These approaches have a common element; they all use the historical distribution of returns to estimate the unknown kernel and thereby link the historical estimate of the natural distribution to the risk neutral distribution

In the next section we will take a different tack and show that the equilibrium system of equations, (10), can be solved without the need to use either historical data or assumptions on preferences.

## Section II: The Recovery Theorem

To gain some insight into equation (10) and to position the apparatus for empirical work from now on we will specialize it to a discrete state space model,

$$
\begin{equation*}
U_{i}^{\prime} p_{i j}=\delta U_{j}^{\prime} f_{i j} \tag{11}
\end{equation*}
$$

where

$$
\begin{equation*}
U_{i}^{\prime} \equiv U^{\prime}(c(i)) \tag{12}
\end{equation*}
$$

and writing this in terms of the kernel

$$
\begin{equation*}
\varphi_{i} \equiv \varphi(1, i)=\delta\left(U_{i}^{\prime} / U_{1}^{\prime}\right) \tag{13}
\end{equation*}
$$

We can interpret the marginal utilities, $\mathrm{U}_{\mathrm{i}}{ }^{\prime}$, as the marginal utility of consumption in state $\mathrm{i}, \mathrm{c}(\mathrm{i})$. We will follow the literature and define the states from the filtration of the stock value, so that the kernel is the projection of the kernel across the broader state space onto the more limited space defined by the filtration of the asset price. Notice that while it is monotone declining in consumption it need not be monotone declining in the asset value, $\mathrm{S}(\mathrm{i})$.

Rewriting the state equations (11) in matrix form we have

$$
\begin{equation*}
D P=\delta F D \tag{14}
\end{equation*}
$$

where P is an mxm matrix, F is the mxm matrix of the natural probabilities and D is the diagonal matrix with the marginal utilities on the diagonal

$$
D=\left(\frac{1}{U_{1}^{\prime}}\right)\left[\begin{array}{ccc}
U_{1}^{\prime} & 0 & 0  \tag{15}\\
0 & U_{i}^{\prime} & 0 \\
0 & 0 & U_{m}^{\prime}
\end{array}\right]=\left(\frac{1}{\delta}\right)\left[\begin{array}{ccc}
\varphi_{1} & 0 & 0 \\
0 & \varphi_{i} & 0 \\
0 & 0 & \varphi_{m}
\end{array}\right]
$$

With a discrete or compact state space for prices we will have to make sure that the model doesn't admit of arbitrage. In a model with exogenous consumption the absence of arbitrage is a simple consequence of an equilibrium with positive state prices which assures that the carrying cost net of the dividend compensates for any position that attempts to profit from the rise out of the lowest asset value or the decline from the highest value.

Returning to our analysis, keep in mind that we observe the martingale prices, P , and our objective is to see what, if anything, we can infer about the natural measure, F ,
and the pricing kernel, i.e., the marginal rates of substitution. Solving for F as a function of P ,

$$
\begin{equation*}
F=\left(\frac{1}{\delta}\right) D P D^{-1} \tag{16}
\end{equation*}
$$

Clearly if we knew D, we would know F. It appears that we only have $\mathrm{m}^{2}$ equations in the $\mathrm{m}^{2}$ unknown probabilities, the marginal utilities, and the discount rate, $\delta$, and this appears to be the current state of thought on this matter. We know the risk neutral measure but without the marginal rates of substitution across the states, i.e., the risk adjustment, there appears to be no way to close the system and solve for the natural measure, F. Fortunately, though, this must satisfy an additional set of m constraints, namely that F is a stochastic matrix whose row sums to 1 .

$$
\begin{equation*}
F e=e, \tag{17}
\end{equation*}
$$

where e is the vector with 1 in all the entries.
Using this condition we have

$$
\begin{equation*}
F e=\left(\frac{1}{\delta}\right) D P D^{-1} e=e \tag{18}
\end{equation*}
$$

or

$$
\begin{equation*}
P z=\delta z \tag{19}
\end{equation*}
$$

where

$$
\begin{equation*}
z \equiv D^{-1} e \tag{20}
\end{equation*}
$$

This is a characteristic root problem and offers some hope that the solution set will be discrete and not an arbitrary cone. The theorem below verifies this intuition and provides us with a powerful result.

## Theorem 1 - The Recovery Theorem

In a world with a representative agent, if the pricing matrix, P , is positive or irreducible, then there exists a unique (positive) solution to the problem of finding F, the discount rate, and the pricing kernel. That is for any given set of state prices there is one and only one corresponding natural measure and, therefore, a unique pricing kernel, $\varphi$. If P has a single absorbing state but the matrix of the remaining $\mathrm{m}-1$ states is irreducible, then it has a unique positive solution for states other than for the absorbing state and if
the diagonal entry of the absorbing state is greater than the positive characteristic root of the other states, then there is a unique strictly positive solution.

## Proof:

Existence follows immediately from the fact that P is assumed to be generated from F and D as shown above, but as a byproduct of our solution we can show existence even if this were not the case. The problem of solving for $F$ is equivalent to finding the characteristic roots (eigenvalues) and characteristic vectors (eigenvectors) of the matrix of state prices, P. If we know $\delta$ and z such that

$$
\begin{equation*}
P z=\delta z \tag{21}
\end{equation*}
$$

then the kernel can be found from $z=D^{-1} e$.
Since $P$ is the matrix of state prices it is a nonnegative matrix. Suppose first that it is strictly positive. Since the martingale measure is absolutely continuous with respect to the natural measure, there are no states that are unattainable and could have zero prices. The Perron-Frobenius Theorem (see Meyer [2000]) tells us that all such matrices have a unique positive characteristic vector, z , and an associated positive characteristic root, $\lambda$, and that there are no other strictly positive characteristic vectors. Since P satisfies

$$
\begin{equation*}
P=\delta D^{-1} F D \tag{22}
\end{equation*}
$$

we know that a positive D must exist that yields P from some given F hence, we have now found it. The characteristic root $\lambda=\delta$ is the subjective rate of time discount.

Now suppose that P is nonnegative and irreducible but not positive, i.e., suppose that there are some zero entries. A zero in the ij entry means that state j cannot be attained from state i in a single step, but the matrix is irreducible if all states are attainable from all other states in $n$ steps. The current price for this state, occurring n periods out, would thus be positive. In this case the Perron-Frobenius Theorem holds and as before there is a unique positive characteristic vector associated with a unique positive characteristic root.

Lastly, suppose that one state has zeros at all points except on the diagonal. This could occur very naturally if the most calamitous state, say state 1 , was absorbing and once entered it cannot be left. In this case the entry $\mathrm{p}_{11}=\delta>0$ and the remaining entries in the first row are zero. As is well known from the theory of Markov chains, P is a reducible matrix since for all $n$, the entries in the first row of $\mathrm{P}^{\mathrm{n}}$ other than the first will remain zero. If P is reducible then there is little known in general about the characteristic roots. However, if we restrict ourselves to the case described above where the worst case is the single absorbing state and the rest of the entries of P are positive we do have a result.

