# THE RELATION BETWEEN THE NUMBER OF SPECIES AND THE NUMBER OF INDIVIDUALS IN A RANDOM SAMPLE OF AN ANIMAL POPULATION 

By R. A. FISHER (Galton Laboratory), A. STEVEN CORBET (British Museum, Natural History) and C. B. WILLIAMS (Rothamsted Experimental Station)

(With 8 Figures in the Text)<br>CONTENTS

Part r. Results obtained with Malayan butterflies. By A. S. Corbet
Part 2. Results obtained by means of a light-trap at Rothamsted. By C. B. Williams . . . 44
Part 3. A theoretical distribution for the apparent abundance of different species. By R. A. FISHER . 54
PART 1. RESULTS OBTAINED WITH MALAYAN BUTTERFLIES
By A. Steven Corbet (British Museum, Natural History)

It is well known that the distribution of a series of biological meásurements usually conforms to one of three types:
(a) the binomial distribution, where the frequencies are represented by the successive terms of the binomial $(q+p)^{n}$;
(b) the normal distribution, in which the results are distributed symmetrically about the mean or average value, and which is the special case of (a) when $p$ and $q$ are equal;
(c) the Poisson series, in which the frequencies are expressed by the series

$$
e^{-m}\left(1+m+\frac{m^{2}}{2!}+\frac{m^{3}}{3!}+\ldots\right)
$$

where $m$ is the mean and $e$ is the exponential base 2.7183 .

The usual practice of calculating the arithmetic mean in a set of measurements of a biological nature, such as wing length of a butterfly, assumes a distribution showing no wide departure from normality, although it does not appear that this procedure has been vindicated.

It is the usual experience of collectors of species in a biological group, such as the Rhopalocera, that the species are not equally abundant, even under conditions of considerable uniformity, a majority being comparatively rare while only a few are common. As far as we are aware, no suggestion has been made previously that any mathematical relation exists between the number of individuals and the number of species in a random sample of insects or other animals. Recently, it has been found (Corbet, 1942) that, leaving out of account the commoner species of which no attempt was made to collect all individuals seen, the number of species $S$ of butterflies of which $n$ individual specimens were collected by a single collector in Malaya was given closely by the expression

$$
S=C / n^{m},
$$

where $C$ and $m$ are constants.* When $m$ is unity, as is the case with the Malayan collection, and has since been found to be a condition which obtains with collections of butterfies from Tioman Island and the Mentawi Islands in which the relation between $S$ and $n$ follows the above equation, the number of species of which $1,2,3,4, \ldots$ specimens were obtained was very close to a series in harmonic progression. Thus, the series can be written

$$
C\left(1+\frac{1}{2}+\frac{1}{3}+\ldots\right)
$$

Although this relation holds accurately with the rarer species, there is less agreement in the region of the common species; in fact, theoretical considerations preclude an exact relationship here.

Prof. Fisher (see Part 3) has evolved a logarithmic series which expresses accurately the relation between species and individuals in a random sample throughout the whole range of abundance:

$$
S=n_{1}\left(\mathrm{I}+\frac{x}{2}+\frac{x^{2}}{3}+\ldots\right),
$$

where $S$ is the total number of species in the sample, $n_{1}$ the number of species represented by single specimens, and $x$ is a constant slightly less than unity but approaching this value as the size of the sample is increased.

The total number of individual specimens, $N$, in the sample at all levels of abundance is given by $N=n_{1} /(\mathrm{I}-x)$ and $N(\mathrm{I}-x) / x$ is a constant $\alpha$ independent of the size of the sample. As the size of the sample is increased, $n_{1}$ approaches $\alpha$.

The Fisher series has been established for all the entomological collections tested in which there was

* This equation may be written

$$
\log S=\log C+m \log n
$$

so that the plot of the logarithms of $S$ and $n$ is a straight line.
reason to believe that the collecting had been unselective (see Table I). It is clear that when $S$ and $N$ are known, as is usually the case, the statistics $n_{1}, x$ and $\alpha$ can be calculated. It is a curious fact that the number of uniques should approach a constant value with increasing size of collection. It is important to ascertain how far this type of distribution of individuals among species holds in other zoological groups, for it would appear that we have here an effective means of testing whether a collection has been made under conditions approaching random sampling or whether some degree of selection has been exercised, a consideration which is often of some importance in faunistic studies.
tinued after 24 specimens had been taken. In such cases, we have the following information:

The total number of species under 25 individuals per species:

$$
S_{(1-24)}=n_{1}\left(1+\frac{x}{2}+\frac{x^{2}}{3}+\ldots+\frac{x^{23}}{24}\right)
$$

The total number of individuals at frequencies below 25 per species:

$$
N_{(1-24)}=n_{1}\left(\mathrm{I}+x+x^{2}+\ldots+x^{23}\right)
$$

Table 2, which gives the results obtained with the Malayan butterflies, is based on these considerations, and shows the very close relation between the observed and the calculated results.

