Abstract

The TREC-8 Question Answering track was the first large-scale evaluation of domain-independent question answering systems. This paper summarizes the results of the track by giving a brief overview of the different approaches taken to solve the problem. The most accurate systems found a correct response for more than 2/3 of the questions. Relatively simple bag-of-words approaches were adequate for finding answers when responses could be as long as a paragraph (250 bytes), but more sophisticated processing was necessary for more direct responses (50 bytes).

The TREC-8 Question Answering track was an initial effort to bring the benefits of large-scale evaluation to bear on a question answering (QA) task. The goal in the QA task is to retrieve small snippets of text that contain the actual answer to a question rather than the document lists traditionally returned by text retrieval systems. The assumption is that users would usually prefer to be given the answer rather than find the answer themselves in a document.

This paper summarizes the retrieval results of the track; a companion paper ("The TREC-8 Question Answering Track Evaluation") gives details about how the evaluation was implemented. By necessity, a track report can give only an overview of the different approaches used in the track. Readers are urged to consult the participants' papers elsewhere in the Proceedings for details regarding a particular approach.

1 The Task

A successful evaluation requires a task that is neither too easy nor too difficult for the current technology. If the task is too simple, all systems do very well and nothing is learned. Similarly, if the task is too difficult, all systems do very poorly and again nothing is learned. Accordingly, we chose a constrained version of the general question answering problem as the focus of the track.

The document collection used in the task was the same as the TREC-8 ad hoc collection, namely the set of documents on TREC disks 4 and 5 minus the *Congressional Record* documents. The documents consist mostly of newspaper articles and thus contain information on a wide variety of subjects. Participants were given 200 fact-based, short-answer questions, such as those given in Figure 1. Each question was guaranteed to have at least one document in the collection that explicitly answered the question.

Participants returned a ranked list of five [*document-id*, *answer-string*] pairs per question such that each answer string was believed to contain an answer to the question. Answer strings were limited to either 50 or 250 bytes, and could either be extracted from the corresponding document or automatically generated from information contained in the document. Human assessors read each string and made a binary decision as to whether the string actually did contain an answer to the question in the context provided by the document. Taking document context into account allowed a system that correctly derived a response from a document that was incorrect to be given full credit for its response.

Given a set of judgments for the strings, the score computed for a submission was mean reciprocal rank, defined as follows. An individual question received a score equal to the reciprocal of the rank at which the first correct response was returned, or 0 if none of the five responses contained a correct answer. The score for a submission was then the mean of the individual questions' reciprocal ranks. The reciprocal rank has several advantages as a scoring metric. It is closely related to the average precision measure used extensively in document retrieval. It is bounded between 0 and 1, inclusive, and averages well. A run is penalized for

- How many calories are there in a Big Mac?
- What two US biochemists won the Nobel Prize in medicine in 1992?
- Who was the first American in space?
- Who is the voice of Miss Piggy?
- Where is the Taj Mahal?
- What costume designer decided that Michael Jackson should only wear one glove?
- In what year did Joe DiMaggio compile his 56-game hitting streak?
- What language is commonly used in Bombay?
- How many Grand Slam titles did Bjorn Borg win?
- Who was the 16th President of the United States?

not retrieving any correct answer for a question, but not unduly so. However, the measure also has some drawbacks. The score for an individual question can take on only six values (0, .2, .25, .33, .5, 1). Question answering systems are given no credit for retrieving multiple (different) correct answers. Also, since the track required at least one response for each question, a system could receive no credit for realizing it did not know the answer.

2 Retrieval Results

Twenty different organizations participated in the Question Answering track. The participants are listed in Figure 2. A total of 45 runs were submitted, 20 runs using the 50-byte limit and 25 runs using the 250-byte limit. Table 1 gives both the mean reciprocal rank and the number of questions for which no answer was found for each run. (Two submissions that contained errors are omitted from the table.) The scores are computed over the 198 questions that comprised the official test set. The table is split between the 50-byte and the 250-byte runs and is sorted by decreasing mean reciprocal rank within run type.

The number of questions for which no answer was found shows that the most accurate systems were able to find an answer for more than 2/3 of the questions. Furthermore, when the answer was found at all it was usually ranked first, as shown by the fact that the mean reciprocal rank is also close to 2/3 for these systems.

While the run with the highest mean reciprocal rank score was a 50-byte run, a direct comparison between 50- and 250-byte submissions from the same participant shows that the 50-byte task is more difficult. For every organization that submitted runs of both lengths, the 250-byte limit run had a higher mean reciprocal rank. This is not a surprising result—a system has a greater chance of including a correct response in a

longer string—but it was not a guaranteed result. That is, longer strings that include a correct response were not always a correct response themselves. Response strings that contained multiple entities of the same semantic type as the answer and did not specifically indicate which of the entities was the answer were marked as incorrect. For example, for the question *What is the capital of Kosovo?* the 50-byte response of

```
0 miles northwest of Pristina, five demonstrators
```

was judged correct, while the 250-byte response of

```
protesters called for military intervention to end "the Albanian uprising."
</P> <P> At Vucitrn, 20 miles northwest of Pristina, five demonstrators were
reported injured, apparently in clashes with police.  </P> <P> Violent clashes
were also repo
```

was judged incorrect since it is unclear from the response whether the capital is Vucitrn or Pristina.

The submissions from AT&T Research Labs demonstrate that existing passage-retrieval techniques can be successful for 250-byte runs, but are not suitable for 50-byte runs [18]. Their question answering system used a traditional vector-based retrieval system to select 50 documents and then scored each sentence within those documents by the number of question words in the surrounding context. For the passage-based runs (`attqa50p` and `attqa250p`), the highest scoring sentences were returned as the response. For their "entity-based" runs (`attqa50e` and `attqa250e`), high scoring sentences were further processed by a linguistic module. The passage-based method was very competitive for the 250-byte limit, but was not nearly as successful when restricted to just 50 bytes. NTT Data Corporation note similar effects in their runs [20]. These results suggest that the relatively simple bag-of-words approaches that are successfully used in text retrieval are not sufficient for extracting specific, fact-based answers.

3 Retrieval Strategies

Many participants used a variant of the following general strategy to the question answering problem. The system first attempted to classify a question according to the type of its answer as suggested by its question word. For example, a question that begins with "who" (*Who is the prime minister of Japan?*) implies a person or an organization is being sought, and a question beginning with "when" (*When did the Jurassic Period end?*) implies a time designation is needed. Next, the system retrieved a small portion of the document collection using standard text retrieval technology and the question as the query. The system performed a shallow parse of the returned documents to detect entities of the same type as the answer. If an entity of the required type was found sufficiently close to the question's words, the system returned that entity as the response. If no appropriate answer type was found, the system fell back to best-matching-passage techniques.

This approach works well provided the query types recognized by the system have broad enough coverage and the system can classify questions sufficiently accurately. Most systems could answer questions that began with "who" very accurately. However, questions that sought a person but did not actually begin with "who" (*Name the first private citizen to fly in space. What Nobel laureate was expelled from the Philippines before the conference on East Timor?*) were much more difficult. More difficult still were questions whose answers were not an entity of a specific type (*What is Head Start? Why did David Koresh ask the FBI for a word processor?*). Of course, pattern matching on expected answer types was not fool-proof even when "good" matches were found. One response to the question *Who was the first American in space?* was Jerry Brown, taken from a document that says

```
As for Wilson himself, he became a senator by defeating Jerry Brown, who has
been called the first American in space.
```

Broadly speaking, each of the following organizations used a variant of the general strategy: AT&T Labs Research [18], CL Research [10], Cymfony, Inc. [19], GE/University of Pennsylvania [13], LIMSI-CNRS [5], MITRE Corporation [2], New Mexico State University [15], NTT Data Corporation [20], Southern Methodist University [12], University of Maryland [14], University of Ottawa/NCR [11], University of Sheffield [8], and Xerox Research Centre Europe [7]. The approach used by IBM Research [16] was very similar in spirit to

this approach except they located entities at indexing time and used a bag-of-words scoring metric that incorporated the entities, thus providing efficient retrieval at question-answering time. The University of Iowa [4] classified questions by type and used their filtering system to learn features of answers. Seoul National University [17] performed an initial document retrieval run and then selected phrases from top-ranking documents by extracting the immediate neighborhood of the highest-weighted question word. Finally, the MultiText Project [3], National Taiwan University [9], Royal Melbourne Institute of Technology/CSIRO [6], and University of Massachusetts [1] used traditional passage retrieval techniques alone.

4 Conclusion

The Question Answering track was the first large-scale evaluation of domain-independent question answering systems. The questions used in the track were deliberately constrained to fact-based, short-answer questions to make the task amenable to evaluation. Systems generally classified a question according to the type of its answer, and then performed a shallow parse of likely documents to find objects of the entailed type. The most accurate systems were able to answer more than 2/3 of the questions correctly. Existing passage-retrieval techniques were adequate for finding answers when relatively long responses were permissible, but more sophisticated processing was need to focus on the answer itself.

There will be another Question Answering track in TREC-9, which will be mostly the same as the TREC-8 track. One change in the track will be to have a test set of 500 questions rather than 200 questions, and to have many fewer of the questions be constructed from a target document.