Partition P as follows where B is $(\mathrm{m}-1) \times(\mathrm{m}-1)$, and C is $(\mathrm{m}-1) \times 1$,

$$
P=\left[\begin{array}{cc}
p_{11} & 0  \tag{23}\\
C & B
\end{array}\right]
$$

and partition the possible characteristic vector as

$$
\left[\begin{array}{l}
y  \tag{24}\\
x
\end{array}\right]
$$

where y is a scalar and x is dimension $\mathrm{m}-1$. In the absorbing state $\mathrm{p}_{11}=\delta$.
To be a characteristic vector we require that

$$
P\left[\begin{array}{l}
y  \tag{25}\\
x
\end{array}\right]=\left[\begin{array}{c}
p_{11} y \\
y C+B x
\end{array}\right]=\delta\left[\begin{array}{l}
y \\
x
\end{array}\right]
$$

If we set $\mathrm{y}=0$, then a characteristic vector is given by the solution to $\mathrm{Bx}=\lambda \mathrm{x}$ which is positive and unique since $B$ is irreducible. To find a strictly positive solution, without loss of generality scale $y=1$. Now we must solve the system

$$
\begin{equation*}
C+B x=\delta x \tag{26}
\end{equation*}
$$

If $\lambda=\delta$ this generally has no solution; the characteristic matrix

$$
\begin{equation*}
[I-\delta B] \tag{27}
\end{equation*}
$$

is singular and the system can be solved only if C is in its span.
In the general case where $\lambda \neq \delta$, the unique solution is given by

$$
\begin{equation*}
x=-[B-\delta I]^{-1} C \tag{28}
\end{equation*}
$$

Since $\lambda$ is the maximal characteristic root of $B$, the inverse is negative for $\delta>\lambda$ and since $\mathrm{C}>0$ this assures that x is strictly positive.

Letting $x$ denote the unique the unique positive characteristic vector with root $\lambda$, we can solve for the kernel as

$$
\begin{equation*}
U^{\prime}(c(i))=\left(\frac{1}{\delta}\right) \varphi_{i}=d_{i i}=\frac{1}{x_{i}} \tag{29}
\end{equation*}
$$

Since $x$ can be arbitrarily scaled without changing the marginal rates of substitution we can choose a reference state, c for the current state, and divide each entry by this marginal utility to obtain the kernel. To get the natural probability distribution, from our previous analysis,

$$
\begin{equation*}
F=\left(\frac{1}{\delta}\right) D P D^{-1} \tag{30}
\end{equation*}
$$

and

$$
\begin{equation*}
f_{i j}=\left(\frac{1}{\delta}\right) \frac{\varphi_{i}}{\varphi_{j}}=\left(\frac{1}{\delta}\right) \frac{U_{i}^{\prime}}{U_{j}^{\prime}} p_{i j}=\left(\frac{1}{\lambda}\right) \frac{x_{j}}{x_{i}} p_{i j} \tag{31}
\end{equation*}
$$

Corollary 1
The subjective rate of discount, $\delta$, is bounded above by the largest interest factor.
Proof:
From The Recovery Theorem the subjective rate of discount, $\delta$, is the positive character root of the price transition matrix, P. From the Perron-Frobenius Theorem (see Meyer [2000]) this root is bounded above by the maximum row sum of P. Since the elements of P are the pure contingent claim state prices, it follows that the row sums are the interest factors and that the maximum row sum is the maximum interest factor.

Now let's turn to the case where the riskless rate is the same in all states.

Theorem 2
If the riskless rate is state independent then the unique natural density associated with a given set of risk neutral prices is the martingale density itself, i.e., pricing is risk neutral.

Proof:

In this case we have

$$
\begin{equation*}
P e=\gamma e \tag{32}
\end{equation*}
$$

where $\gamma$ is the interest factor. It follows that $\mathrm{Q}=(1 / \gamma) \mathrm{P}$ is the risk neutral martingale probability matrix and, as such, e is its unique positive characteristic vector and 1 is its characteristic root.

From Theorem 1

$$
\begin{equation*}
F=\left(\frac{1}{\gamma}\right) P=Q \tag{33}
\end{equation*}
$$

Given the apparent ease of creating intertemporal models satisfying the usual assumptions without risk neutrality this result seems a bit odd, but it's a consequence of having a finite irreducible process for state transition. Apparently when we extend the recovery result to multinomial processes that are unbounded this is no longer the case.

Before going on to implement these results, there is a simple extension of this approach that appears not to be well known and is of interest in its own right.

Theorem 3

The risk neutral martingale density for consumption and the natural density for consumption have the single crossing property and the natural density stochastically dominates the risk neutral density. Equivalently, in a one period world, the market natural density stochastically dominates the risk neutral density.

Proof:

From

$$
\begin{equation*}
\varphi(x, y)=\frac{p(x, y)}{f(x, y)}=\frac{\delta U^{\prime}(c(y)}{U^{\prime}(c(x))} \tag{34}
\end{equation*}
$$

we know that $\varphi$ is declining in $c(y)$. Since both densities integrate to one and since $\varphi$ exceeds $\delta$ for $\mathrm{c}(\mathrm{y})<\mathrm{c}(\mathrm{x})$, it follows that $\mathrm{p}>\mathrm{f}$ for $\mathrm{c}(\mathrm{y})<\mathrm{c}\left(\mathrm{y}^{*}\right)$ where $\delta \mathrm{U}^{\prime}\left(\mathrm{c}^{*}\left(\mathrm{y}^{*}\right)\right)=$ $\mathrm{U}^{\prime}(\mathrm{c}(\mathrm{x}))$ and $\mathrm{p}<\mathrm{f}$ for $\mathrm{c}>\mathrm{c}^{*}$. This is the single crossing property and verifies that f stochastically dominates $p$. In a single period model, terminal wealth and consumption are the same.

Corollary 2
In a one period world the market displays a risk premium, i.e., the expected return on the asset is greater than the riskless rate.

Proof:
In a one period world consumption coincides with the value of the market. From stochastic dominance at any future date, T ,

$$
\begin{equation*}
S^{*} \sim S-Z+\in \tag{35}
\end{equation*}
$$

where the asterisk denotes the price in the martingale risk neutral measure, Z is strictly nonnegative and $\varepsilon$ is a mean zero error term. Taking expectations we have

$$
\begin{equation*}
E[S]=r+E[z]>r \tag{36}
\end{equation*}
$$

The Recovery Theorem embodies the central intuitions of recovery and is sufficiently powerful for the subsequent empirical analysis. But, before leaving this section we should note that while there are extensions to continuous state spaces, as developed here the Recovery Theorem relied heavily on the finiteness of the state space. In the next section we will take a different tack and derive a recovery theorem when the state space is infinite and generated by a binomial or multinomial process.

## Section III: A Binomial and Multinomial Recovery Theorem

While the Recovery Theorem can be applied to a binomial or multinomial process, doing so requires a truncation of the state space. To avoid this step and since these processes are so ubiquitous in finance (see Cox, Ross Rubinstein [1979]), it is useful to look at them separately. Throughout this analysis the underlying metaphorical model is a tree of height H that grows exogenously and bears exogenous fruit, 'dividends', that is wholly consumed. Tree growth is governed by a multinomial process and the state of the economy is $\langle\mathrm{H}, \mathrm{i}\rangle, \mathrm{i}=1, \ldots, \mathrm{~m}$. The multinomial process is state dependent and the tree grows to $\mathrm{a}_{\mathrm{j}} \mathrm{H}$ with probability $\mathrm{f}_{\mathrm{ij}}$. In every period the tree pays a consumption dividend kH where k is a constant. Notice that the state only determines the growth rate and the current dividend depends only on the height of the tree and not of the state. The value of the tree, the market value of the economy's assets, is given by $\mathrm{S}=$ $\mathrm{S}(\mathrm{H}, \mathrm{i})$. Since tree height and, therefore, consumption follow a multinomial process, S also follows a multinomial, but, in general, jump sizes will change with the state.