Table 1. Entomological collections examined showing the relation between the numbers of species and individuals

|  | Observations |  |  |  | Calculations |  |  |  |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |
|  |  |  |  | No |  |  |  |  |
|  | indi- <br> viduals | between 1 and 24 | Total species | between 1 and 24 | $x$ | $\begin{gathered} n_{1} \\ \text { calc. } \end{gathered}$ | found | $\alpha$ |
| Malayan Rhopalocera | - | 3306 | 620 | 50 r | 0.997 | 135.05 | 118 | 135.47 |
| Rhopalocera from Tioman Island (east coast of Malaya) (Malay collector, 1931) | ${ }^{1} 57$ | -- | 41 | - | 0.887 | 15.96 | 19 | 18.00 |
| Rhopalocera from Mentawi Islands (excluding Hesperiidae) (C. Boden Kloss and N. Smedley, 1924) | 1,878 | 890 | 135 | 110 | 0.983 | 3277 | 37 | 33.35 |
| Karakorum Rhopalocera (Mme J. <br> Visser-Hooft; vide Evans, 1927) | 403 | $\begin{array}{r} 195 \\ (\mathrm{I}-28) \end{array}$ | 27 | $\begin{gathered} 24 \\ (\mathrm{I}-28) \end{gathered}$ | 0.984 | 6.42 | 6 | $6 \cdot 52$ |
| Mexican Elmidae (Col.) (H. E. Hinton; vide Hinton, 1940) | 11,798 |  | 35 | - | 0.9998 | 4.72 | 4 | $4^{\prime 72}$ |

How far the results obtained with any particular collection can be regarded as representative of the distribution of the same species group in the area in which the collection was made must obviously depend on the uniformity or otherwise of the conditions prevailing when the collection was made and to the extent to which these conditions are representative of the habitat. In an equatorial forest-clad island with no mountain heights above 2000 ft ., conditions are very uniform as far as such orders as Leipidoptera are concerned; although even here some allowance must be made for the fact that collections of butterflies made in such regions are usually poor in the crepuscular species. In temperate climates, it is evident that results obtained during one period of the year are usually inapplicable to other seasons or to the year as a whole. It would appear that the results obtained with the moth trap at Harpenden (see Part 2) can be regarded as giving an accurate picture of the distribution frequencies of the phototropic moths in the area, and it is probable that the same is true of the collection of Mexican Elmidae.

With many collectors, and for a variety of reasons, the collecting of common species is discontinued once a certain number of specimens of these are obtained. In the case of the Malayan Rhopalocera cited, collecting of all individuals seen was not con-

Table 2. Calculated and observed distribution frequencies of butterfies collected in Malaya
The values in the second column are obtained from the Fisher series given on p. 42, taking $x=0 \cdot 997$.

| $n$ | $S$ (calc.) | $S$ (found) | Deviations |
| :---: | :---: | :---: | :---: |

For the above series in Table 2, $\chi^{2}=19.270$, degrees of freedom $=23$, and $P$ is between 0.90 and 0.80 , showing the deviations of the observed results from the calculated values are not significant.

## PART 2. RESULTS OBTAINED BY MEANS OF A LIGHT-TRAP AT ROTHAMSTED

By C. B. Williams

This gives an account of the application of Fisher's series (see Part 3 of this paper) for the frequency of occurrence of species of different levels of abundance in a random sample, to collections of nocturnal Lepidoptera made by means of a light-trap at Rothamsted Experimental Station, Harpenden, Herts, England, during the four years 1933-6. The trap and insects caught in it have already been discussed in a series of papers (Williams, 1939, 1940).

It was necessary to choose, from the material collected, groups in which all or nearly all of the specimens had been identified to species. For this certain families of Lepidoptera were most suited, and the discussion below deals with the captures in the Sphingidae, Noctuidae, Arctiidae, Geometridae and a few other related families. In the Geometridae the genus Eupithecia was omitted owing to difficulties of identification. Altogether 15,609 individuals belonging to 240 species were captured. The names and details of numbers for each species will be found in Williams (1939, Tables 6-8).

## The frequency of species of different abundance

Table 3 shows the frequency distribution of the species for the four years added together. It will be seen that 35 species were represented by a single individual each; that 85 (including the 35 above) were represented by 5 or fewer individuals; 115 by 10 or fewer; and 205 species by 100 or fewer individuals; leaving therefore 35 species with over 100 individuals per species. The highest total of one species was 2349 individuals of Agrotis exclamationis. The results up to 50 individuals per species are represented diagrammatically by the vertical lines in Fig. 1A, giving a curve closely resembling a hyperbola.

If, however, the log number of species is plotted against the $\log$ number of individuals as in Fig. 2A it will be seen that, while the straight-line distribution expected for a hyperbala holds approximately true for the rarer species, the number of commoner species is distinctly below the hyperbolic expectation
in the Western Karakorum, N.W. India.' Tijds. Ent. 70: 158-62.

Hinton, H. E. (1940). 'A monographic revision of the Mexican water beetles of the family Elmidae.' Nov. Zool. 42: 217-396.
and falls rapidly away from it at higher numbers of individuals per species.

Fisher suggests (see Part 3) that the true series is represented not by

$$
n_{1}, \frac{n_{1}}{2}, \frac{n_{1}}{3}, \frac{n_{1}}{4}, \ldots
$$

which would be the hyperbolic series and which would require an infinite number of species and an infinite number of individuals; but by the series

$$
n_{1} \ldots \frac{n_{1} x}{2} \ldots \frac{n_{1} x^{2}}{3} \ldots \frac{n_{1} x^{8}}{4} \ldots,
$$

when $n_{1}$ is the number of species with $I$ individual and $x$ is a number less than r .

