The relationship between index testing and California Bearing Ratio values for natural road construction materials in South Africa

I J Breytenbach, P Paige-Green, J L Van Rooy

IZAK BREYTENBACH (Pr Sci Nat, Visitor SAICE) obtained his MSc degree in Environmental and Engineering Geology from the University of Pretoria in 2009. He is a Professional Natural Scientist registered with the South African Council for Natural Scientific Professions and a member of the South African Institute for Engineering and Environmental Geologists (SAIEG). He works as a consultant in the engineering geology and geotechnical field.

LOUIS VAN ROOY (Pr Sci Nat) obtained his PhD degree in Engineering Geology at the University of Pretoria in 1992. He started lecturing in the Department of Geology at the University of Pretoria in 1985 and has lectured to undergraduate and postgraduate mining, civil engineering, engineering geology and geology students. His research interests include durability of basic igneous rocks for use in civil engineering construction, problem soils and safe development on dolomite land. Prof Van Rooy has supervised a number of MSc and PhD students and is author or co-author of more than 30 papers in journals and for conferences.

Research was done to determine whether a relationship can be established between index testing and CBR (California Bearing Ratio) results. The process involved compiling a database of test results for a range of rock material types across moist and dry regions in southern Africa. The database was compiled in such a way that it represents natural gravels sampled (mostly) for construction or rehabilitation of road layer works. The database included a location description, material description, Weinert N-value, Atterberg Limits, grading analysis and CBR values. In addition, the linear shrinkage product, shrinkage product, grading coefficient, grading modulus and dust ratio were calculated and also used in the analyses. Data were grouped based on climate, rock material type and compaction, and analysed separately. The data were compared with existing prediction models, after which linear and Weibull regressions were performed to derive new models. Over 130 regressions were derived. The results proved poor and this is ascribed to data variability. The data variability, in turn, is the result of test methods with poor reproducibility and repeatability. In short, the test methods (the CBR in particular) resulted in inconsistent data and subsequently poor results, making accurate predictions nearly impossible.

INTRODUCTION

To date, much criticism has been directed at the California Bearing Ratio (CBR) test, including its cost, the time required to perform the test and its reproducibility. While some authors feel the test should be replaced (e.g. Savage 2008), no effective alternative method has been developed or implemented in South Africa. In addition to the time required for the four-day soaked CBR test, the amount of testing required by ongoing engineering projects places strain on the material testing industry, which is often overwhelmed by the sheer volume of testing to be done. Currently, an empirical prediction model developed by Kleyn (1955) is commonly used as a predictor of the CBR in South Africa. Models developed by Davel (1989), Netterberg (1994), Sood et al (1978), Stephens (1990, 1992) and others are also used to a lesser extent.

In search of a solution to limit the onerous requirements of this material testing, the relationship between index testing and the CBR was investigated in an attempt to develop empirical prediction models from data related to index testing. The motivation behind this was the reduced cost and time that would be required to execute index testing, compared with CBR testing. The aim of the research was not to replace the CBR test, but to develop a preliminary method of identifying potentially suitable materials to limit the amount of CBR testing that has to be performed. It was also anticipated that by grouping like materials together, better prediction models than are currently available could be developed.

DISCUSSION

CBR properties

A large disadvantage associated with the CBR is its poor reproducibility and repeatability. This was also confirmed by discussion with an experienced soils laboratory manager, Mr David Ventura (2008, personal communication, CSIR, Pretoria) and is shown by the precision limit determination in the current draft revision of the CBR test method by the SABS (SANS 3001-GR40 – SABS 2008). Performing confirmatory testing would become non-viable due to the amount of material required in addition to the (already) substantial volume of material required to perform the standard CBR test. As such, finding an empirical relationship between the index test results and the CBR may be considered challenging due to the variability of the CBR itself.

An example of the above was observed while collecting and entering data. A single

Table 1 Summary of Weinert's rock classification scheme (adapted from Weinert 1980)

Class	Group	Rock types
Decomposing	Basic crystalline	■ Diorite, gabbro, norite, peridotite, serpentinite, anorthosite, diabase, dolerite, andesite, basalt, phonolite ■ Metamorphic: Amphibolite and greenschist
	Acid crystalline	■ Granite, pegmatite, syenite, felsite, rhyolite ■ Metamorphic: Gneiss
Disintegrating	High silica	■ Igneous: Vein quartz, quartz porphyry ■ Sedimentary: Chert ■ Metamorphic: Hornfels, quartzite
	Arenaceous	■ Sedimentary: Arkose, conglomerate, gritstone, sandstone ■ Metamorphic: Mica schist
	Argillaceous	■ Sedimentary: Shale, mudstone, siltstone ■ Metamorphic: Phyllite, sericite schist, slate
	Carbonate	■ Sedimentary: Dolomite, limestone ■ Metamorphic: Marble
Special	Diamictites	■ Tillite, breccia
	Metalliferous	■ Ironstone, magnetite, magnesite, haematite
Soils	Pedogenic	■ Calcrete, ferricrete, silcrete, phoscrete, gypcrete
	Soil	■ Transported soils

sample was compacted to the same compactive effort on two occasions (with an identical test) and, although most of the other parameters (e.g. plasticity index) correlated closely, the first CBR value measured was ten times greater than that of the duplicate.

Data compilation

Research was focused on materials occurring in the South African geological environment. Data were collected from a number of sources, including the following:

■ A collective database of results obtained during ongoing research at the CSIR
■ The Transvaal Roads Department's *Report on investigation of existing road pavements in the Transvaal*, Report L1/75 and field data volumes 1–12, compiled by Burrows (1975)
■ Data from the defunct National Databank for Roads (CSIR)
■ Laboratory results obtained from work done during routine consulting
■ Data courteously provided by the Namibian Roads Department

The data collected were required to have index test results and CBR test results for the same sample in order to attempt to correlate the properties. Test results considered in the research included the following test parameters:

■ Rock material type
■ Weinert N-value or location from which to derive the Weinert N-value
■ Atterberg Limits (including bar linear shrinkage)
■ Grading analysis (percentages passing 37,5; 26,5; 19,0; 13,2; 4,75; 2,0; 0,425 and 0,75 mm screens)

■ CBR values at 100, 98 and/or 95% Mod. AASHTO density

From the available data, the following additional parameters were calculated:

■ Linear shrinkage product
■ Shrinkage product
■ Grading modulus
■ Grading coefficient (Paige-Green 1999)
■ Dust ratio

Although most of the testing was known to have been conducted according to TMH1 (NITRR 1979, 1986) methods, the possibility of some of the testing deviating from these test methods cannot be excluded. It should also be noted that many of these properties can have considerable variability depending on the sampling, test preparation and operator, and this could not be controlled in the data set. All data collected were entered into Microsoft® Excel as a spreadsheet to facilitate data handling.

METHODOLOGY

Data grouping

Data were divided into classes, based on three main functions, producing nearly 60 different data groups. All data were initially assigned to a climatic group (i.e. moist or dry climate), based on the N-value system proposed by Weinert (1980). Regions with an N-value of less than 5 were considered to be a moist climate, while regions with an N-value of 5 and more were considered to have a dry climate. The second division of data was a function of the relative compaction used for the CBR test. Only three densities were considered (i.e. 95, 98 and 100% Mod. AASHTO densities). The final data division was based on the rock

material groups described by Weinert (1980), as illustrated in Table 1. Although every attempt was made to include a representative range of materials, not all of the rock material groups were represented by the data. This is ascribed to the fact that not all materials are ideal for layer work construction (e.g. metalliferous rock, due to high haulage costs) or that some materials are simply not common (or suitable for use) in a given climatic zone (e.g. calcrete in a moist climate).

In addition to the rock groups described, a group consisting only of non-plastic samples was created for each climatic zone and compaction. The group therefore has no reference to rock material type. Groups for colluvial and alluvial materials were also compiled.

Existing methods

After the dataset had been divided into the subgroups described above, each of the groups was compared with existing models. Numerous different research outcomes – largely identified by Netterberg (1994) – were identified and the methods and results produced compared with the newly created database. The models ranged from locally used systems (e.g. Kleyn 1955) to numerous systems applied abroad (e.g. Sood et al 1978, Dhir et al 1987, etc). The work considered utilises a range of input variables for the prediction of CBR values. As the number and length of individual models proposed are substantial, only a summary of the variables used by different authors is given:

■ Linear shrinkage product (Netterberg & Paige-Green 1988)
■ Linear shrinkage and grading (Lawrance & Toole 1984)
■ Grading modulus and plasticity index (Kleyn 1955 & Stephens 1988)
■ Linear shrinkage and grading (Gawith & Perrin 1962)
■ Atterberg Limits, grading and a group index number (Wermers 1963)
■ Grading, plastic limit and liquid limit (Stephenson et al 1967)
■ Grading, liquid limit and plasticity index (De Graft-Johnson et al 1969)
■ Grading modulus, linear shrinkage and grading (Haupt 1980)
■ Grading modulus (Davel 1989)

The (full) existing models were entered into the spreadsheets in the empirical format provided and predicted CBR values calculated using the database. In total, 28 equations were considered for each (of the nearly 60) data sets to derive the final CBR values predicted by each model. A mean CBR of the tested dataset was then compared with the mean CBR values calculated for each of the existing models to identify which models showed potential for accurate prediction.
Figure 1 Schematic model of model derivation and selection

However, results using the existing models on the dataset developed were poor, at best.

After the predictions of existing models had been assessed, it was decided to abandon further attempts to refine them, but instead to develop new models based on a sensible, statistical approach. However, the model of Kleyn (1955) was retained in the analysis, as the model is generally used in South Africa. The original method proposed by Kleyn (1955) is in a graphical format, though, and as such the empirical equation of Kleyn's model, as given by Stephens (1988), was considered for further analyses.

DATA ANALYSIS

The statistical analysis of each data set for the different groups described was done using Microsoft® Excel, SAS® 9.1 and SPSS® 15.0 for Windows®. Initially, general descriptive statistics were derived, followed by a principal component analysis for each group. These analyses were done to identify variables showing peculiar characteristics (e.g. strong correlation with the CBR) or trends prevalent in the data.

Model derivation

Linear regression models
Three linear models were used for empirical prediction. The first was derived by performing a simple linear regression. The second linear model was that developed by Kleyn (1955) and derived empirically by Stephens (1988). Finally, a modified version of Kleyn's model was developed by deriving a new linear model using only the grading modulus, the plasticity index and a constant.

The linear and modified Kleyn models were developed for each group individually.

Weibull regression model
Concern was raised about the (common) use of linear models to predict CBR values from other variables, as it was argued that the relationship is not necessarily a linear one and, as such, the basic assumption of a linear relationship is fundamentally flawed. Consequently, the Weibull regression was selected on the recommendation of Dr S Das (2008, personal communication, CSIR, Pretoria), as it is used in so-called survival analysis and reliability engineering. Weibull (1951) emphasised the flexibility of the model in application to natural and biological fields. The method proposed by Weibull (1951) is ideal for analysis of the project data for a number of reasons:

- It was clear from data verification that the data (and hence any predicting model) is not necessarily linear.
- Little else is known concerning the models to be derived, particularly with regard to their nature (e.g. logarithmic distribution). This was proven by the variability in the general statistics. Hence a method is required that is flexible enough to "adjust" to the data.
- All parameters have positive values ranging between zero and 100, with the exception of the shrinkage product and linear shrinkage product, both of which have maximum values exceeding 100.

Data manipulation
The first step in data manipulation was to normalise the grading to 100% passing the 37,5 mm screen, keeping in mind the average size of an indicator or foundation indicator sample. This normalisation is also necessary for calculating the grading coefficient. In addition, CBR values were restricted to a maximum of 100% (i.e. any CBR value exceeding 100% was considered as a CBR of 100%). The reason for this was that the predicted range of the Weibull regressions was limited to 100% considering that CBR values exceeding 100% have no significance in classification schemes such as the COLTO system.

The largest difficulty, however, lay with the cumulative percentages of particle constituents passing the sieve screens. The consistently decreasing percentage impeded regression and introduced some multi-collinearity. The problem was overcome by calculating the individual percentages retained on each screen, rather than the cumulative percentages passing them, as the percentage retained was not increasing or decreasing relative to smaller or larger screen sizes.

Table 2 Prediction model summary for colluvium (moist areas, 95% Mod. AASHTO)

Material	n	Mean CBR (%)	Model	Equation	Estimated mean CBR (%)	MSPE
Colluvium	52	13	Weibull	CBR = Exp[log(-log(0,5)) × 0,3223 + (2,6954 + (0,0243 × PL) − (0,0573 × LS) − (0,1436 × DR))]	12	26
			Kleyn	CBR = Exp[(((12×GM) - PI) ÷ 18,5) + ln(16,7)]	18	1503
			Adapted Kleyn	CBR = 13,984 − (0,254 × PI) + (1,963 × GM)	13	0
			Linear	CBR = 17,181 − (7,394 × DR)	13	<1

Table 3 Selected model for colluvium (moist areas, 95% Mod. AASHTO)

Material	% Mod. AASHTO	n	CBR range (%)	Estimated CBR range (%)	Model	Equation	Range of parameters	
Colluvium	95	52	7–25	10–16	Model	CBR = 13,984 − (0,254 × PI) + (1,963 × GM)	PI	0–21
					Upper confidence	CBR = 18,113 − (0,019 × PI) + (5,284 × GM)	GM	0,21–1,97
					Lower confidence	CBR = 9,854 − (0,490 × PI) - (1,359 × GM)		

From a practical point of view, the data assessed were also limited. Different CBR ranges were considered for moist and dry regions, as available CBR values did not allow similar ranges to be assessed (i.e. dry areas were characterised by significantly higher mean CBR values than moist areas). The CBR ranges considered were as follows:

- Moist regions: 7 to 25%
- Dry regions: 7 to 50%

Finally, the parameters for the plasticity of non-plastic or semi-plastic materials were entered into the regression processes as values of zero.

Model comparison

After four prediction models for each group analysed had been derived (i.e. Kleyn's model, modified Kleyn's model, linear model and Weibull model), some form of direct comparison was required in order to identify the most suitable model unambiguously. This was, however, not a simple task as a single parameter would not necessarily indicate the most suitable model. To address the problem, the following was done for each group:

- The mean square prediction error (MSPE) was calculated for each model, as derived from residual CBR values.
- The predicted range was compared with the true range of CBR values in the data set.

The model producing the best combination of accuracy and range was selected as the most suitable model. In most instances, the selected model was the one with the lowest MSPE. The entire process is illustrated in Figure 1.

RESULTS

Table 2 illustrates the results produced and the ultimate selection of the most suitable model. This table applies to colluvial materials

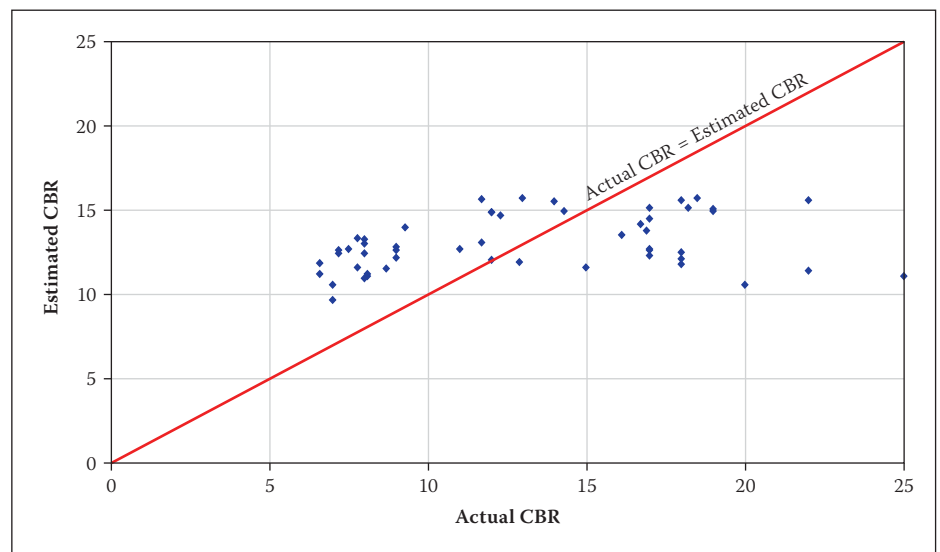

Figure 2 Actual vs predicted CBR values

compacted to 95% Mod. AASHTO density in a moist region. Of the four models derived, the modified Kleyn model had the lowest MSPE (a value of zero) and a mean estimated CBR of 13%. This mean value corresponds to the value calculated from the tested CBR values (i.e. the calculated mean is the same as the predicted mean). The fact that the linear model had an MSPE of less than one emphasises that model selection was not simple, particularly as the linear model also had a mean predicted CBR value of 13%. The final result produced for each material group (in respective compaction classes and climatic areas) mirrors that illustrated in Table 3, although this table applies only to colluvial materials, as discussed above.

Despite the apparent good correlation between the actual and predicted values (based on the MSPE values), the comparison between actual and predicted values was found to be poor. Figure 2 illustrates that even though the selected model is the best of the models tested, it still predicts only a

very limited range of values (i.e. CBR values between 9 and 15% for actual values between 7 and 25%) and is not representative of tested CBR values. Therefore, despite predicting a similar mean CBR value as calculated for the data set and producing the lowest MSPE, the model is not a good one.

The example of a colluvial material was chosen to illustrate the typical model fit. Similar models were developed for each material group, climate and compaction class, giving a total of about 190 different models, of which the best was selected for each group. This resulted in about 50 specific models, with ten groups having insufficient data. Details regarding these models and the correlations in terms of the MSPE (only five models had MSPE values greater than 1) are provided by Breytenbach (2009).

Ultimately, though, the selected models were not ideal and mostly produced very limited prediction ranges, regardless of the regression model used. The model described above, for example, had a restricted

predicted range of CBRs compared with the measured range of CBRs. This occurrence was prevalent throughout all of the predictive models derived.

CONCLUSION

A large database, which included CBR values as well as the indicator tests results for the same samples, was developed from existing test results. The use of the database to evaluate the many existing prediction models indicated very poor ability to predict the CBR values accurately. Although problems with the high variability for both the CBR and the indicator tests were recognised, attempts were made to develop new prediction models for the CBR.

Despite the application of numerous steps of refinement and the grouping of materials according to rock groups and climatic character, no relationship between the CBR and typical indicator tests could be proven with a high degree of confidence. None of the four models developed for any of the groups showed reliable or particularly accurate predictive ability, even when the most suitable model was selected by means of elimination.

The study has shown that the prediction of CBR from empirical models is not very good and even when a range of available prediction models is used, little confidence should be placed in the predicted CBR values. A possible reason for the poor predictability is the high variability in both the CBR and indicator test results.

RECOMMENDATIONS

After consideration of all data and each respective model derived, the new empirical equations cannot be recommended for general use, although they could be of benefit as preliminary indicators of testing requirements. It is also recommended, after assessment of a number of existing models, that they too should be used only as preliminary indicators and not as substitutes for laboratory CBR testing for South African soils.

Although the grouping of material test results into rock groups did not prove effective, it is recommended that similar research be done using different material classifications which focus on the material type (e.g.

clay or silty sand, possibly using the Unified Soil Classification System as the divisions) rather than the material origin, and bearing the test variability problems in mind. The use of the limited input ranges of CBR results is also recommended.