The initial marginal utility of consumption is $\mathrm{U}^{\prime}(\mathrm{kH})$ which is independent of the state variable, $i$, and, without loss of generality we can set $\mathrm{U}^{\prime}(\mathrm{kH})=1$. The equilibrium equations are

$$
\begin{equation*}
p_{i j}(H)=\delta U^{\prime}\left(k a_{j} H\right) f_{i j} \tag{37}
\end{equation*}
$$

or, in terms of the undiscounted kernel,

$$
\begin{equation*}
p_{i j}(H)=\delta \varphi_{j} f_{i j} \tag{38}
\end{equation*}
$$

In matrix notation,

$$
\begin{align*}
P & =\delta F D  \tag{39}\\
F & =\left(\frac{1}{\delta}\right) P D^{-1} \tag{40}
\end{align*}
$$

and since F is a stochastic matrix

$$
\begin{equation*}
F e=\left(\frac{1}{\delta}\right) P D^{-1} e=e \tag{41}
\end{equation*}
$$

or

$$
\begin{equation*}
P D^{-1} e=\delta e \tag{42}
\end{equation*}
$$

Assuming P is of full rank, this solves for the kernel, D, as

$$
\begin{equation*}
\left(\frac{1}{\delta}\right) D^{-1} e=P^{-1} e \tag{43}
\end{equation*}
$$

Now F is recovered as

$$
\begin{equation*}
F=\left(\frac{1}{\delta}\right) P D^{-1} \tag{44}
\end{equation*}
$$

Proceeding along the tree in the same fashion, node by node, we can recover the distribution at all future nodes.

Notice that this analysis recovers F and $\delta \mathrm{D}$ but not $\delta$ and $\varphi$ separately. By taking advantage of the recombining feature of the process, though, we can recover $\delta$ and $\varphi$ separately. For simplicity, consider a binomial process with jumps to a or b. The binomial is recurrent, i.e., it eventually returns arbitrarily close to any starting position. Along with the transition matrix being of full rank, this was one of the key assumptions of the Recovery Theorem. For a binomial, with jumps of $a$ and $b$, if we were to expand it into an infinite matrix the matrix would have only two nonzero elements in any row, and at a particular node we would only see the marginal price densities at that node. To observe the transition matrix we want to return to that node from a different path. For example, if the current stock price is 1 and there is no exact path that returns to 1 , then we can get arbitrarily close to 1 along a path where the number of a steps, $i$ and the number of down steps, $n-i$, satisfy

$$
\begin{equation*}
\frac{i}{n-i} \rightarrow-\frac{\log b}{\log a} \tag{45}
\end{equation*}
$$

for large n .
Sparing the obvious continuity analysis, we will simply assume that the binomial recurs in two steps, i.e., $a b=1$. That implies that it must satisfy the further state equation when it returns to H from having gone to aH ,

$$
\begin{equation*}
p_{a b}(a H)=\delta\left(\frac{U^{\prime}(k H)}{U^{\prime}(k a H)}\right) f_{a b}=\delta\left(\frac{1}{\varphi_{a}}\right) f_{a b} \tag{46}
\end{equation*}
$$

Since we can recover $\delta \varphi_{\mathrm{a}}=\left(\mathrm{P}^{-1}\right)_{\mathrm{a}} \mathrm{e}$, we can solve separately for $\delta$ and $\varphi_{\mathrm{a}}$ and, more generally, for $\delta$ and $\varphi$. The analysis is similar for the general multinomial case.

Notice, too, that while we might currently be in state a, say, and not observe $p_{b a}(H)$ and $p_{a b}(H)$, we can compute them since the prices of going from the current state to a or b in three steps along the paths $(\mathrm{a}, \mathrm{b}, \mathrm{a})$ and $(\mathrm{a}, \mathrm{b}, \mathrm{b})$ when divided by the price of
going to 1 in two steps by the path $(\mathrm{a}, \mathrm{b})$ are $\mathrm{p}_{\mathrm{ab}}$ and $\mathrm{p}_{\mathrm{ba}}$, respectively. Alternatively, if we know the current price of going to 1 in two steps, $\mathrm{p}_{\mathrm{a} \cdot 1}$, then

$$
\begin{gather*}
p_{a \cdot 1}=p_{a a}(k H) p_{a b}(k a H)+p_{a b}(k H) p_{b a}(k b H)  \tag{48}\\
=\delta^{2}\left[\varphi_{a} f_{a}\left(\frac{1}{\varphi_{a}}\right)\left(1-f_{a}\right)+\varphi_{b}\left(1-f_{a}\right)\left(\frac{1}{\varphi_{b}}\right)\left(1-f_{b}\right)\right] \\
=\delta^{2}\left(1-f_{a}\right)\left(1+f_{a}-f_{b}\right)
\end{gather*}
$$

is an independent equation which completes the system and allows it to be solved for $\delta$, $F$, and $\varphi$.

If the riskless rate is state independent, then P has identical row sums and if it is of full rank, then, as with the first Recovery Theorem, we must have risk neutrality. To see this, let

$$
\begin{equation*}
P e=\gamma e \tag{49}
\end{equation*}
$$

Hence

$$
\begin{equation*}
\left(\frac{1}{\delta}\right) D^{-1} e=P^{-1} e=\left(\frac{1}{\gamma}\right) e \tag{50}
\end{equation*}
$$

all the marginal utilities are identical and the natural probabilities equal the martingale probabilities.

If P is not of full rank, by the maintained assumption we know that there is a solution to

$$
\begin{equation*}
F e=P D^{-1} e=e \tag{51}
\end{equation*}
$$

In general, though, there is a (nonlinear) subspace of potential solutions with dimension equal to the rank of P and, not surprisingly, while we can restrict the range of potential solutions, we cannot uniquely recover the kernel and the probability matrix. As an example, consider a simple binomial process that jumps to a with probability $f$ and $b$ with probability (1-f). In this case P has two identical rows and recombining gives us a total of three equations in the four unknowns, $\delta, \mathrm{f}, \varphi_{\mathrm{a}}$ and $\varphi_{\mathrm{b}}$ :

$$
\begin{align*}
& p_{a}=\delta \varphi_{a} f  \tag{52}\\
& p_{b}=\delta \varphi_{b}(1-f) \tag{53}
\end{align*}
$$

and

$$
\begin{equation*}
p_{a .1}=2 \delta^{2} f(1-f) \tag{54}
\end{equation*}
$$

which, with positivity, has a cone of solutions of dimension $4-3=1$.
In the special case where the interest rate is state independent, though, even if the matrix is of less than full rank than it's easy to see from the above that risk neutrality is one of the potential solutions. We summarize these results in the following theorem.

Theorem 4 - The Multinomial Recovery Theorem
Under the assumed conditions on the process, the kernel, the transition probability matrix and the subjective rate of discount of a binomial (multinomial) process can be recovered at each node from a full rank state price transition matrix alone. If the state prices are independent of the state, then the kernel must be risk neutral. If the transition matrix is of less than full rank, then we can restrict the potential solutions, but we cannot recover uniquely.

Proof:
See above.

These results are, of course, implicit in the much studied work on the binomial model, but perhaps because they haven't been the focus of study or perhaps because of the assumption that because of the arbitrary choice of a kernel it would not be possible to separate risk aversion from probabilities, they appear to have gone unnoticed. Which Recovery Theorem should be used in any particular case depends on the exact circumstances.