If this is correct he shows that ( 1 ) the total number of individuals $(N)$ is finite and $=\frac{n_{1}}{1-x}$, (2) the total number of species $(S)$ is finite and

$$
=n_{1} \frac{-\log _{a}(1-x)}{x}
$$

## Table 3 (continued)

Values above 50
(1) Total of 4 years: 5 I (4) $52,53,54$ (2) $57,58(2), 60(3), 61,64,67,73,76(2), 78,84,89,96,99,109,112,120$, 122, 129, 135, 141, 148, 149, 151, 154, 177, 181, 187, 190, 199, 211, 221, 226, 235, 239, 244, 246, 282, 305, $306,333,464,560,572,589,604,743,823,2349=15,609$ individuals of 240 species.
(2) Average of 1 year: $5 \mathrm{I}(0.75), 52(0.50), 53(0.50), 54(0.25), 58(0.50), 60(0.50), 61(0.25), 64(0.50), 65(0.25)$, $69(0.25), 73(0.75), 75(0.50), 76(0.25), 77(0.25), 80(0.25), 82(0.25), 83(0.25), 87(0.25), 88(0.50), 90(0.25)$, $93(0.25), 99(0.50), 100(0.50), 104(0.25), 105(0.50)$, and the following all $(0.25)$ each: 107, 109, 110, 111, $115,126,132,138,139,141,144,145,153,159,165,173,179,197,200,201,219,223,232,275,294,323$, $329,603,1799=3902$ individuals of 176 species.
(3) Average of $\frac{1}{8}$ year: $79(0 \cdot 13), 109\left(0 \cdot r_{3}\right)=440$ individuals of 89.875 species.
(4) Capsidae $=53,80,85,158,206,237,298=1414$ individuals of 57 species.

Log of number of individuals per species
Fig. 2

Thus if $N$ and $S$ are known both $n_{1}$ and $x$ can be calculated, and hence the whole series is known.

If $N$ is large $n_{1}$ tends to become a constant value $\alpha$, and Fisher shows that for all levels of sampling for the same population $x=\frac{N}{N+\alpha}$.

Applying these formulae to our Macrolepidoptera with 15,609 individuals of 240 species we find

$$
\alpha=40.24, n_{1}=40.14, x=0.997429 .
$$

The calculated values for $n_{2}, n_{3}$, etc., are shown in Table 3 opposite the observed figures and also by curves in Figs. 1 A and 2.A. In the latter the log of the frequency is plotted against the log of the number of individuals per species.

It will be seen that for both common and rare species the calculated values are very close indeed to the observed. The calculated number of species with one individual is slightly larger ( 40.14 ) than the observed (35). By calculation there should be $116 \cdot 9$
species with 10 or fewer individuals and the observed number was 115 . The close resemblance at higher frequencies is best seen in Fig. 2A.

If, instead of adding the four years together, we take the average number of individuals in each year and the average number of species with $1,2,3$, etc., individuals we find the observed results in the trap to be as in the second column of Table 3. There are 3902 individuals of 176 species. Calculations from these figures show that $x=0.990356$ and $n_{1}=37.55$. The calculated series is shown up to 50 individuals per species in Table 3 and diagrammatically in Fig. 2B. The calculated $n_{1}$ is slightly smaller than the observed.

Fig. 3
A still smaller sample was obtained by dividing the catches in the year 1933 into 8 samples, the first including those insects caught in the ist...9th...17th day, the second on the 2nd...1oth...18th day, etc. The average for the 8 samples is shown in the third column of Table 3, together with the calculated figures. The number of individuals was 440, the number of species 89.9 , from which $n_{1}=31^{\prime} 77$ and $x=0.9278$. The calculated $n_{1}$ is slightly smaller than the observed. Results are shown diagrammatically in Figs. IB and 2C. The close resemblance in both the two series of the observed and calculated results is very striking.

Thus in the Macrolepidoptera caught in the lighttrap at Harpenden samples as large as 15,609 individuals and as small as 440 individuals both agree very closely with the results calculated from Fisher's series.

The only other group of insects captured in the light-trap in which the majority of the specimens were identified was the family Capsidae of the Heteroptera. These were identified by D. C. Thomas (1938). In the four years 1414 individuals of 57 species were captured. The observed and calculated results are shown in the fourth column of Table 3 and in Fig. 3. The calculated $n_{1}$ is 11.87 and $x=0.9916$.

It will be seen that the fit is not so good as in the Lepidoptera. The observed number of species represented by only one individual is 18 and the calculated less than 12. In general there are rather more of the rarer species than the calculated series indicates, and fewer of the commoner species.

Table 4 shows a summary of all the various samples taken from the Lepidoptera and the Capsidae. It will be seen that there is a slight general tendency for the calculated value of $n_{1}$ to be below the observed. In the Macrolepidoptera for one or more years this is not so obvious, but it is distinct in the one-eighth year samples. In the Noctuidae only there are four results below and two practically equal to the observed figure; but in the Capsidae there are five below and only one equal. This requires further investigation.

Fig. 4
The relation between the number of species and total number of individuals in the sample
In Tables 4 and 5 are shown a number of samples of different size taken from the light-trap captures with the number of individuals in the sample and the number of species represented.
Fig. 4 shows diagrammatically the number of species in relation to the number of individuals for all the different samples of Lepidoptera. It will be seen that there is a very regular relation between the observed numbers. This form of diagram is, however, not very suitable for showing large samples,

and in Fig. 5 (heavy line) the same data are shown with the number of individuals in the sample expressed as a logarithm.

According to Fisher's theory, any population should have a constant value of $\alpha$ for samples of any size taken from it under identical conditions. Thus it follows that for any population, if the value of $\alpha$ is obtained from one sample, the values of

$$
x\left(=\frac{N}{N+\alpha}\right)
$$

and hence of $S$ can be calculated for other samples of different sizes from the same population. In

Log of number of individuals in sample
Fig. 5
Fig. 5 there are shown as dotted lines typical calculated relations between the number of individuals and number of species for different values of $\alpha$. It will immediately be seen that the observed values for the Lepidoptera fit very closely to the calculated relation for $\alpha=40$. The slight difference between the observed and calculated figures will be discussed below.

It will also be seen that the observed values for the Noctuidae alone fit very closely to a value of $\alpha=17.5$, but that the observed values for the Capsidae cut rather rapidly across the $\alpha$ lines giving too few species in small samples and too many in large samples (when they are taken, as in the light-trap, in more than one year). The various calculated values of $\alpha$ in the different samples together with their standard deviation as calculated from Fisher's formula are given in Table 4. It is suggested that the para-
meter $\alpha$ should be known as the 'index of diversity' of the population.