## A. Relative Risk Aversion

An alternative approach to recovery that allows for more flexibility in the process is to assume a functional form for the kernel. Suppose, for example, that the kernel is generated by a constant relative risk aversion utility function and that we specialize the model to a binomial with tree growth of a or $\mathrm{b}, \mathrm{a}>\mathrm{b}$. State prices are given by

$$
\begin{equation*}
p_{x y}(H)=\varphi(k H, k y H) \delta f_{x y} \tag{55}
\end{equation*}
$$

Hence,

$$
\begin{equation*}
S(a, H)=p_{a a}(H)[S(a, a H)+k a H]+p_{a b}(H)[S(b, b H)+k b H] \tag{56}
\end{equation*}
$$

and

$$
\begin{equation*}
S(b, H)=p_{b a}(H)[S(a, a H)+k a H]+p_{b b}(H)[S(b, b H)+k b H] \tag{57}
\end{equation*}
$$

Assuming constant relative risk aversion,

$$
\begin{equation*}
\varphi(x, y)=\left(\frac{y}{x}\right)^{-R} \tag{58}
\end{equation*}
$$

this system is linear with the linear solution

$$
\begin{equation*}
S=\gamma_{x} H \tag{59}
\end{equation*}
$$

where

$$
\binom{\gamma_{a}}{\gamma_{b}}=\left[\begin{array}{cc}
1-\delta f_{a} a^{1-R} & -\delta\left(1-f_{a}\right) b^{1-R}  \tag{60}\\
-\delta\left(1-f_{b}\right) a^{1-R} & 1-\delta f_{b} b f^{1-R}
\end{array}\right]^{-1}\binom{\delta f_{a} k a^{1-R}+\delta\left(1-f_{a}\right) k b^{1-R}}{\delta f_{b} k b^{1-R}+\delta\left(1-f_{b}\right) k a^{1-R}}
$$

Thus the stock value S follows a binomial process and at the next step takes on the values $S(a, a H)$ or $S(b, b H)$ depending on the current state and the transition,

$$
\begin{align*}
& S(a, H)=\gamma_{a} H \rightarrow \gamma_{a} a H=S(a, a H) \text { or } \gamma_{b} b H=S(b, b H)  \tag{61}\\
& S(b, H)=\gamma_{b} H \rightarrow \gamma_{a} a H=S(a, a H) \text { or } \gamma_{b} b H=S(b, b H) \tag{62}
\end{align*}
$$

Notice, though, that even if $\mathrm{ab}=1$, the binomial for S is not a recombining tree. If it starts at $S(a, a H)$, and then first goes up and then down it returns to $S(b, a b H)=S(b, H) \neq$ $S(a, H)$, but if it first goes down and then up it does return to $S(a, b a H)=S(a, H)$.

Without making use of recombination, the state price equations for this system are given by:

$$
\begin{gather*}
p_{a a}=\delta f_{a} a^{-R}  \tag{63}\\
p_{a b}=\delta\left(1-f_{a}\right) b^{-R}  \tag{64}\\
p_{b a}=\delta\left(1-f_{b}\right) a^{-R} \tag{65}
\end{gather*}
$$

and

$$
\begin{equation*}
p_{b b}=\delta f_{b} b^{-R} \tag{66}
\end{equation*}
$$

These are four independent equations in the four unknowns, $, R, f_{a}, f_{b}$, and the solution is given by

$$
\begin{align*}
\binom{f_{a}}{f_{b}} & =\left(\frac{p_{a b} p_{b a}}{p_{a a} p_{b b}}-1\right)^{-1}\binom{\frac{p_{a b}}{p_{b b}}-1}{\frac{p_{b a}}{p_{a a}}-1}  \tag{67}\\
R & =\frac{\ln \left(\frac{f_{a}}{1-f_{a}}\right)+\ln \left(\frac{p_{a a}}{p_{a b}}\right)}{\ln \left(\frac{b}{a}\right)} \tag{68}
\end{align*}
$$

and

$$
\begin{equation*}
\delta=p_{a a} f_{a} a^{R} \tag{69}
\end{equation*}
$$

This example also further clarifies the importance of state dependence. With state independence there are only two equilibrium state equations in the three unknowns, $\mathrm{R}, \mathrm{f}$, and $\delta$,

$$
\begin{align*}
& p_{a}(H)=\delta f a^{-R}  \tag{70}\\
& p_{a}(H)=\delta(1-f) b^{-R} \tag{71}
\end{align*}
$$

Nor can this be augmented by recombining since, assuming $\mathrm{ab}=1$,

$$
\begin{equation*}
p_{a}(b H)=\delta f\left(\frac{1}{b^{-R}}\right)=\delta f b^{R}=\delta f a^{-R} \tag{72}
\end{equation*}
$$

which is identical to the first equation. In other words, while the parametric assumption has reduced finding the two element kernel to recovering a single parameter, R , it has also eliminated one of the equations. As we have shown, though, assuming meaningful state dependency once again allows full recovery.

This approach also allows for recovery if the rate of consumption is state dependent. Suppose, for example, that consumption is $\mathrm{k}_{\mathrm{a}}$ or $\mathrm{k}_{\mathrm{b}}$ in the respective states, a and $b$. The equilibrium state equations are now

$$
\begin{gather*}
p_{a a}=\delta f_{a} a^{-R}  \tag{73}\\
p_{a b}=\delta\left(1-f_{a}\right)\left(\frac{k_{a}}{k_{b}}\right)^{R} b^{-R}  \tag{74}\\
p_{b a}=\delta\left(1-f_{b}\right)\left(\frac{k_{b}}{k_{a}}\right)^{R} a^{-R} \tag{75}
\end{gather*}
$$

and

$$
\begin{equation*}
p_{b b}=\delta f_{b} b^{-R} \tag{76}
\end{equation*}
$$

These are four independent equations which can be solved for the four unknowns, $\delta, R, f_{a}$, and $f_{b}$.

As a final example, the Appendix applies the Multinomial Recovery Theorem to a case where the representative agent has Epstein-Zin [1989] recursive preferences.

To recover the natural distribution in Section 5 below we will use the Recovery Theorem but we could also use the Multinomial Recovery Theorem. Which will work better will ultimately be an empirical question.

Section IV: Some Test Applications of the Recovery Theorem

## Example 1

Consider a model with a lognormally distributed payoff at time T and a representative agent with a constant relative risk aversion utility function,

$$
\begin{equation*}
\mathrm{U}\left(\mathrm{~S}_{\mathrm{T}}\right)=\frac{\mathrm{S}_{\mathrm{T}}{ }^{1-\mathrm{R}}}{1-\mathrm{R}} \tag{77}
\end{equation*}
$$

The future stock payoff, the consumed 'fruit' dividend, is lognormal,

$$
\begin{equation*}
S_{T}=e^{\left(\mu-\frac{1}{2} \sigma^{2}\right) T+\sigma \sqrt{T} z} \tag{78}
\end{equation*}
$$

where the parameters are as usual and z is a unit standard normal variable.
The pricing kernel is given by

$$
\begin{equation*}
\varphi_{T}=\frac{e^{-\delta T} U^{\prime}\left(S_{T}\right)}{U^{\prime}(S)}=e^{-\delta T}\left[\frac{S_{T}}{S}\right]^{-R} \tag{79}
\end{equation*}
$$

where $S$ is the current stock dividend that must be consumed at time 0 .
Given the natural measure and the kernel, state prices are given by

$$
\begin{equation*}
P_{T}\left(S, S_{T}\right)=\varphi_{T}\left(\frac{S_{T}}{S}\right) n_{T}\left(\frac{S_{T}}{S}\right)=e^{-\delta T}\left[\frac{S_{T}}{S}\right]^{-R} n\left(\frac{\ln \left(\frac{S_{T}}{S}\right)-\left(\mu-\frac{1}{2} \sigma^{2}\right) T}{\sigma \sqrt{T}}\right) \tag{80}
\end{equation*}
$$

where $n(\cdot)$ is the normal density function.
In this model we know both the natural measure and the state price density and our objective is to see how accurately we can recover the natural measure and, thus, the kernel from the state prices alone using the Recovery Theorem. Setting T = 1, Table I displays natural transition probability matrix, F, the pricing kernel, the time discount, $\delta$, and the matrix $P$ of transition prices. The units of relative stock movement, $\mathrm{S}_{\mathrm{T}} / \mathrm{S}$, are the grid of units of sigma from -5 to +5 . Sigma can be chosen as the standard deviation of the derived martingale measure from P , but alternatively we chose the current at-themoney implied volatility from option prices as of March 15, 2011. [Insert Table I]

With an assumed market return of $8 \%$, a standard deviation of $20 \%$ we calculate the characteristic vector of P . As anticipated there is one positive vector and it exactly
equals the pricing kernel shown in Table I and the characteristic root is $\mathrm{e}^{-.02}=.9802$ as was assumed. Solving for the natural transition matrix, F, we have exactly recovered the posited lognormal density.

This example fits the assumptions of the Recovery Theorem closely except for having a continuous distribution rather than a discrete one. The closeness of the results with the actual distribution and kernel provides comfort that applying the theorem by truncating the tails is an appropriate approach. Notice that since we can take the truncated portions as the cumulative prices of being in those regions, there is no loss of accuracy in estimating cumulative tail probabilities.

## Example 2

The second example deals explicitly with the case where returns are independent of price and can lead to growing values. This would occur, for example, in any model where future prices are some return multiplied by current prices. Assume that returns follow a traditional lognormal distribution

$$
\begin{equation*}
d S / S=\mu d t+\sigma d z \tag{81}
\end{equation*}
$$

where z is a standard Brownian process. Terminal wealth is now lognormally distributed,

$$
\begin{equation*}
\mathrm{S}_{\mathrm{T}}=S \mathrm{e}^{\left(\mu-\frac{1}{2} \sigma^{2}\right) \mathrm{T}+\sigma \sqrt{\mathrm{T} \mathrm{z}}}, \tag{82}
\end{equation*}
$$

There are several ways to approach modeling preferences in this example. We could simply assume that there is a representative agent with preferences over consumption which, in this simple example, could be a dividend from the stock price. An easier and more straightforward approach is to assume that preferences are over returns. In the absence of arbitrage this is equivalent in a one period setting to preferences over terminal outcomes. Using the constant relative risk aversion utility function, the kernel is given by

$$
\begin{equation*}
\varphi_{T}=e^{-\delta T} U^{\prime}\left(\frac{s_{T}}{s_{0}}\right)=e^{-\delta T}\left[\frac{s_{T}}{s_{0}}\right]^{-R} \tag{83}
\end{equation*}
$$

While this looks the same as before it is not; here we are not holding the distribution of the terminal value constant, rather we assume a distribution for the relative value.

If the distribution was assumed independent over time, then we would have an awkward problem because the ex ante equilibrium would be the same independent of the return realization and that would make the interest rate constant which would mean that the only equilibrium would be one in which the characteristic vector of implied prices is the same across states, i.e., the model degenerates to risk neutrality.

An easy way to see this is to look closely at the discrete pricing equation

$$
\begin{equation*}
U_{i}^{\prime} p_{i j}=\delta U_{j}^{\prime} f_{i j} \tag{84}
\end{equation*}
$$

Since preferences depend on the relative return the pricing equation is amended to

$$
\begin{equation*}
p_{i j}=\delta U^{\prime}\left(R_{i j}\right) f_{i j}=\delta U^{\prime}\left(R_{j}\right) f_{j} \tag{85}
\end{equation*}
$$

where both the return, R , and the probability are assumed independent of the previous return. It follows, then that

$$
\begin{equation*}
p_{i j}=\delta f_{j} U^{\prime}\left(R_{j}\right) \equiv p_{j} \tag{86}
\end{equation*}
$$

independent of state i. Hence, the resulting transition pricing matrix has all the same rows and it must have the same interest rate for all states. This is very similar to the paradox that occurs in an intertemporal equilibrium portfolio model where the opportunity set is unchanging and, as a consequence, asset prices don't change either making any assumed capital gains process inconsistent. Once again, one possible solution is that the natural probabilities equal the martingale probabilities, but the space of possible solutions is $\mathrm{m}-1$ dimensional and the natural distribution cannot be recovered.

To make the model interestingly state dependent so that we can apply the Recovery Theorem we make the distribution of current returns depend on past returns through the linkage of returns and implied volatility. A simple regression of implied volatility, v , on past returns produces a very significant relation of the form,

$$
\begin{equation*}
\ln \left(v_{t+1} / v_{t}\right)=-\beta \ln \left(R_{t}\right) \tag{87}
\end{equation*}
$$

Where, for this example, we set $\beta=0.5$. Now the transition probability matrix from state $i$ returns, $R_{i}$ to state $j$ returns, $R_{j}$ is given by

$$
\begin{equation*}
f_{i j}=f\left(R_{i}, R_{j}\right)=n\left(\frac{\ln \left(R_{j}\right)-\left(\mu-\frac{1}{2} \sigma^{2} R_{i}^{-2 \beta}\right) T}{\sigma R_{i}^{-\beta} \sqrt{T}}\right) \tag{88}
\end{equation*}
$$

and

$$
\begin{equation*}
\varphi=\varphi\left(R_{j}\right)=\left(R_{i}\right)^{-R} \tag{89}
\end{equation*}
$$

which is assumed independent of the initial state, $i$.
Keep in mind that even though we might have modeled preferences incorrectly, we are working backwards from the observed state prices and have found the unique set of probabilities and prices that could have generated it given the assumed model. Our
problem is to interpret the resulting pricing kernel and our construction has found the unique one associated with the observed state prices.

We were able to find the exact solution in this case by applying the Recovery Theorem because we made preferences a function of returns and not of levels as would be more usual in a typical intertemporal consumption model. As such, we didn't need to have the utility function generating the kernel be a constant relative risk aversion function, but, if it is, then the model and the example are identical, i.e., the marginal rates of substitution as a function of levels actually depend only on the relative returns just as if we had assumed that was the case. If we do assume a constant relative risk aversion function, though, we can just proceed as in Example 1 and use the Recovery Theorem to extract its single parameter, the constant coefficient of relative risk aversion, R. The numerical results are shown in Table II. [Insert Table II]

Alternatively, instead of constant relative risk aversion, to make levels matter we can assume preferences are represented by a constant absolute utility function. Now the kernel is given by

$$
\begin{equation*}
\varphi\left(S_{t}, S_{t+1}\right)=\frac{\delta U^{\prime}\left(S_{t+1}\right)}{U^{\prime}\left(S_{t}\right)}=\frac{-\delta A e^{-A S_{t+1}}}{-A e^{-A S_{t}}}=\delta e^{-A\left(S_{t+1}-S_{t}\right)}=\delta e^{-A S_{t}\left(R_{i j}-1\right)} \tag{90}
\end{equation*}
$$

where $A$ is the coefficient of absolute risk aversion, $S_{t}$ is the index value at time $t$, and $R_{i j}$ is the gross return from the transition from state $i$ to state $j$. Notice that the kernel depends on the level of the index as well as on the return, and the state transition will be a transition from one level to another and one volatility level to another.