The differences between the observed and calculated values for Lepidoptera and for Capsidae are shown diagrammatically on a larger scale in Fig. 6. In the Lepidoptera (Fig. 6A) it will be seen that more species are obtained in a sample spread over several years than would be expected in a sample of the same size taken in a single year. Thus when a sample of $15,609(\log .4 \cdot 19)$ Lepidoptera was captured in four years 240 species were represented. If the same number had been caught in one year it will

Fig. 6
be seen (by finding where the $\alpha=37.91$ line cuts $\log 4 \cdot 19$ ) that only about 226 species would have been expected. Otherwise about 14 extra species have been captured owing to the new biological conditions introduced by sampling over a longer period. The same effect on an even larger scale is obvious between samples captured throughout a whole year and those captured in one-eighth of the year. Thus the departure of the observed from the calculated results is immediately explicable by the alteration of conditions introduced by spreading sampling over a longer period of time.
The Capsidae (Fig. 6B) show the same effect in a more extreme form. With 1414 individuals caught in four years 57 species were obtained, whereas if the same-sized sample had been taken in one year we would only have expected about 36 species. There is thus a considerable increase of species by spreading
the cat h over a longer period. This is indicated also by a fact that I have already pointed out (Williams, 1939, p. 96) that in the Capsidae $50 \%$ of the 57 species occurred only in a single year, as compared with a figure of only $19 \%$ in the Macrolepidoptera. The Capsidae fauna therefore is much more variable from year to year than is the Lepidoptera.

Since with high number of $N$ the relation between the number of species and log number of individuals becomes practically a straight line (both theoretically and observationally) it is possible to extrapolate the observed curve for the Macrolepidoptera with some interesting and suggestive results. In the first place it should be noted that the number of British species in the families of Macrolepidoptera dealt with is 68 r , and the number of species already recorded for Hertfordshire (where the trap vas situated) was 46 I.

Thus in four years we have captured approximately 16,000 individuals representing 240 species. After ten years we would have captured approximately 40,000 individuals which would contain about 275 species. After 50 years the $\mathbf{2 0 0 , 0 0 0}$ individuals would

## The seasonal changes of $\alpha$ in the Macrolepidoptera

If the Macrolepidoptera captured in the light-trap during the four years are tabulated month by month the numbers of individuals and species in each month (excluding the five winter months when numbers are too small) are shown in Table 6 together with the approximate value of $\alpha$. The changes in $\alpha$ are shown in Fig. 7.

There is a regular seasonal change which is almost identical in each year; the value of $\alpha$ rises from a low value in April to a maximum in July and back to a low value in October. There is a very much greater difference between the $\alpha$ values for two different months than there is for the same month in two different years. For example, the number of insects caught in July 1935 was almost seven times as great as the number in July 1936, and yet the values of $\alpha$ are almost identical; but rather more insects in August 1936 than in July gives a considerably smaller value, and an almost identical number of insects in

Table 6. Number of individuals and of species of Macrolepidoptera in each of the summer months of the four light-trap years, with the approximate values of $\alpha$

| Oct. | 220 | 14 | 3.0 | 152 | 14 | $3 \cdot 5$ | 171 | 18 | $5 \cdot 0$ | 59 | 14 | 5.0 |

include 340 species. After 100 years the 400,000 would include 365 species or only 25 new species in 50 years.

To get the Hertfordshire fauna (46r species) we would have to collect over three million insects, and this would take, at the present rate, nearly 1000 years. When this level was reached only one new species would be added in 20 years' trapping. To get the British fauna ( 681 species) we would have to trap about 1800 million insects which would take nearly half a million years!

Doubling the number of insects caught (and hence the time of trapping) at any level, except for very small samples, always adds about 30 species to the total.

These figures are based on the curve allowing for captures of 4000 insects per year. If the whole number were caught in one year (assuming that to be possible) the number of species would be less in each case. So that 400,000 individuals would give 350 species (instead of 368 ), the Hertfordshire fauna would require 8 million insects, and the British fauna 3200 million.

Fig. 7
September 1936 gives a value of $\alpha$ only about onethird as great.

There is no doubt whatever that there is a seasonal
change in $\alpha$ or in the 'richness of species' quite independent of the seasonal change in numbers of insects.

## Value of $\alpha$ for a single night in a month

In the month of July 1935, which was a month of high catches of Lepidoptera in the light-trap, 2,586 Noctuidae were captured, belonging to 56 species. This gives $\alpha$ (for Noctuidae only) $=10.09$.

The following were the captures on seven selected nights in the month:

| Date | $N$ | $\log N$ | $S$ |
| :---: | :---: | :---: | :---: |
| 1 | 429 | 2.63 | 18 |
| 6 | 143 | 2.16 | 10 |
| 11 | 394 | 2.60 | 18 |
| 16 | 11 | 1.04 | 7 |
| 21 | 47 | 1.67 | 17 |
| 26 | 64 | 1.80 | 11 |
| 31 | 53 | 1.72 | 10 |
|  | Mean | 1.95 | 13 |

From these figures $\alpha=4.2$. Thus it is considerably smaller for a short period of sampling than for a longer period. This would be expected, as the variety of species available for catching on a single night must be less than that on a series of different nights.

## Comparison of results from two light-traps a short distance apart

During the autumn of 1933 two light-traps were kept running simultaneously from 8 August to 3 I October. One was in the fields at Rothamsted (the standard trap used in all the previous calculations) and the other was about 400 yards away on the roof on the Entomology building at a height of about 35 ft . from the ground. This overlooked a more varied environment with gardens and mixed vegetation.

The captures of Noctuidae in the two traps were as follows:

|  | Field trap |  | Roof trap |  |
| :---: | :---: | :---: | :---: | :---: |
| 1933 | N | $S$ | $N$ | $S$ |
| 8-31 Aug. | 419 | 26 | 706 | 36 |
| Sept. | 355 | 18 | 593 | 32 |
| Oct. | 155 | 9 | 557 | 19 |
|  | 929 | 40 | 1856 | 58 |
|  | $\alpha=8$ | $\pm 0 \cdot 7$ | II 3 |  |

The difference between the two values of $\alpha$ is 2.8 and the standard error of the difference approximately $1 \cdot 0$, so that difference is probably significant. The roof trap has caught a larger number of individuals but a still larger number of species. This is probably due, as mentioned above, to the considerably more varied vegetation that it overlooked.

## The effect on number of species of increasing the size of a sample

Fisher has shown that

$$
S=\alpha \log _{e}\left(\mathrm{I}+\frac{N}{\alpha}\right) .
$$

If the sample is large so that $N$ is large compared with $\alpha$ we can neglect the I in comparison with $N / \alpha$. Hence for large samples

$$
S=\alpha \log _{\theta} \frac{N}{\alpha}
$$

hence

$$
S_{2 N}-S_{N}=\alpha\left(\log _{e} \frac{2 N}{\alpha}-\log _{e} \frac{N}{\alpha}\right)=x \log _{e} 2
$$

So the number of species added to a large sample by doubling it is $\alpha \log _{\theta} 2 x=0.693 \alpha$. Similarly, if the sample were increased 10 times the number of new species added $=\alpha \log _{\theta} 10=2 \cdot 3^{\alpha}$ approximately. On the other hand, if the size of the sample is multiplied by $e(=2.7183)$ the additional number of species is $\alpha \log _{s} e$, which is equal to $\alpha$.

For example, with the Macrolepidoptera in the light-trap $\alpha=$ approximately 40 , so doubling a large catch will at any level add approximately 28 new species, multiplying it by 10 will add approximately 92 species.

To add one new species to a large sample $\alpha \log _{0} z$ must equal r , when $z$ is the factor by which the sample must be multiplied, i.e.

$$
\log _{\varepsilon} z=1 / \alpha
$$

for example, if $\alpha=40$ as in the Macrolepidoptera above

$$
\log _{e} z=0.025, \quad z=\mathrm{I} .0255 ;
$$

hence the number of insects must be increased by just over $1 / 39$ of the original sample to add one additional species.

## Diagram showing the interrelation of $N, S, \propto$ and the standard error of $\alpha$

From the formulae provided by Prof. Fisher $\alpha$ and the error of $\alpha$ can be calculated if $N$ and $S$ are known, and similarly $S$ can be calculated if $N$ and $\alpha$ are known. These calculations can be made to any number of decimal places. For many purposes, however, a close approximation to $\alpha$ and its error is all that is necessary, and if this can be obtained rapidly without calculation so much the better.

For this purpose Fig. 8 has been drawn up. In this the vertical axis is the number of species and the horizontal the log of the number of individuals in the sample. A large number of values of $\alpha$ have been inserted as diagonals, with the result that if any two of these three factors is known the third can be easily estimated. Thus with a sample of 1000 individuals ( $\log =3.0$ ) containing 60 species $\alpha=14$. Or with $\alpha=25$ a sample of 10,000 individuals should

contain about 149 species. Or in a population with $\alpha=40,180$ species would be produced by a sample of 1000 individuals.

Further, by following along one of the $\alpha$ curves it is possible to find the number of species in samples of different sizes from the same population. Thus if a sample of 1000 individuals for a population produced 73 species, then a sample of 10,000 from the same population should produce about 112 species, but a sample of ioo individuals would only contain about 34 species $(\alpha=18)$. In addition, on the diagram the standard error (as a percentage of the value of $\alpha$ ) has been indicated by dotted contours. Thus a sample containing 100 individuals and 24 species gives $\alpha=10 \pm$ about $17 \%$, say $10 \pm 17$; a sample of rooo individuals and 46 species gives $\alpha=10 \pm 0.75$ (i.e. $7.5 \%$ ); while a sample of 10,000 individuals containing 69 species gives $\alpha=10 \pm 0.45(4.5 \%)$.

Thus the size of sample necessary to give $\alpha$ to any required degree of accuracy can rapidly be obtained from the figure.

Table 7 shows values of $S$ correct to two decimal places for various combinations of $\alpha$ and $N$, and Table 8 shows the standard error of $\alpha$ to three significant figures for various values of $N$ and $\alpha$.

Table 8. Standard error of $\propto$ for different values of $N$ and $\alpha$

# PART 3. A THEORETICAL DISTRIBUTION FOR THE APPARENT ABUNDANCE OF DIFFERENT SPECIES 

By R. A. Fisher

## (1) The Poisson Series and the Negative Binomial distribution

In biological sampling it has for some time been recognized that if successive, independent, equal samples be taken from homogeneous material, the number of individuals observed in different samples will vary in a definite manner. The distribution of the number observed depends only on one parameter, and may be conveniently expressed in terms of the number expected, $m$, in what is known as the Poisson Series, given by the formula

$$
\begin{equation*}
e^{-m} \frac{m^{n}}{n!} \tag{I}
\end{equation*}
$$

Here $n$ is the variate representing the number observed in any sample, $m$ is the parameter, the number expected, which is the average value of $n$, and need not be a whole number. Obviously, $m$ will be proportional to the size of the sample taken, and to the density of organisms in the material sampled. For example, $n$ might stand for the number of bacterial colonies counted on a plate of culture medium, $m$ for the average number in the volume of dilution added to each plate. The formula then gives the probability of obtaining $n$ as the number observed.

The same frequency distribution would be obtained for the numbers of different organisms observed in one sample, if all were equally frequent in the material sampled.

If the material sampled were heterogeneous, or if unequal samples were taken, we should have a mixture of distributions corresponding to different values of $m$. The same is true of the numbers of different organisms observed in a single sample, if the different species are not equally abundant.

An important extension of the Poisson series is provided by the supposition that the values of $m$ are distributed in a known and simple manner. Since $m$ must be positive, the simplest supposition as to its distribution is that it has the Eulerian form (well known from the distribution of $\chi^{2}$ ) such that the element of frequency or probability with which it falls in any infinitesimal range $d m$ is

$$
\begin{equation*}
d f=\frac{1}{(k-1)!} p^{-k} m^{k-1} e^{-m / p} d m . \tag{2}
\end{equation*}
$$

If we multiply this expression by the probability, set out above, of observing just $n$ organisms, and integrate with respect to $m$ over its whole range from o to $\infty$, we have

$$
\int_{0}^{\infty} \frac{1}{(k-1)!} p^{-k} m^{k-1} e^{-m ; p} e^{-m} \frac{m^{n}}{n!} d m,
$$

which, on simplification, is found to have the value

$$
\begin{equation*}
\frac{(k+n-1)!}{(k-1)!n!} \frac{p^{n}}{(I+p)^{k+n}}, \tag{3}
\end{equation*}
$$

which is the probability of observing the number $n$ when sampling from such a heterogeneous population. Since this distribution is related to the negative binomial expansion

$$
\left(1-\frac{p}{1+p}\right)^{-k}=\cdot \sum_{n=0}^{\infty} \frac{(k+n-1)!}{(k-1) \mid n!}\left(\frac{p}{1+p}\right)^{n},
$$

it has become known as the Negative Binomial distribution. It is a natural extension of the Poisson series, applicable to a somewhat wider class of cases.

The parameter $p$ of the negative binomial distribution is proportional to the size of the sample. The expectation, or mean value of $n$, is $p k$. The second parameter $k$ measures in an inverse sense the variability of the different expectations of the component Poisson series. If $k$ is very large these expectations are nearly equal, and the distribution tends to the Poisson form. If heterogeneity is very great $k$ becomes small and approaches its limiting value, zero. This second parameter, $k$, is thus an intrinsic property of the population sampled.

## (2) The limiting form of the negative binomial, excluding zero observations

In many of its applications the number $n$ observed in any sample may have all integral values including zero. In its application, however, to the number of representatives of different species obtained in a collection, only frequencies of numbers greater than zero will be observable, since by itself the collection gives no indication of the number of species which are not found in it. Now, the abundance in nature of different species of the same group generally varies very greatly, so that, as I first found in studying Corbet's series of Malayan butterflies, the negative binomial, which often fits such data well, has a value of $k$ so small as to be almost indeterminate in magnitude, or, in other words, indistinguishable from zero. That it is not really zero for collections of wild species follows from the fact that the total number of species, and therefore the total number not included in the collection, is really finite. The real situation, however, in which a large number of species are so rare that their chance of inclusion is small, is well represented by the limiting form taken by the negative binomial distribution, when $k$ tends to zero.
The limiting value $k=0$ cannot occur in cases where the frequency at zero is observable, for the
distribution would then consist wholly of such cases, If, however, we put $k=0$ in expression (3), write $x$ for $p /(p+1)$, so that $x$ stands for a positive number less than unity, varying with the size of the sample, and replace the constant factor ( $k-1$ )! in the denominator, by a new constant factor, $\alpha$, in the numerator, we have an expression for the expected number of species with $n$ individuals, where n now cannot be zero,

$$
\begin{equation*}
\frac{\alpha}{n} x^{n} \tag{4}
\end{equation*}
$$

These two relationships enable the series to be fitted to any series of observational data, for if $S$ is the number of species observed, and $N$ the number of individuals, the two equations

$$
S=-\alpha \log _{e}(1-x), \quad N=\alpha x /(1-x)
$$

are sufficient to determine the values of $\alpha$ and $x$. The solution of the equations is, however, troublesome and indirect, so that to facilitate the solution in any particular case I have calculated a table (Table 9) from which, given the common logarithm

Table 9. Table of $\log _{10} N / \alpha$ in terms of $\log _{10} N / S$, for solving the equation

$$
S=\alpha \log _{t}\left(1+\frac{N}{\alpha}\right), \text { given } S \text { and } N
$$

The total number of species expected is consequently

$$
\sum_{n=1}^{\infty} \frac{\alpha}{n} x^{n}=-\alpha \log _{\theta}(1-x)
$$

so that our distribution is related to the algebraic expansion of the logarithm, as the negative binomial distribution is to the binomial expansion. Next, it is clear that the total number of individuals expected is

$$
\sum_{n=1}^{\infty} \alpha x^{n}=\frac{\alpha x}{I-x} .
$$

of $N / S$, we may obtain that of $N / \alpha$. Five-figure logarithms are advisable, such as those in Statistical Tables. If $x$ be eliminated from the two equations, it appears that

$$
N=\alpha\left(e^{s / \alpha}-1\right), \quad S=\alpha \log _{\varepsilon}\left(1+\frac{N}{\alpha}\right),
$$

and

$$
\frac{N}{S}=\left(e^{s / \alpha}-1\right) \div S / \alpha,
$$

from which Table 9 has been constructed.

## (3) Fitting the series

The use of the table is shown, using Williams's extensive data for the Macrolepidoptera at Harpenden (total catch for four years). Symbols + and - are used to indicate numbers to be added and subtracted respectively.

|  |  |  |
| :---: | :---: | :---: |
| Symbol | Number | Common logarithm |
| $S$ | 240 | -2.38021 |
| $N$ | 15609 | $\begin{array}{r} \\ +4.19338 \\ \hline\end{array}$ |
| $N / S$ | - | 1.81317 |
| From the table | $\log (N / S)$ | $\log (N / \alpha)$ |
|  | - r .8 r | $\mathrm{C}^{-2.58484}$ |
|  | $\underline{+1.82}$ | +2.59684 + |
| Difference | $0 \cdot 01$ | 0.01200 |
| Proportional parts | $\begin{gathered} 0.00317 \\ 1 \cdot 81317 \end{gathered}$ | $\begin{aligned} & 0.00380 \\ & 2.58864 \end{aligned}$ |
| Then | Number | Common logarithm |
| $N /{ }^{N / \alpha}$ | - | -2.58864 |
| $N$ | - | +4.19338 |
| $\alpha$ | 40.248 | 1.60474 |

For constructing the distribution we should then calculate

$$
x=\frac{N}{N+\alpha}=\frac{15609}{15649.248}=0.997428 \mathrm{r} .
$$

The quantity $\alpha$ is independent of the size of sample, and is proportional to the number of species of the group considered, at any chosen level of abundance, relative to the means of capture employed. Values of $\alpha$ from different samples or obtained by different methods of capture may therefore be compared as a measure of richness in species. To this end we shall need to know the sampling errors by which an estimate of $\alpha$ may be affected.

## (4) Variation in parallel samples

Whatever method of capture may be employed, it is to be expected that a given amount of activity devoted to it, e.g. a given number of hours exposure of a light-trap, or a given volume of sea water passed through a plankton filter, will yield on different occasions different numbers of individuals and of species, and, consequently, varying estimates of $\alpha$. The amount of variation of these kinds attributable to chance must form the basis of all conclusions as to whether variations beyond chance have occurred in the circumstances in which two or more samples were made.

In strictly parallel samples, i.e. equivalent samling processes applied to homogeneous material, the numbers caught of each individual species will be distributed in a Poisson series, and it easily follows that the same is true of the aggregate number, $N$, of all species. Since $N$ is a large number of hundreds
or thousands, this is equivalent to $N$ being normally distributed with a variance equal to its mean, so that to any observed value $N$ we may attach a standard error (of random sampling) equal to $\pm \sqrt{ } N$.

For the variation of $S$ we must obtain the distribution of species according to the number $m$ expected in the sample; modifying expression (2) in the same way as (3) has been modified, this is found to be

$$
\begin{equation*}
\alpha e^{-\alpha m / \Sigma} d m / m . \tag{5}
\end{equation*}
$$

The probability of missing any species is $e^{-m}$, so that the contribution to the sampling variance of $S$ due to any one species being sometimes observed and sometimes not, is

$$
e^{-m}\left(\mathbf{I}-e^{-m}\right) .
$$

Multiplying this by the frequencies in (5) and integrating over all values of $m$, we have
$\alpha \int_{0}^{\infty} e^{-m(N+\alpha) / \Sigma}\left(\mathrm{I}-\frac{m}{2}+\frac{m^{2}}{6}-\ldots\right) d m=\alpha \log _{e}\left(\frac{2 N+\alpha}{N+\alpha}\right)$,
which is the sampling variance of $S$. For large samples this is approximately (0.693I) $\alpha$.

Variations of $S$ and $N$ in parallel samples are not, however, independent. When present, a species must contribute on the average $m /\left(\mathrm{r}-e^{-m}\right)$ individuals, which exceeds the expectation in all samples by

$$
\frac{m e^{-m}}{\mathrm{I}-e^{-m}}
$$

and as the frequency of occurrence is $1-e^{-m}$, each species must contribute $m \cdot e^{-m}$ to the covariance of $S$ and $N$. The covariance is thus found to be

$$
\frac{\alpha N}{N+\alpha}
$$

From these three values it is possible by standard methods to find the sampling variance of $S$ in samples having a given number of specimens $N$, which is

$$
V(S), \text { given } N,=\alpha \log _{e} \frac{2 N+\alpha}{N+\alpha}-\frac{\alpha^{2} N}{(N+\alpha)^{2}}
$$

and, the variance of $\alpha$,

$$
V(\alpha)=\frac{\alpha^{3}\left\{(N+\alpha)^{2} \log _{e} \frac{2 N+\alpha}{N+\alpha}-\alpha N\right\}}{(S N+S \alpha-N \alpha)^{2}} .
$$

We may, therefore, complete the example of the last section by calculating the standard error of $\alpha$. Using the values obtained, the variance comes to $1 \cdot 125 \mathrm{I}$, of which the square root is $\mathrm{I} \cdot 0607$.
The estimate obtained for $\alpha, 40 \cdot 248$, has, therefore, a standard error of 1.0607 , available for comparison with like estimates.

## (5) Test of adequacy of the limiting distribution

From the manner in which the distribution has been developed it appears that we never have theoretical grounds for supposing that $k$ is actually zero;
but, on the contrary, must generally suppose that in reality it has a finite, though perhaps a very small, value. Our reasons for supposing this small value to be negligible must always be derived from the observations themselves. It is, therefore, essential to be able to test any body of data in respect to the possibility that in reality some value of $k$ differing significantly from zero might fit the data better than the value zero actually assumed.

The most sensitive index or score by which any departure of the series of frequencies observed from those expected can be recognized, is found by the general principles of the Theory of Estimation, as, for example, in the author's Statistical Methods for Research Workers, to be

$$
S\left\{a_{n}\left(\mathrm{I}+\frac{1}{2}+\frac{1}{3}+\ldots+\frac{\mathrm{I}}{n-\mathrm{I}}\right)\right\}
$$

when $a_{n}$ is a number of species observed with $n$ individuals in each. If the values of $a_{n}$ conformed accurately with expectation, the total score would be equal to

$$
\frac{S^{2}}{2 \alpha}
$$

If, on the contrary, the series were better fitted by a negative binomial with a value of $k$ differing from zero, we should expect the difference

$$
S\left\{a_{n}\left(1+\frac{1}{2}+\frac{1}{3}+\ldots+\frac{1}{n-1}\right)\right\}-\frac{S^{2}}{2 \alpha}
$$

to show a positive discrepancy.
Applying this test to Williams's distribution for 240 species of Macrolepidoptera, one finds, after a somewhat tedious calculation,

$$
\begin{align*}
S\left\{a_{n}\left(1+\frac{1}{2}+\frac{1}{3}+\ldots+\frac{1}{n-1}\right)\right\} & \frac{724.86}{2 \alpha} \\
& \frac{715.57}{+9.29}
\end{align*}
$$

The series, therefore, shows a deviation in the direction to be expected for the negative binomial, though apparently quite a small one. In order to test the
significance of such discrepancies, I give in Table 10, for the same range of observable values of the average number of specimens in each species $N / S$, the values of $i / S$, where $i$ is the quantity of information, in respect of the value of $k$, which the data supply.

Table 10. The amount of information respecting $k$, supposed small, according to the numbers of individuals ( $N$ ) and species ( $S$ ) observed

| $\log _{10} N / S$ | $i / S$ | $\log _{10} N / S$ | $i / S$ |
| :---: | :---: | :---: | :---: |
| 0.4 | 0.1971 |  |  |
| 0.5 | 0.2882 |  |  |
| 0.6 | 0.3914 | 2.1 | 3.1047 |
| 0.7 | 0.5054 | 2.2 | 3.3606 |
| 0.8 | 0.6295 | 2.3 | 3.6260 |
| 0.9 | 0.7639 | 2.4 | 3.9009 |
| 1.0 | 0.9076 | 2.5 | 4.1854 |
| 1.1 | 1.0608 | 2.6 | 4.4791 |
| 1.2 | 1.2232 | 2.7 | 4.7825 |
| 1.3 | 1.3950 | 2.8 | 5.0954 |
| 1.4 | 1.5762 | 2.9 | 5.4178 |
| 1.5 | 1.7665 | 3.0 | 5.7498 |
| 1.6 | 1.9661 | 3.1 | 6.0912 |
| 1.7 | 2.1751 | 3.2 | 6.4421 |
| 1.8 | 2.3934 | 3.3 | 6.8026 |
| 1.9 | 2.6211 | 3.4 | 7.1726 |
| 2.0 | 2.8582 | 3.5 | 7.5521 |

Entering the table with our value 1.81317 for $\log _{10} N / S$ we have $i / S=2 \cdot 4656$, or $i=591 \cdot 7$. This quantity may now be used for two purposes. In the first place it is the sampling variance of the discrepancy observed, so that, taking its square root, the standard error is found to be 24.33 . This suffices to test the significance of the discrepancy, since $9.29 \pm 24.33$ is clearly insignificant.

If, on the contrary, a significant discrepancy had been found, an estimate of the value of $k$ required to give a good fit to the data could be made by dividing the discrepancy by $i$. In fact

$$
\frac{9 \cdot 29}{591 \cdot 7}=0.016
$$

would have been the value of $k$ indicated by the data, if any value other than zero had been required.

## SUMMARY

Part 1. It is shown that in a large collection of Lepidoptera captured in Malaya the frequency of the number of species represented by different numbers of individuals fitted somewhat closely to a hyperbola type of curve, so long as only the rarer species were considered. The data for the commoner species was not so strictly 'randomized', but the whole series could be closely fitted by a series of the logarithmic type as described by Fisher in Part 3. Other data for random collections of insects in the field were also shown to fit fairly well to this series.

Part 2. Extensive data on the capture of about 1500 Macrolepidoptera of about 240 species in a light-trap at Harpenden is analysed in relation to Fisher's mathematical theory and is shown to fit extremely closely to the calculations.

The calculations are applied first to the frequency of occurrence of species represented by different numbers of individuals-and secondly to the number of species in samples of different sizes from the same population.

The parameter ' $\alpha$ ', which it is suggested should be called the 'index of diversity', is shown to have a regular seasonal change in the case of the Macrolepidoptera in the trap. In addition, samples from two traps which overlooked somewhat different vegetation are shown to have ' $\alpha$ ' values which are significantly different.

It is shown that, provided the samples are not small, ' $\alpha$ ' is the increase in the number of species obtained by increasing the size of a sample by e ( $2 \cdot 718$ ). A diagram is given (Fig. 8) from which any one of the values, total number of species, total number of individuals and index of diversity ( $\alpha$ ), can be obtained approximately if the other two are known. The standard error of $\alpha$ is also indicated on the same diagram.

Part 3. A theoretical distribution is developed which appears to be suitable for the frequencies with which different species occur in a random collection, in the common case in which many species are so rare that their chance of inclusion is small.

The relationships of the new distribution with the negative binomial and the Poisson series are established.

Numerical processes are exhibited for fitting the series to observations containing given numbers of species and individuals, and for estimating the parameter $\alpha$ representing the richness in species of the material sampled; secondly, for calculating the standard error of $\alpha$, and thirdly, for testing whether the series exhibits a significant deviation from the limiting form used.

Special tables are presented for facilitating these calculations.