Setting A $=1$, the results of applying the Recovery Theorem are displayed in Table III. The recovered kernel and the recovered natural distribution agree perfectly with their assumed values. In a second exercise we changed the marginal utilities at the extreme values, -5 and +5 sigma, and again we were able to perfectly recover the assumed distribution and kernel. [Insert Table III]

Implicitly in these exercises we are recovering an assumed constant marginal utility beyond the extreme values and we are recovering that value. In practice we will observe the state prices from market prices and we will recover the constant marginal utility that would be consistent with the prices beyond the extremes, e.g., the cumulative distribution of prices above +5 sigma and below -5 sigma.

## Example 3

The natural densities in the above examples are well known limits of binomial processes as the jumps grow more frequent and the jump sizes diminish (see Cox, Ross Rubinstein [1979]). For state dependent binomials we can apply the Multinomial Recovery Theorem, recover the jump probability, f, the subjective discount factor, $\delta$, and the pricing kernel or, more precisely, the projection of the kernel onto the space generated by the binomial. Suppose, though, that the process is state independent. One way to solve this is to alter the process by truncating it in the tails for very large and very small outcomes.

Making the appropriate assumption in the tails, it is possible to fully recover the kernel, f and $\delta$, by applying the Recovery Theorem. For simplicity, suppose that the process exactly recovers in k up steps and $\mathrm{n}-\mathrm{k}$ down steps,

$$
\begin{equation*}
a^{k} b^{n-k}=1 \tag{91}
\end{equation*}
$$

Order the possible states achievable in n or less steps, from $1, \ldots, \mathrm{~m}$, where a given state i is

$$
\begin{equation*}
a^{t} b^{v}, \quad 0 \leq t+v \leq n \tag{92}
\end{equation*}
$$

Letting $a(i)$ denote the number of up jumps in state $i$ and $b(i)$ denote the number of down jumps, for all but the bottom and top states, $(\mathrm{i}, \mathrm{j}) \neq(1,1)$ or $(\mathrm{m}, \mathrm{m})$, the state probability transition matrix is given by

$$
\begin{align*}
& f_{i j}=f \text { if }(a(j)=a(i)+1, b(j)=b(i))  \tag{93}\\
& 1-f \text { if }(a(j)=a(i), b(j)=b(i)+1)
\end{align*}
$$

and 0 otherwise
For the bottom state, we set

$$
\begin{equation*}
f_{11}=1-f \tag{94}
\end{equation*}
$$

and for the top state we set

$$
\begin{equation*}
f_{m m}=f \tag{95}
\end{equation*}
$$

In other words, we truncate the process at 1 and m and lump together the infinity of states below 1 into a lower mega state and those above $m$ into an upper mega state.

Since the process is recurrent in n steps the matrix F is irreducible and we can now fully recover F and, therefore, $\mathrm{f}, \delta$, and the pricing kernel, $\phi$. Given that we were
unable to recover the process from the state equations for the simplest recombining process, this is a quite surprising result. We were able to apply the Recovery Theorem to solve the system because we closed the model and put it into an irreducible form by lumping the bottom and top states into two mega states. This is equivalent to assuming that the market is indifferent between going from the really calamitous to the even more calamitous and between nirvana and more nirvana, i.e., fixing the marginal rates of substitution in the extreme mega states at unity.

Section V: Applying the Recovery Theorem
With the rich market for derivatives on the S\&P 500 index, the market is effectively complete along dimensions related to the index, both value and the states of the return process. The Recovery Theorem relies on knowledge of the martingale transition matrix and given the widespread interest in using this for pricing derivative securities it is not surprising that the literature on this problem is very extensive (see, e.g., Rubinstein [1994], Rubinstein and Jackwerth [1996] and Jackwerth [1999], Derman and Kani [1994] and [1998], Dupire [1994], Ait-Sahalia and Lo [1998], Figlewski [2008]). We draw on only the most basic findings of this work and make no effort to extend it.

Figure 1 displays the surface of implied volatilities on S\&P puts and calls, the 'vol surface', on March 20, 2011 drawn as a function of time to maturity, 'tenor', and the strike. Option prices are typically quoted in terms of implied volatilities from the BlackScholes, i.e., the volatilities that when put into the model give the market premium for the option, but doing so in no way is a statement of the validity of the Black-Scholes model, rather it is simply a transformation of the market determined premiums. The source of the data used in this paper is a bank over the counter bid/offer sheet. While the data is in broad agreement with exchange traded options, we chose this source since the volume on the over the counter market is approximately six times that on the exchange even for common at-the-money contracts.

The surface displays a number of familiar features. There is a 'smile' with out of the money and in the money options having the highest implied volatilities. The shape is actually a 'smirk' with more of a rise in implied volatility for out of the money puts (in the money calls). One explanation for this is that there is an excess demand for out of the money puts to protect long equity positions relative to the expectations the market has about future volatilities. Notice, too, that the surface has the most pronounced curvature for short dated options and that it rises and flattens out as the tenor increases. A story supporting this is the demand for long dated calls by insurance companies that have sold variable annuities. Whatever the merit of these explanations, these are persistent features of the vol surface at least since the crash in 1987.

Implied volatilities are a function of the risk neutral probabilities, the product of the natural probabilities and the pricing kernel - risk aversion and, as such, they embody all of the information needed to determine state prices. Since all contracts can be formed as portfolios of options (Ross [1976]) it is not surprising that from the vol surface we can derive the state price distribution, $p(S)$ :

$$
\begin{equation*}
C(K)=\int_{0}^{\infty}[S-K]^{+} p(S) d S=\int_{K}^{\infty}[S-K] p(S) d S \tag{96}
\end{equation*}
$$

and differentiating twice we obtain the Breeden Litzenberger [1978]) result that

$$
\begin{equation*}
p(S)=C^{\prime \prime}(K) \tag{97}
\end{equation*}
$$

Numerically approximating this second derivative as a second difference along the surface at each tenor yields the distribution of state prices looking forward from the current state. Setting the grid size of index movements at $0.5 \%$ the S\&P 500 call options on April 27, 2011 produced the marginal state price densities reported in Table IV. The results are broadly sensible with the exception of the relatively high implied interest rates at longer maturities which we will address below. [Insert Table IV]

To apply the Recovery Theorem we need not just the marginal state prices as of the future dates, but also the state price transition matrix. Unfortunately, there isn't a rich forward market for options and we don't directly observe the price transition function, P $=\left[p_{i j}\right]$. Instead we will derive it from the state price distributions at different tenors. For a discrete system with m states we have the mxm matrix:

$$
\begin{equation*}
P=[p(i, j)] \text { denotes pricing from state } i \text { to state } j \tag{98}
\end{equation*}
$$

At the current date we are in some state, $\theta$, and observe the current prices of options across strikes and tenors, and, as shown above, we can extract from the state prices at each future date T ,

$$
\begin{equation*}
p^{T}=<p(1, T), \ldots, p(m, T)> \tag{99}
\end{equation*}
$$

Letting the stock price and the past return index the states (this allows, for example, for states to depend on price paths) and denoting the current stock price as $S, p^{1}$ is column $S$ of $P$. To solve for the remaining elements of $P$ we apply the forward equation recursively to create the sequence of $\mathrm{m}-1$ equations:

$$
\begin{equation*}
p^{t+1}=p^{t} P, t=1, \ldots, m \tag{100}
\end{equation*}
$$

This is a system of $\mathrm{m}^{2}$ individual equations in the $\mathrm{m}^{2}$ variables $\mathrm{P}_{\mathrm{ij}}$ and since we know the current prices, $\mathrm{p}^{\mathrm{t}}$ it can be solved by recursion.

Since our intention is illustrative we ignore the potential state dependence on past returns and identify the states only by the price level. For relatively short periods this may not be much different than if we also used returns since the final price over, say a quarter, is a good surrogate for the price path. The grid is chosen to be from -5 to +5 standard deviations with a standard deviation of $9 \% /$ quarter. This seemed a reasonable compromise between fineness and coverage in the tails. The analysis above was then implemented numerically to derive the transition pricing matrix, P by varying the choice of P so as to minimize the sum of squared deviations between the resulting prices and the state price vectors of Table IV. The resulting forward transition price matrix, P , is shown in Table IV under the table of the marginal state price densities.

The final step is to apply the Recovery Theorem to the transition pricing matrix, P. Table V displays the recovered pricing kernel and the resulting natural probability (quarterly) transition matrix. The kernel declines monotonically as the stock value rises, but this need not be the case. Interestingly the nearly block diagonal form for the probability transition matrix mirrors the subordinated $\log$ normal with volatility dependent on past returns of Examples 2 and 3 of Section 4. [Insert Table V]

Figure 2 displays the pricing kernel, normed with the current marginal utility set at 1 , and compares it with a best fit constant relative risk aversion utility function chosen to minimize the sum of squared deviations. Notice that the fitted kernel function is higher in the region of low and high returns than the recovered kernel indicating that its impact on pricing will be exaggerated in these regions. There are no doubt better utility functions to use, but it does give some pause about the ubiquitous use of these functions in intertemporal financial portfolio analysis. Intriguingly, the best fit is close to a log utility function, i.e., the growth optimal criterion.

Table VI shows the recovered marginal distributions at the future dates and compares them with the historical distribution estimated by a bootstrap of S\&P 500 returns from 60 years of data (1960 - 2010). TableVI also displays the implied volatilities from the option prices on April 27, 2011. Not surprisingly, the densities display a slight upward drift as the horizon (tenor) increases. The summary statistics display some significant differences between the recovered and the historical distributions. For the recovered, which is a forward looking measure, the annual expected return at all horizons is approximately $5 \% /$ year as compared with $10 \% /$ year for the historical measure. The standard deviation, on the other hand, is comparable at about $15 \% /$ year; a not surprising result given the greater accuracy inherent in implied volatilities and the fact that with diffusions they coincide - albeit with bias - more closely with realized volatilities than do expected returns and realized returns. [Insert Table VI]

The state prices should sum to the riskless interest factor. The rates are relatively accurate out to about 1 but then rise from $1.85 \%$ at 1 year to $7.93 \%$ at 3 years. This is significantly higher than 3 year (swap) rates at the time and indicative of a bias in the computation of the state prices. With this high and incorrect rate the risk premium turns negative 2 years out, and, the Sharpe ratio also must turn negative as well. Some of this is explainable by the omission of dividends, but it is no doubt mostly a consequence of the error in our computation of state prices and the risk free rates and speaks to the need for a more refined estimation.

Notice that the at-the-money implied volatilities are significantly higher than those derived from the recovered distribution. This is a phenomena closely related to the observation that implied volatilities are generally significantly greater than realized volatility and it is not surprising that the volatilities from the recovered distribution have a similar relation to realized volatility.

Table VII displays and compares the recovered natural density and distributions with those obtained from the bootstrap, and Figure 3 plots these densities. Of particular interest is what they say about the long standing concern with tail events. Rietz [1988] argued that a large but unobserved probability of a catastrophe - 'tail risk' - could explain the equity risk premium puzzle, i.e., the apparent dominance of stocks over bonds and related questions. Barro [2006] lent support to this view by expanding the data set to include a wide collection of catastrophic market drops beyond what one would see with a single market and Weitzmann [2007] provided a deep theoretical argument in support of fat tails. Somewhat more pithily, Merton Miller observed after the 1987 crash that 10 standard deviation events seemed to be happening every few years. [Insert Table VII]

As we said in the introduction, tail risk is the economists' version of the cosmologists' dark matter. It is unseen and not directly observable but it exerts a force that can change over time and that can profoundly influence markets (or galaxies). By separating the risk-averse kernel from the subjective probabilities embedded in option prices, though, we get can shed some light on the dark matter and estimate the market's probability of a catastrophe. As Figure 3 show, the recovered density has a fatter left tail than the historical distribution. Table VII puts the probability of a six month drop in excess of $32 \%$ at .0008 or 4 in 5000 bootstraps. By contrast, the recovered density puts this probability at $1.2 \%$. Similarly, the historical probability of a drop in excess of $26 \%$ in a six month period is .002 ( 10 times in 5000 bootstraps) while the recovered market probability of .0223 is 10 times greater at over $2 \%$.

This is only a crude first pass at applying the Recovery Theorem, and it is intended to be indicative rather than conclusive. There is an enormous amount of work to be done beginning with a more careful job of estimating the state price density from option prices and, from there, estimating the state price transition matrix from the state price density at different horizons and strikes. There are also many improvements required to accurately recover the kernel and the natural measure implicit in the state prices.

## Section VI: Testing the Efficient Market Hypothesis

It has long been thought that tests of efficient market hypotheses are necessarily joint tests of both market efficiency and a particular asset pricing model. Using the Recovery Theorem we can separate these two assumptions and derive model free tests of the efficient market hypothesis. In Ross [2005] an approach to testing efficient market hypotheses was proposed that depended on finding an upper bound to the volatility of the pricing kernel.

Assume that $\mu$ is stochastic and depends on some unspecified or unobserved conditioning information set, I. From the Hansen - Jagannathan bound [1991] we have a lower bound on the volatility of the pricing kernel

$$
\begin{equation*}
\sigma(\varphi) \geq\left(e^{-r T}\right) \frac{\mu}{\sigma} \tag{101}
\end{equation*}
$$

where $\mu$ is the excess return and $\sigma$ is the standard deviation on any asset which implies that $\sigma(\phi)$ is bounded from below by the discounted maximum observed Sharpe ratio.

Equivalently, this is also an upper bound on the Sharpe ratio for any investment. From the recovered marginal density function reported in Table VI we can compute the variance of the kernel at, say, one year out. The computation is straightforward and the resulting variance is

$$
\begin{equation*}
\sigma^{2}(\varphi)=.1065 \tag{102}
\end{equation*}
$$

or an annual standard deviation of

$$
\begin{equation*}
\sigma(\varphi)=.3264 \tag{103}
\end{equation*}
$$

Ignoring the small interest factor, this is the upper limit for the Sharpe ratio for any strategy to be consistent with efficient markets and not be 'too good' a deal (see Cochrane [1999] and Bernado and Ledoit [1999] for a discussion of good deals and Ross [1976] for an early use of the bound for asset pricing).

Similarly, we can decompose excess returns on some asset or portfolio strategy as

$$
\begin{equation*}
x_{t}=\mu\left(I_{t}\right)+\epsilon_{t} \tag{104}
\end{equation*}
$$

where the mean depends on the particular information set, I , and where the residual term

$$
\begin{equation*}
\sigma^{2}\left(x_{t}\right)=\sigma^{2}\left(\mu\left(I_{t}\right)\right)+\sigma^{2}\left(\epsilon_{t}\right) \leq E\left[\mu^{2}\left(I_{t}\right)\right]+\sigma^{2}\left(\epsilon_{t}\right) \tag{105}
\end{equation*}
$$

Hence, we have an upper bound to the $\mathrm{R}^{2}$ of the regression in an efficient market

$$
\begin{equation*}
R^{2}=\frac{\sigma^{2}\left(\mu\left(I_{t}\right)\right)}{\sigma^{2}\left(x_{t}\right)} \leq \frac{E\left[\mu^{2}\left(I_{t}\right)\right]}{\sigma^{2}\left(x_{t}\right)} \leq e^{2 r T} \sigma^{2}(\varphi) \tag{106}
\end{equation*}
$$

i.e., the $\mathrm{R}^{2}$ is bounded above by the volatility of the pricing kernel. Of course, the kernel can have arbitrarily high volatility by simply adding orthogonal noise to it, so the proper maximum to be used is the volatility of the projection of the kernel on the stock market, and, hence, these are tests on strategies that are based on stock returns and the filtration they generate. A potential advantage of the tests such as these is that they depend on the second moments, much like the volatility tests of efficiency, and, as such might be more robust than standard t -statistic tests on coefficient.

Using our estimate of the variance of the pricing kernel we find that the maximum it can contribute to the $\mathrm{R}^{2}$ of an explanatory regression is about $10 \%$. In other words, $10 \%$ of the annual variability of an asset return is the maximum amount that can be attributed to movements in the pricing kernel and $90 \%$ should be idiosyncratic in an efficient market. Hence any test of an investment strategy that uses, say, publicly available data, and has the ability to predict future returns with an $\mathrm{R}^{2}>10 \%$ would be a violation of efficient markets independent of the asset pricing model being used. Of course, any such strategy must overcome transactions cost to be an implementable violation, and a strategy that could not overcome those costs would be purely of academic interest.

## Section VII: Summary and Conclusions

If we can observe or estimate the transition price matrix then the Recovery Theorems allow us to recover the pricing kernel, i.e., the marginal rates of substitution of the representative agent, and the (ex ante) natural distribution of asset returns implicit in market prices. Armed with the market's risk aversion - the pricing kernel - and the market's subjective assessment of the distribution of returns, there is a cornucopia of applications. Currently economists and investors are regularly asked to fill out surveys to determine some consensus estimate for the expected return on the stock market. Now we can directly assess this much as we use forward rates as forecasts of future spot rates. Institutional asset holders, such as pension funds, use historical estimates of the risk premium on the market as an input into asset allocation models. The market's current subjective forecast would probably be superior and certainly of interest. Risk control models such as VAR, typically use historical estimates to determine the risk of various books of business and this, too, would be enhanced by using the recovered distribution.

These results are also applicable across a variety of markets, e.g., currency, futures, and fixed income. For the stock market, they can be used to examine the host of market anomalies and, more specifically, market efficiency for which we have presented one of many possible tests based on the recovered distribution. The ability to better assess the market's perspective of the likelihood of a catastrophic drop will have both practical and theoretical implications. The kernel is important on its own since it measures the degree of risk aversion in the market. For example, just as the market portfolio is a benchmark for performance measurement and portfolio selection, the pricing kernel serves as a benchmark for preferences. Knowledge of both the kernel and the natural distribution will also shed light on the controversy of whether the market is too volatile to be consistent with rational pricing models (see, e.g., Leroy and Porter [1981], Shiller [1981]).

On the theoretical front we need to further explore the Multinomial Recovery Theorem and determine which recovery approach will prove most practical. We also need to extend the recovery theory to continuous time and states and to specialize it to particular processes such as state dependent diffusions where recovery will be about the parameters governing the return processes. Typically, the estimated process for stock returns and for volatility may involve many latent variables for which no market prices exist and this suggests that it would be valuable to combine recovery results with time series estimation. We also need to examine the boundaries of recovery, and particularly the robustness of the underlying assumptions on the existence of the state independent kernel.

In conclusion, contrary to finance folklore, it is possible to separate risk aversion from the natural distribution and estimate each of them from market prices. With a pun intended, we have only scratched the surface of discovering the forecasts imbedded in market prices both for the market itself and, more generally, for the economy as a whole.

## Appendix

## Epstein-Zin Recursive Preferences

The recursive utility function is:

$$
\begin{equation*}
U_{t}=\left[(1-\delta) c_{t}^{\frac{1-R}{\rho}}+\delta E_{t}\left[U_{t+1}^{1-R}\right]^{\frac{1}{\rho}}\right]^{\frac{\rho}{1-R}} \tag{1}
\end{equation*}
$$

where R is the relative risk aversion, and $\rho$ is the inverse of the intertemporal elasticity of substitution. The kernel is the intertemporal marginal rate of substitution, and is a function of consumption growth and the return on the market from $t$ to $t+1$,

$$
\begin{equation*}
\varphi_{t, t+1}=\delta\left[\frac{c_{t+1}}{c_{t}}\right]^{-\rho \frac{R-1}{\rho-1}}\left[\frac{S_{t+1}}{S_{t}}\right]^{\frac{\rho-R}{1-R}} \tag{2}
\end{equation*}
$$

State prices are given by

$$
\begin{equation*}
p_{x y}(H)=\varphi(k H, k y H) \delta f_{x y} \tag{3}
\end{equation*}
$$

Hence, for the state dependent binomial

$$
\begin{equation*}
S(a, H)=p_{a a}(H)[S(a, a H)+k a H]+p_{a b}(H)[S(b, b H)+k b H] \tag{4}
\end{equation*}
$$

and

$$
\begin{equation*}
S(b, H)=p_{b a}(H)[S(a, a H)+k a H]+p_{b b}(H)[S(b, b H)+k b H] \tag{5}
\end{equation*}
$$

As with the constant relative risk aversion utility function, this system is linear with the linear solution

$$
\begin{equation*}
S=\gamma_{x} H \tag{6}
\end{equation*}
$$

and for the state dependent binomial, without making use of recombination, the state price equations for this system are given by:

$$
\begin{gather*}
p_{a a}(H)=\delta f_{a} a^{-\rho\left[\frac{R-1}{\rho-1}\right]} a^{\frac{\rho-R}{1-\rho}}=\delta f_{a} a^{-R}  \tag{7}\\
p_{a b}(H)=\delta\left(1-f_{a}\right) b^{-\rho\left[\frac{R-1}{\rho-1}\right]\left[\frac{\gamma_{b}}{\gamma_{a}}\right]^{\frac{\rho-R}{1-\rho}} b^{\frac{\rho-R}{1-\rho}}=\delta\left(1-f_{a}\right)\left[\frac{\gamma_{b}}{\gamma_{a}}\right]^{\frac{\rho-R}{1-\rho}} b^{-R}} . \tag{8}
\end{gather*}
$$

$$
\begin{equation*}
p_{b a}(H)=\delta\left(1-f_{b}\right) a^{-\rho\left[\frac{R-1}{\rho-1}\right]}\left[\frac{\gamma_{a}}{\gamma_{b}}\right]^{\frac{\rho-R}{1-\rho}} a^{\frac{\rho-R}{1-\rho}}=\delta\left(1-f_{b}\right)\left[\frac{\gamma_{a}}{\gamma_{b}}\right]^{\frac{\rho-R}{1-\rho}} a^{-R} \tag{9}
\end{equation*}
$$

and

$$
\begin{equation*}
p_{b b}(H)=\delta f_{b} b^{-\rho\left[\frac{R-1}{\rho-1}\right]} a^{\frac{\rho-R}{1-\rho}}=\delta f_{b} b^{-R} \tag{10}
\end{equation*}
$$

These are four independent equations in the five unknowns, $\delta, R, \rho$, and $f_{a}, f_{b}$, and recombining will give us an independent fifth equation to close the system and permit all of the parameters to be recovered:
