THE WELFARE OF SMALL LIVESTOCK PRODUCERS IN VIETNAM UNDER TRADE LIBERALISATION -
INTEGRATION OF TRADE AND HOUSEHOLD MODELS

Pham Thi Ngoc Linh[1], Michael Burton[1], David Vanzetti[2]

Contributed paper at the Eleventh Annual Conference on Global Economic Analysis,
Helsinki, Finland June 12-14, 2008.

Abstract

Vietnam has negotiated a series of bilateral and multilateral trade agreements and has made significant steps in integrating into the world economy. This integration is likely to have both positive and negative effects on different stakeholders in the economy. This paper measures the effects on the welfare of Vietnam's small livestock producers' by linking a household model and the GTAP trade model. A GTAP utility SplitCom is used to separate out pig and poultry prior to running several trade liberalisation scenarios. A recursive household model with a two-stage LES-AIDS model on the consumption side and Cobb-Douglas functions on the production side is used to estimate the likely impacts on the behavior and welfare of the farm household. The household model is linked to the trade model through changes in the prices of inputs and outputs arising from different trade scenarios.

Keywords: Vietnam, livestock, trade, household models.

I. Introduction

Vietnam joined the WTO on 11 January 2007 as its 150th member. This culminated a long process to integrate the Vietnamese economy into international markets. The integration started in 1986, when the Doi Moi restructuring process began. Since then, Vietnam negotiated deals with more than 100 trade partners. Among them, a trade agreement with the European Union (EU) was signed in 1992, an agreement to become an official member of ASEAN in 1995 and joint ASEAN Free Trade Area (AFTA) in 1996 was implemented, and in 2000 Vietnam entered into a bilateral trade agreement (BTA) with the USA.

Each time such a major agreement was reached, Vietnam's trade with that region expanded, and these trade agreements were clearly an impetus to ongoing domestic economic reforms in Vietnam to become a more open economy in the process of integration into the global economy. Implementation of multilateral and bilateral trade agreements is likely to provide benefits for the economy and increase welfare for society. In case of the livestock sector, trade liberalisation may bring both opportunities and threats, and have effects on both the supply side and demand side. For example, income growth may increase demand for meat, but the domestic industry may also have to compete with imported products. Reducing tax on imported maize/or soybean may reduce feed prices, but the opportunity cost of labour in livestock production may increase.

Livestock in Vietnam are predominantly raised in small-scale household production units. At present, small holder producers supply the majority of the meat in the market, with most households operating individually in the production and marketing of livestock and livestock products. For most of those households, raising livestock is an important source of cash income, providing at least 50 percent of cash income in small households (Lapar, Vu & Ehui 2003). The small household's livestock production is constrained by poor access to markets, a very low scale of operation, poor access to improved genetics and to high-quality forage and concentrates, and poor animal husbandry and animal nutrition. In that context, it is not clear whether the small livestock households will be worse off or better off from the effects of trade liberalisation.

Objective of the Study and Paper's Structure

The objective of the study is to analyze implications of trade liberalisation on Vietnam's small scale livestock producers. The paper will examine how household production, consumption and welfare are affected when prices change due to trade liberalisation.

The paper is organized as follows: in the next section, a methodology is presented that links the international trade model with the household model to quantify welfare impacts on the small households as a consequence of trade liberalisation. The following section presents the trade model and household model, and the results of linking the two models together. The results of changes in welfare and production and consumption behaviors of the household are presented, with some conclusions drawn at the end of the paper.

II. Methodology and the models

To model trade liberalisation, both bilateral as well as multilateral trade agreements between Vietnam and the others countries, a multi-country general equilibrium model is used. The Global Trade Analysis Project model (GTAP), with its focus on worldwide trade policy, is suitable for this purpose. Since the latest version and the most recent database of GTAP include data for Vietnam, the Vietnamese economy with all its factor and activity flows is represented in the model.

Given the aim of investigating welfare changes of the household, and the reaction of the household production and consumption behaviors, price changes for consumption commodities, as well as production factors, including labour in the agricultural sector, shall be incorporated. This price information can be derived from the results of the GTAP simulation. The analysis only examines one-way effects of trade liberalisation on households, but not their influence on trade. Therefore, an approach that incorporates feedback from the households to the international system is not required. In this study, an approach of combining the GTAP general equilibrium model with a micro level of a household model is chosen. By linking to a household model, response of the household to price signals in terms of substitution between commodities in consumption and production, and also in labour allocation, will be captured.

Since the target of the study is small households in the livestock sector, especially the households raising pigs and chicken, how trade liberalisation affects individual sub-sectors is especially considered. For this reason the GTAP utility SplitCom is used to separate pig and poultry out of the aggregate group of livestock in the standard GTAP aggregation.

1. Trade Model – GTAP and SplitCom

GTAP was initially developed in 1992 at Purdue University in the USA. It is a standard CGE model based on the neoclassical theory of firm and household behavior assuming perfect competition, constant returns to scale and utility maximizing behavior. It is designed to be a multi-region, general equilibrium model with bilateral trade flows between all regions and linkages between economies and between sectors within economies. The model uses the Armington approach by which products are differentiated by origin and are assumed to substitute imperfectly for one another forming a composite import aggregate that substitutes imperfectly for domestically produced goods. Primary factors (land, unskilled labour, skilled labour, capital and natural resources) are substitutable but as a composite are used in fixed proportions to intermediate inputs. The standard model is comparative static which means that after introducing an exogenous shock such as a policy change the model works out a new equilibrium in all markets and determines new values for the endogenous variables.

Simulations are undertaken using the GTAP version 6.2 database. The database has 96 countries and regions and 57 sectors and includes tariffs, export subsidies and taxes, subsidies on output and on inputs such as capital, labor and land that presents the world economy in 2001. In the region/country aggregation, ASEAN countries are split out in the database as much as possible to distinguish the economic effects of trade liberalization to these countries and highlight the importance of regional economic relations. Other important trade partners of Vietnam, such as United State of America, Japan, China, Korea and Australia are detailed. Meanwhile, groups of countries with similar economic conditions, such as European countries or some developed countries, are aggregated together. African and Latin American countries are also grouped together, since with them Vietnam has quite limited trade.

Since the study is interested in the impacts of trade liberalisation on the households who raise pig and chicken as their main source of income, price changes of these two commodities are especially considered. That is the reason of implementation of SplitCom, (developed by Mark Horridge, Centre of Policy Studies, Monash University) in 2005 to split commodity groups, hence introduce new sectors for pigs and chicken into the GTAP database. Generating a new GTAP database takes the following steps:

Step 1: Aggregating 18 sectors from 57 individual sectors of GTAP version 6.2. The aggregation attempts to split out sectors with significant protection, such as textiles and

apparel, manufactures, and electronics, while grouping some sectors that have similar characteristics in production and approximate protection level together. In the initial aggregation sectors, out of the 18 sectors, there are 7 which belong to agriculture, and 4 processed sectors that use inputs from agriculture.

Step 2: Applying SplitCom to disaggregate the live animals sector (OAP) into three new sectors: live pig, live poultry and other animals. SplitCom is software that provides a tool necessary for splitting GTAP commodities into homogeneous and differentiated sub-groups. The program works with 3 sub-folders: Input, Work, and Output. The original GTAP database and its associated files (*basedata.har, default.prn,* and *sets.har*) were copied into an input folder. The files *SplitSec.har* and *UserWgt.har* were created automatically by SplitCom, once the commands of creating new split and new database are set up. As a default, SplitCom only creates equal weights for the new commodities, but if information is available the user can improve on this situation by supplying her own weights by adding new headers[3] TWGT, RWGT, CWGT, and XWGT to the *userwgt.har* file. For this purpose, data on bilateral trade among countries/regions in year 2001 are taken from UN Comtrade, International Statistics, and WITS, data on production and consumption of pig, chicken and other animals are explored from FAOStat, and Social Accounting Matrices (SAMs) of countries[4], and some assumptions are made that some countries have similar economy conditions would have similar production activity. In this application SplitCom was used with updated *userwgt.har* file to get the final split. Finally, the new expanded GTAP database is stored in the Output folder of the SplitCom, and is ready for loading to run GTAP model. The database now is disaggregated to a total of 20 commodity groups and 20 regions and countries for simulation (detail in Annex A1 and A2).

---

[3] These headers can be found in the file named *nuweght.har* in the work folder of the SplitCom. These headers are originally designed to introduce the user weights for sales, costs, self uses and trade data into SplitCom.

[4] SAMs of countries are used from source of International Food Policy Research Institute (IFPRI)

Source: GTAP v.6.2

The default solution method for the GTAP model is Gragg's method where the model is solved several times with an increasingly fine grid until convergence is achieved. The resulting price changes for commodities as well as for production factors are used in the simulation analysis of the household model.

The study applies the GTAP model with two modifications of the standard GTAP closure:

Closure A: Based on an assumption that there are significant unemployment in developing countries, the real wages for unskilled labour in all developing countries are fixed, and labour supply is endogenous. This allows the unemployed or underemployed

to sell additional labour should there be demand for unskilled-labour intensive goods and services.

Closure B: Fixing the wage of unskilled labour in all developing countries, except Vietnam. In this closure, there is a limit on the maximum increase in unskilled labour in Vietnam of 12 percent. If a trade liberalization scenario results in a simulated increase in labour of 12 percent, then the increase in labour is fixed at 12 percent and wages rise to get the market in equilibrium. The reason of doing so is based on an assumption that there is an unemployment situation in Vietnam and those unemployed are willing to work at current wage level. However, the number can not increase over the total number of unemployed of the society.

According to statistics of Vietnam's General Statistics Office, the unemployment rate of labour in urban areas is 6.28 percent, and under-employment in rural areas is 25.81 percent (GSO, 2001). With about 65 percent of population working in rural areas, the labour force can be mobilized at maximum level about 16 percent[5] at the current wage. We assume that about 12 percent out of that 16 percent of unemployed can find a job, due to limitations of information accession, transportation, skill, etc. Therefore, the closure now fixes the maximum increase in labour supply of Vietnam at 12 percent. When the demand of labour market increase over that level, wage would increase since the elasticity of labour supply is perfectly inelasticity.

Trade Scenarios of Trade Liberalisation Simulation

In this study, several scenarios are explored using the GTAP model:

(1) Unilateral Vietnam trade liberalisation; Vietnam completely removals all of its trade taxes. This voluntary liberalisation enables Vietnam to obtain some benefit itself without negotiating with others. However, the market access benefits are limited because other countries do not open their markets.

(2) AFTA. The second scenario is when Vietnam and all other ASEAN countries fully eliminate all tariff and subsidies, and apply a free trade area in ASEAN. The trade barriers among the other countries still stay the same.

---

[5] According International Labour Organization (ILO), a country is hard to reduce unemployment rate to under 3 percent of the population, even though a very developed economy. Assume that unemployment people are willing to work at the current wage level, the maximum labour can absorb into labour market = 100% - %labour in working - 3% limited = 0.65* (25.81% - 3%) + 0.35*(6.28% - 3%) = 15.97%.

(3) AFTA plus 3. The third scenario involves the extension of AFTA by expanding the free trade area to include Japan, Korea and China. In this scenario, China is a competitor of many ASEAN economies, with its large, low-cost labour force, and it may have some impacts for adjustment in the economies of ASEAN in general and Vietnam in particular.

Bilateral trade agreements are relatively easy to negotiate but are of limited value if the two economies are similar. For developing countries, agreements with large developed countries are generally considered the most beneficial. Two options are investigated:

(4) VNM-USA. An agreement between Vietnam and the USA.

(5) VNM-EU25. Between Vietnam and EU.

Reasons for choosing USA and EU is that both of them are big economies, the USA seems to be potentially an exporter of maize and soybean to Vietnam and it may effect the livestock sector, and both USA and EU are big trade partners of Vietnam in apparel and textile trading.

Multilateral liberalisation refers to a potential WTO agreement. To simplify the analysis the sixth scenario is:

(6) Multilateral. A 50 per cent reduction in tariffs, exports subsidies and domestic support for all regions.

(7) Global. The final simulation is full global liberalization, without any trade barriers among countries over the world that indicate the potential gains from trade liberalisation and the opportunity cost of not liberalising fully.

The GTAP model is firstly run with closure A for all scenario simulations. Where scenarios result in an increase in unskilled labour of more than 12 percent in comparison with the baseline, the simulations are rerun applying closure B.

Table 2: Alternative Trade Scenarios

Scenarios	Description	*Change in tariffs*
1 Unilateral	Vietnam unilateral trade liberalisation	- 100% import tax in VNM
2 AFTA	Free trade area in ASEAN	ASEAN countries exempt 100% import tax to each others
3 AFTA+3	Free trade area in ASEAN plus China, Japan and Korea	ASEAN countries and JPN, KOR, CHN exempt 100% import tax to each others
4 VNM-USA	Bilateral trade between VNM and USA	VNM and USA exempt 100% on trade between 2 countries
5 VNM-EU25	Bilateral trade between VNM and EU	VNM and EU25 exempt 100% on trade between 2 regions
6 Multilateral	Multilateral trade liberalisation	- 50% import tax of all countries
7 Global	Free trade over the world	- 100% tax all regions

2. The Household Model

The Theoretical Framework of a Household Model

This section will present the theoretical framework of a household model. The model of household behavior presented here is a semi-commercial family farm with a competitive labour market. As in other LDCs countries, this type of farm is common in Vietnam, and lies on a continuum between wholly commercialized farms employing only hired labour and marketing all output and a pure subsistence farm using family labour and producing solely for home consumption.

In general, an agricultural household is assumed to maximize its utility function. This is specified as a function of market purchased goods, home produced goods, and leisure time, and is written succinctly as:

$$U = U(L, C, M, a_i) \qquad \qquad i = 1, \ldots, \qquad \qquad (1)$$

where:

L = leisure,

C = own-consumption of agricultural output,

M = consumption of market purchased goods,

a_i = household characteristics (for example, number of dependents)

Clearly, *L, C,* and *M* can be vectors of commodities or leisure consumption for different members of the household. This optimization is subject to certain constraints. In the household model the objective function is constrained by the three restrictions on the household's actions.

The first one is the technology constraint(s):

$$F = F(D, d_{j}, A) \qquad\qquad j=1,\dots, \qquad\qquad (2)$$

where:

F = total agricultural output,

D = total labour inputs (both family and hired) used in production of F,

d_j = other variable inputs,

A = area of land used in F production,

The production function of the household is assumed to be quasi-convex and increasing in inputs, but marginal product is decreasing in inputs. The household can produce more than one output, and hence can have more than one technology constraints. However, the total land for cultivation activity is (here) assumed to be fixed.

The household has the opportunity of utilizing its total endowment of time in either working on or outside its farm, or taking leisure:

$$T = L + H_f + H_{off} \qquad\qquad (3)$$

As mentioned above, the total working time on farm, *D*, includes both family working labour, and labour hired from outside (if needed)

$$D = H_f + H_{hired} \qquad\qquad (4)$$

So by combining (3) and (4) together, we can rewrite the time constraint of the household as follows:

$$T = L + D + H_{off} - H_{hired} \qquad\qquad (5)$$

where

T = total household time available for labour,

L = leisure,

D = total labour inputs (both family and hired) used in production of F,

H_f = time working on its farm of family labour,

H_{off} = time working off- farm of family labour,

H_{hired} = working time of labour hired in for farm,

The household maximizes its utility subject to a budget constraint, which defines that total expenditure for physical commodities can not exceed the total money that household can get from work plus exogenous income. Assume that family labour and hired labour are perfect substitutes and face with the same wage rate.

$$qM + pC = w(H_{off} - H_{hired}) + R + pF - \sum w_j d_j \qquad (6)$$

where

R = non-wage, non-farm net other income,

q = price of M,

p = price of C,

w = wage-rate,

H_{off} = time working off- farm of family labour,

H_{hired} = working time of labour hired in for farm,

w_j = prices of other variable factors.

In order to simplify the problem, those three constraints can be collapsed into a single constraint, namely the "full income" constraint as follows:

$$qM + pC + wL = \Pi + R + wT \qquad (7)$$

where $\Pi = pF(D) - wD - \sum w_j d_j$ is net profit from the household's agricultural production. The left-hand side of equation (7) is total expenditure of the household, includes the "expenditure" on leisure and the right-hand side is an augmented version of Becker's concept of "full income", which is the sum of any non-wage, non-farm net other income (R), a measure of the farm's profits (Π), and the value of the household's stock of time (wT) (Becker, G. 1965). Since land is treated as a fixed factor, the rent payments or receipts, if any, are captured in the definition of R.

This "full income" constraint in particular distinguishes agricultural household models from other approaches and highlights the interdependency between consumption and production decisions made at the household level. Farm technology, quantities of fixed inputs, and prices of variable inputs and outputs affect household consumption decisions since they determine the size of the farm profit portion of the full income constraint.

Thus, this approach permits the identification of the linkages between farm household production and consumption decisions.

By rearranging the full income constraint, the problem of the household becomes one of maximizing its utility (1) with the full income constraint (7). The household can choose quantities of the consumption for commodities and labour input for agricultural production. Forming the Lagrangian, the household problem takes the following form:

$$\Re = U(L,C,M) + \lambda(Y^* - qM - pC - wL) \tag{8}$$

Where λ is the Lagrangian multiplier and Y^* is the value of the full income that results from profit maximizing behavior:

$$Y^* = wT + R + \Pi^* = wT + R + pF(D^*, d_j, \overline{A}) - \sum w_j d_j - wD^* \tag{9}$$

where D^* is labour input that household chose for farm's agricultural production to get maximum profit Π^*, with the land cultivation fixed $\overline{A}$. The Kuhn-Tucker marginal conditions at the point of the optimum are:

$$\frac{\partial \Re}{\partial L} = \frac{\partial U}{\partial L} - \lambda w = 0 \tag{10a}$$

$$\frac{\partial \Re}{\partial M} = \frac{\partial U}{\partial M} - \lambda q = 0 \tag{10b}$$

$$\frac{\partial \Re}{\partial C} = \frac{\partial U}{\partial C} - \lambda p = 0 \tag{10c}$$

$$\frac{\partial \Re}{\partial \lambda} = Y^* - qM - pC - wL = 0 \tag{10d}$$

The marginal conditions of the equations (10) can be solved to yield demand equations for choice variables X_i, which can be *C, M, L* as follows:

$$X_i = X_i(q, p, w, Y^*, a_i) \tag{11}$$

The demand system follows neoclassical theory, where demand depends upon prices, income, and possibly household characteristics. However, in the household model, full income, Y^*, is determined by technological production in the equation (9). Therefore changes in the factors that will influence production, profit, and hence change in Y^* will lead to changes in consumption.

The model is also set up under some simplifying assumptions, which help consumer demand equations and output supply and variable input demand equations be derived by modeling the farm household decision making process recursively as two separate stages, despite their simultaneity in time. These assumptions include: the household is price-taker in all markets and all markets exists; commodities are homogeneous, including the labour market; decisions relating to the total stock of land and labour are treated as given; intertemporal allocation and risk are omitted. (Barnum & Squire 1979).

Results of Econometric Models

This section presents results of econometric estimation for production and consumption aspects of the household model. The production segment is analysed employing a Cobb-Douglas (CD) production function. The consumption side is specified using two stages: the Linear Expenditure System (LES) for a broad grouping of goods and expenditures in the first stage, with the integration between demand for commodities and the allocation of time for leisure and labour supply. In the second stage, expenditure for each of individual commodities in the main food group is allocated using the Linear Approximation Almost Ideal Demand System (LA-AIDS).

The data used in the econometric models are from primary data of the Vietnam Household Living Standard Survey (VHLSS) 2004, a multi-purpose household survey, and is focused on about 7000 households which represent for 8 ecological regions and 64 provinces. Four regions Red River Delta, the Northern upland (includes North East and North West), the Central region (includes North Central Coast, South Central Coast and Central Highland), and the South (includes Mekong River Delta and North East South) have been analyzed, but the current paper only considers a model for 1 region: Red River Delta (RRD), one of the two main important deltas of the country for agricultural production, with 1,533 households. The region accounts for 21.68 percent of the total VHLSS sample.

Production Functions

Assume that the household only takes part in three agricultural production activities: rice cultivation, pig and chicken raising. The production functions take the specific forms as follows:

$$F_{rice} = \alpha_{0r} A^{\alpha_{1r}} D^{\alpha_{2r}} V^{\alpha_{3r}} \tag{12a}$$

$$F_i = \alpha_{0i} G_i^{\alpha_{1i}} D_i^{\alpha_{2i}} V_i^{\alpha_{3i}} \qquad\qquad i = \text{pig, chicken} \qquad\qquad (12b)$$

where A is land cultivation for rice production, D is labour requirement, V are variable inputs, and G is feed for pig or chicken. It is assumed that these production functions can be estimated independently. The result from ordinary least squares estimation of the CD production functions reported in Annex A6, in detail. Here, the estimated production functions for RRD can be summarised by:

$$F_{rice} = 751.48 A^{0.61} D_{rice}^{0.059} V_{seed}^{0.048} V_{fertilizer}^{0.223} V_{pesticide}^{0.058}$$

$$F_{pig} = 0.98 G_{pig}^{0.584} D_{pig}^{0.171} V_{pig}^{0.095}$$

$$F_{chicken} = 0.78 G_{chicken}^{0.46} D_{chicken}^{0.21} V_{chicken}^{0.137}$$

Consumption with Linear Expenditure System (LES) Model in the First Stage

The first stage of demand analysis operates at an aggregate level, and identifies demand functions for food commodities, other expenditure, and at the same time, the household labour supply function is also obtained.

An assertion of the classical theory of consumer demand is that the consumer-worker acts as if maximizing its own-utility function. In this section, a direct utility function is used, based on the Linear Expenditure System (LES) (Stone 1954), which is extremely useful because it assumes consumption is a linear function of prices and disposable income. Since the intra-household distribution can not be considered in detail, it is assumed that the household maximizes its joint utility function, and the utility function for each individual member is identical and is additive over the number of household member. For an individual member of the family the utility function is written as:

$$u = \sum \beta_i \ln(x_i - \gamma_i) \qquad\qquad i=1,\ldots,n, \qquad\qquad (15)$$

where x_i indicates per capita quantity consumption of the ith commodity, and γ_i are committed quantity of ith commodity for consumption, n is total member of the household, and i here includes leisure as a consumption good, with $\sum \beta_i = 1$, and $(x_i - \gamma_i) > 0$

It is assumed that the household in this research consumes three broad groups of purchased commodities: main food, other food and other expenditure (including the industrial commodity group and other daily expenditure), and leisure. Dependents are assumed to consume all their available time in the form of leisure and to consume the

same quantities of other goods as do working family members. The household has n_1 working members and the n_2 dependents, and the total number of members is $n = n_1 + n_2$. For the present application, the following household utility is defined as:

$$U = n_1\beta_1 \ln(l - \gamma_1) + n_2\beta_1 \ln(t - \gamma_1) + n\beta_2 \ln(c_{fd} - \gamma_2) + n\beta_3 \ln(c_{ofd} - \gamma_3) + n\beta_4 \ln(m - \gamma_4)$$

(16)

subject to

$$wL + p_{fd}C_{fd} + p_{ofd}C_{ofd} + qM = E \tag{17}$$

where c_{fd} is per capita consumption of main food group of commodity C_{fd}, c_{ofd} is per capita consumption of commodity group of other foods C_{ofd}, m is per capita consumption of industrial goods and other expenditure M, l is leisure for working member, and L is total leisure time; w, p_{fd}, p_{ofd}, and q are wage of labour, price indices of main food group, other food group, and industrial goods and other expenditure group, respectively. E is full income as defined previously.

By expanding equation (16) with constraint (17) we now have a demand system of equations for the main food group, other food group, and industrial goods and other expenditure (18b-d), and a supply function of labour (18a). The detail of expansion can be found out in the Annex A7.

$$- ws = -\overline{\gamma}w + \beta_1(b + w'\overline{\gamma} - p_{fd}\gamma_2 - p_{ofd}\gamma_3 - q\gamma_4) \tag{18a}$$

and

$$p_{fd}c_{fd} = \gamma_2 p_{fd} + \beta_2(b + w'\overline{\gamma} - p_{fd}\gamma_2 - p_{ofd}\gamma_3 - q\gamma_4) \tag{18b}$$

$$p_{ofd}c_{ofd} = \gamma_3 p_{nfd} + \beta_3(b + w'\overline{\gamma} - p_{fd}\gamma_2 - p_{ofd}\gamma_3 - q\gamma_4) \tag{18c}$$

$$qm = \gamma_4 q + \beta_4(b + w'\overline{\gamma} - p_{fd}\gamma_2 - p_{ofd}\gamma_3 - q\gamma_4) \tag{18d}$$

In this system of equations, there is an intuitively appealing interpretation that each member of the household firstly sets aside subsistence expenditures on the commodities and leisure, then allocates the difference between full income (per capita) and the minimum subsistence expenditures, among leisure time and the various commodities in the fixed proportions β_i.

In estimation of the above system of equations, parameters of γ_i and β_i need to be estimated. The parameters $\overline{\gamma}, \gamma_2, \gamma_3, \gamma_4$ appear in each of the three expenditure and labour

supply equations, and thus the estimation procedure is chosen that constrains the estimates of the $\gamma's$ to be consistent across equations. This is achieved by noting that, for the marginal budget shares to sum to 1, $k\beta_1 + \beta_2 + \beta_3 + \beta_4$ must equal unity: that is, an estimate of β_1 can be obtained from estimates of $\beta_2, \beta_3, \beta_4$. In order to estimate appropriate parameters, identifying prices of each commodity group and the opportunity cost for each day of labour is very important[6].

Estimation of the LES proceeds under the assumption that the disturbance terms in each equation are independent and have zero means and uniform variances. The equation of labour supply was omitted from the system in estimation to avoid singularity of the variance-covariance matrix, hence its parameter, β_1, was obtained from the restriction that the marginal budget shares are add up to 1.

Table 3: Estimated Parameters of the LES of the Household in RRD

Commodity group	Coefficient	Estimate	*T-statistic*
Labour supply	β_1^*	0.223	
	$\bar{\gamma}$	206.35	67.70
Main foods	β_2	0.308	36.93
	γ_2	61.363	42.26
Other foods	β_3	0.334	34.09
	γ_3	-9.07E-14	-3.84
Industry and others	β_4	0.136	21.02
	γ_4	4.024	23.10

: Derived from the restriction that $k\beta_1 + \beta_2 + \beta_3 + \beta_4 = 1$. In calculating β_1, k was set at mean value of 0.682

The estimation of the LES is difficult due to non linearity in the coefficients γ_i and β_i which enter in a multiplicative form. Therefore the technique of Seemingly Unrelated Regression, with an iterative approach is applied to overcome this difficulty. Given initial estimates of the β_i, the remaining parameters were estimated, and then the β_i, re-estimated

---

[6] In the initial method of LES estimation, the wage of labour, or in other words, opportunity cost of each day of labour is based on the market wage. However, some households in the dataset do not take part in the labour market in either selling or buying labour, they only work on their farm. The main reasons may be those households face constraints in seeking off-farm jobs, due to seasonal features of the agricultural sector, or the households live in the isolated areas. For them, using the market wage as the opportunity cost of labour may overstate, or undervalue the cost of family labour, and lead to an inaccurate estimation of their reaction in demand. This raises the need of applying a technique of accounting implicit value of family labour, however, in the limitation of the paper, the technique can not be presented here in detail, but only the result of applying that technique.

given these results. This was continued, iteratively, until parameter estimates converged. The table below presents parameters of the linear expenditure system for households in RRD:

Consumption with Linear Approximately-Almost Ideal Demand System (LA-AIDS) Model in the Second Stage

In the second step of estimating the demand function and assessing the effect of expenditure and price to demand for commodities in the main food group, the AIDS model, proposed by Deaton and Muelbauer (1980) is used.

In the AIDS model, demand is represented by the budget share of each commodity, while prices and income are expressed in logarithms.

The function form of the AIDS model can be expressed as follows:

$$\omega_i = \alpha_i + \sum_j \gamma_{ij} \ln(p_j) + \beta_i \ln(\frac{M}{P}) + \mu_i \tag{19}$$

Where:
w_i is the budget share of a given food commodity
p_i is the price of commodity i
i = rice, pork, chicken, fish and prawn, vegetable, and other meats
M is a measure of household welfare, typically per capita income or per capita expenditure for main food group
μ_i is random disturbances assumed with zero mean and constant variance
P is a translog price index, and defined by

$$\ln P = \alpha_0 + \sum_k \alpha_k \ln p_k + \frac{1}{2} \sum_k \sum_l \gamma_{kl}^* \ln p_k \ln p_l \tag{20}$$

Where k is = 1, …6, l=1,…,6, and the γ_{ij} parameters are defined under symmetry as follows:

$$\gamma_{ij} = \frac{1}{2}(\gamma_{ij}^* + \gamma_{ji}^*) = \gamma_{ji} \tag{21}$$

However, the AIDS model may be difficult to estimate because the price index is not linear in the parameters. In addition, the theory of the household does not provide any empirically plausible value for α_0. Therefore, due to its simplicity, the Linear

Approximate Almost Ideal Demand System (LA/AIDS) with the Stone index is widely used (Asche & Wessells 1997). The Stone's price index (P^*) is calculated as follows:

$$\ln(P^*) = \sum_i w_i \ln(p_i) \qquad (22)$$

Where w_i is the budget share among the commodities, and p_i is price of each individual commodity. But since prices will never be perfectly collinear, it is widely cited that applying the Stone index will introduce some measurement error (Moschini, 1995). The Stone index does not satisfy the fundamental property of index numbers because it is variant to changes in the units of measurement for prices. One solution is to ensure that prices are scaled by their sample mean. Following Moschini's suggestion, a Laspeyres price index can be used to overcome the measurement error. Specifically, the log-linear analogue of the Laspeyres price index is obtained by replacing w_i with $\overline{w_i}$, which is a mean budget share. Hence the Laspeyres price index becomes a geometrically weighted average of prices:

$$\ln(P^L) = \sum_i \overline{w_i} \ln(P_i)$$

An LA/AIDS model with the Laspeyers price index is applied for this study.

$$\omega_i = \alpha_i^{**} + \sum_j \gamma_{ij} \ln(p_j) + \beta_i (\ln(M) - \sum \overline{w_j} \ln(p_j)) + \mu_i^{**} \qquad (23)$$

where $\alpha_i^{**} = \alpha_i - \beta_i (\alpha_0 - \sum_j \overline{w_j} \ln(\overline{p_j}))$

In estimation of the LA-AIDS model, one equation has to be dropped (here other meats), and the Seemingly Unrelated Regression technique was used. The other demand equations are estimated with homogeneity and symmetry restrictions imposed. Estimated parameters of the LA/AIDS and demand elasticities for 6 commodities in the main food group can be found in Annex A8. The results show that all goods in the main food group are inelastic in demand, and also are indicated as necessary goods. The other meat is the most sensitive to expenditure change, followed by pork, fish, and chicken, meanwhile the least sensitive to income are rice and vegetable, which are consistent with prior expectations.

III. Results of Implementation of Trade Liberalisation in the GTAP Model and Linkage between GTAP and Household Model

With the closure A, scenarios (1), (3) and (7) had a simulated increase in labour in excess of 12 percent, and hence had to be resolved using the Closure B.

The results of the GTAP simulations are presented in some broad categories. Table 4 below gives an overview of the output effects of the various scenarios.

Table 4: Initial Values and Percentage Changes in Vietnamese Outputs under the Alternative GTAP Scenarios

Source: GTAP simulations

Significant adjustments in the production can be observed following trade liberalisation. In all scenarios, rice, pig and poultry output increases or at least stays the same. Textile, electronic, and service sectors experience very positive production effects. Meanwhile manufacturing, meats and processed food sectors reduce their production. Of interest is the difference in unilateral and regional or multilateral production. In the unilateral scenario, as countries other than Vietnam do not reduce their tariffs, there is no expansion

in export markets, most sectors contract, except textile and electronic sectors. With liberalisation in AFTA, and AFTA+3 there is an increase in Vietnamese production of oilseeds and chemical plastic products. EU liberalisation leads to an increase in Vietnamese livestock production. This limits the flow of labour into electronics.

Table 5: Initial Value and Percentage Changes in Vietnamese Exports from Alternative Scenarios

Source: GTAP simulations

A more obvious effect on Vietnam of trade liberalisation is the change in trade flows. Table 5 presents changes in exports across the scenarios. Two sectors with a positive change in production, textiles and electronics, also show an increase in exports in the scenarios. These sectors are export oriented. Textile exports are 60 per cent of production and electronics 85 per cent. As with output, the increase in trade is greatest with

unilateral liberalisation. The trade increases are driven by domestic reforms rather than improved market access. In the livestock sector, there is a tendency of reductions in exports in all scenarios, even though production increases. This implies that other countries are sourcing their supplies from elsewhere as a result of lower costs of production in response to tariff changes. The boom in exports of oilseed, dairy products, and chemical and rubber in scenario AFTA+3 can be partly attributed to the importance of China, on Vietnam's doorstep.

In the model closure used here there is no requirement in an individual country that import value must equate to export value. Any increase in the trade deficit will be accommodated by capital inflows. The removal of tariff leads, as expected, to a significant increase in all imports as shown in the table 6. There is a big increase in processed meat consumption, but much of this includes the other meats category. There is significant variation across the scenarios, with the AFTA+3 and the globalisation scenario being most important.

Table 6: Initial Values and Percentage Changes in Vietnamese Imports from Alternative Scenarios

Sector	Initial imports (US$m)	Unila-teral (1)	AFTA (2)	AFTA +3 (3)	VNM-USA (4)	VNM-EU (5)	Multi-lateral (6)	Glob-al (7)

Source: GTAP simulations

Welfare indicators can be seen as a summary of policy changes. They incorporate changes in consumption, production, price and trade flows. The GTAP model uses the concept of equivalent variation[7] (EV) in income to measure welfare effects.

Figure 1 below presents the changes in welfare of Vietnam in the trade liberalisation scenarios. Scenarios of unilateral and multilateral give similar welfare changes for Vietnam. The smallest welfare change happens with bilateral trade liberalization with USA. As expected the biggest welfare gain occurs following full trade liberalisation where the benefits of improved markets access are coupled with improved resource allocation. Also of interest are the quite large gains from unilateral liberalisation, as the reallocation of resources bring huge welfare gains to the economy without the necessity to negotiate with trade partners. Modifying the standard closure of GTAP improves employment situation or unemployment threats in specific sectors and helps enhance the welfare gains of Vietnam.

Figure 1: Vietnam's Welfare Changes Following Alternative Trade Scenarios
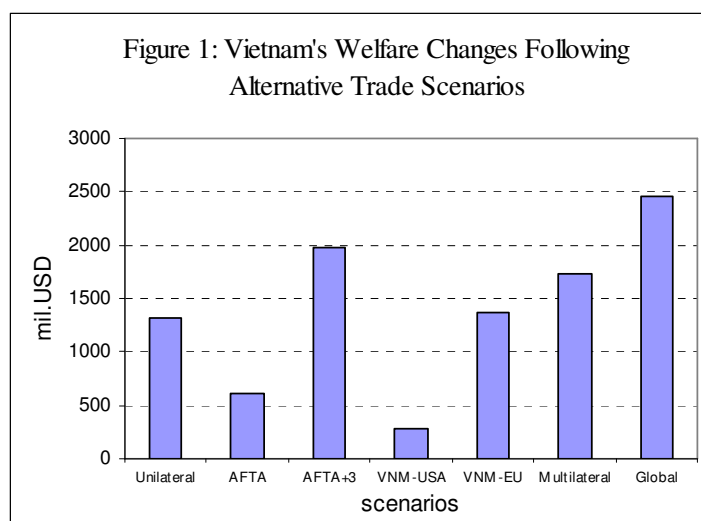

Source: GTAP simulations

---

[7] EV represents the money-metric equivalent to the utility change brought about by a change in prices. It measures the amount of money that would need to be taken away from the consumer before the price change to leave her as well off as she would be after the change in prices.

In order to examine the welfare effects on the household from trade liberalisation scenarios, the price changes from the GTAP model are linked with the household model. Certain assumptions are made to match the different sectors or commodities of GTAP with those in household model. The sectors available in the GTAP database and the aggregation and/or splitting sector/commodities chosen for the liberalisation simulation have to be matched with those of the household model (Refer Annex A6 for more detail). Table 7 below presents changes in market prices taken from GTAP simulations, which have impact on the production behavior of the household.

Table 7: Market Prices Changes of Selected Commodities (percentage)

Sector	Unila-teral	AFTA	AFTA +3	VNM-USA	VNM-EU	Multi-lateral	Glob-al
	(1)	(2)	(3)	(4)	(5)	(6)	(7)
Paddy and processed rice	1.23	3.43	9.39	0.49	3.37	3.34	9.54
Vegetable and fruit	0.63	2.62	9.89	0.27	3.47	3.79	9.69
Other crops	0.22	0.94	4.65	0.27	2.13	1	4.01
Live Pig	0.95	2.71	9.5	0.52	4.39	4.12	9.14
LivePoultry	1.84	4.83	13.66	0.7	5.92	6.85	11.77
Fish	1.06	1.51	3.84	0.9	4.29	2.67	2.36
Oilseed and vegetable oil	-1.06	6.5	11.97	0.37	2.44	2.02	7.9
Processed food	-0.19	0.83	4.4	0.47	3.14	1.74	4.02
Chemical, rubber, plastic	-0.04	0.04	2.75	0.43	2.34	0.89	3.82
Unskilled labour wage	0.31	-1.03	4.44	0.24	2.00	-0.23	8.23

Source: GTAP simulations

Note that scenarios (2), (4), (5) and (6) all assumed that there was sufficient labour available for the market to reach equilibrium without any increase in the unskilled wage. Changes in wages in the table above may thus seem counterintuitive. However, note that this applies to real prices and wages. In the simulation the real wage is maintained, but nominal wage may change as other prices in the system alter.

The differences between the changes in prices of pig and chicken in the scenarios simulations in this table also shows the necessity of splitting pig and chicken separately from the group of live livestock in GTAP database.

Changes in prices of consumption commodities that have impact on household consumption can be seen in the table 8.

Table 8: Change on Consumer Price of Commodities under Alternative Scenarios (percentage)

Source: GTAP simulation

In calculating the welfare impacts on the livestock producing households using the household model, a measure of compensating variation (CV) in income is applied. That is the amount of money which, when taken away from the household after price and income change, leaves the household with the same utility as before the change (Varian 1996)[8]:

$$CV = Y^1 - Y^0 - \left[e(p^1, u^0) - e(p^0, u^0) \right]$$

---

[8] This differs from the equivalent variation used in the GTAP model to measure welfare.

where: Y^1 is income after the price change from p^0 to p^1, Y^0 is income in the baseline period, and the expenditure function e(p,u) is the minimum income which is necessary to reach the level utility u at given price p.

The compensating variation of the household measured as the change in utility for each scenario is presented in figure 2 below:

Figure 2: Household's Welfare Changes Following Alternative Trade Scenarios
Source: Household model simulation

Total welfare gain of livestock households is relatively small in the scenario of multilateral and regional liberalisation within ASEAN, meanwhile bilateral trade agreements with EU make the household worse off in terms of welfare. The most significant gain is obtained with full liberalisation over the world, with the household's welfare increasing more than 18 percent in comparison with the base line.

Going along with tendency of increased production of chicken over the country (see table 4 above), in almost all simulations, the household increases its chicken production (figure 3 below).

Figure 3: Changes of Household's Production Following Alternative Trade Scenarios
Source: Household model simulation

As expected, in the regional and multilateral trade simulations, due to a more open economy and decreased taxes, the domestic consumers get more benefit from consuming cheaper commodities, and the result is an improvement of household's utility from consumption of more food as well as industrial goods, as shows in the figure 4 below:

Figure 4: Changes of Household Consumption Following Alternative Trade Scenarios
Source: Household model simulation

In Figure 5, the change in household's welfare through trade scenarios can be explained by changes in consumption of the household. Only three scenarios are reported, ranging from those with the smallest welfare change to the largest. Decrease of all commodity consumption as well as leisure is the reason for the decrease of welfare in the simulation

of bilateral trade with EU, which is totally opposite to the increase in consumption of the household in the other scenarios, which show household welfare increasing.
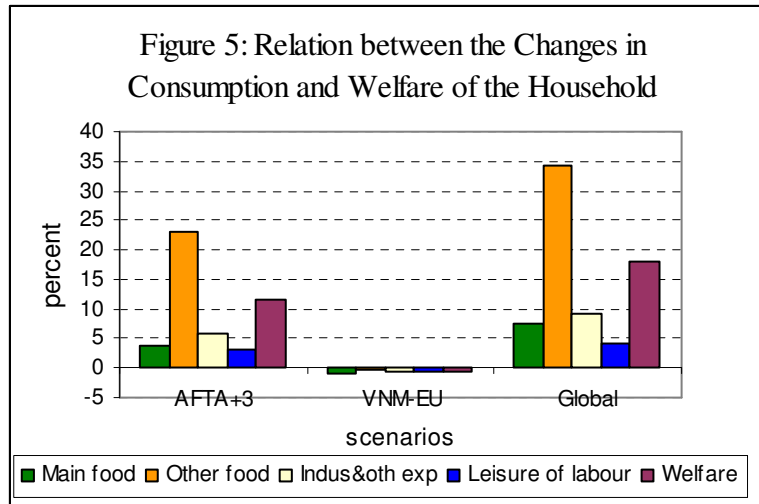

Source: Household model simulation

IV. Conclusions

The current paper develops a link between GTAP results and a household model to examine welfare changes of small livestock producers in Vietnam following trade liberalisation. GTAP has been used since 1992, and there have been some previous applications to Vietnam. Household models have been developed for around 30 years and applied to many countries, but this is the first application to the livestock sector in Vietnam (although there have been some other microeconomic models developed). This is the first application that links a GTAP macro model to a household micro-level model for the livestock sector in Vietnam.

By linking GTAP with a household model, in this paper we examine how small livestock households react to changes in economic policies, especially in the context of trade liberalisation. This is especially important, given that livestock plays a very important role in the agricultural sector and small households are dominant in livestock production in Vietnam. Analytical results from the household model also allow one to see how the household behaviors change when they are both consumers and producers. Taking into account how income effects from production, via profit, influences consumption, gives a more accurate assessment. Using SplitCom allows the pig and chicken sectors to be disaggregated from aggregate data, and hence a more accurate measure of the change in household production to different price signals is captured.

Regarding the impacts of trade liberalisation on the household, the results from different liberalisation scenarios show that Vietnam's small households in the livestock sector would benefit from regional and multilateral trade liberalisation. The largest benefit that households can have is if full trade liberalisation occurs over the world. The welfare of the household is dominated by the effect of the household's labour decision, working or taking leisure, rather than the increase in production profit and consumption on commodities only.

A7: Expansion of demand system LES

The household utility is defined as:

$$U = n_1\beta_1 \ln(l - \gamma_1) + n_2\beta_1 \ln(t - \gamma_1) + n\beta_2 \ln(c_{fd} - \gamma_2) + n\beta_3 \ln(c_{ofd} - \gamma_3) + n\beta_4 \ln(m - \gamma_4)$$

(16)

subject to

$$wL + p_{fd}C_{fd} + p_{ofd}C_{ofd} + qM = E$$

(17)

Substituting $l=t-s$ to the equation (16), where t is the total time available per individual, s is the quantity of time supplied to work activities, and dividing equally the household utility function for n, the problem now is maximizing individual member's utility function:

$$u = k\beta_1 \ln(t - s - \gamma_1) + (1 - k)\beta_1 \ln(t - \gamma_1) + \beta_2 \ln(c_{fd} - \gamma_2) + \beta_3 \ln(c_{ofd} - \gamma_3) + \beta_4 \ln(m - \gamma_4)$$

(16a)

subject to
$$kw(t - s) + p_{fd}c_{fd} + p_{ofd}c_{ofd} + qm = E/n$$
(17a)

where $k = n_1/n$. Let $\beta_1' = k\beta_1$ and $w' = kw$, then it is apparent that the problem is that of the standard linear expenditure system, for which the expenditure equations are

$$w(t - s) = \gamma_1 w + \beta_1(E/n - w'\gamma_1 - p_{fd}\gamma_2 - p_{ofd}\gamma_3 - q\gamma_4)$$

(a1)

$$p_{fd}c_{fd} = \gamma_2 p_{fd} + \beta_2(E/n - w'\gamma_1 - p_{fd}\gamma_2 - p_{ofd}\gamma_3 - q\gamma_4)$$

(b1)

$$p_{nfd}c_{nfd} = \gamma_3 p_{nfd} + \beta_3(E/n - w'\gamma_1 - p_{fd}\gamma_2 - p_{ofd}\gamma_3 - q\gamma_4)$$

(c1)

$$qm = \gamma_4 q + \beta_4(E/n - w'\gamma_1 - p_{fd}\gamma_2 - p_{ofd}\gamma_3 - q\gamma_4)$$

(d1)

However, one of the problems in estimating the model is that the measurement of leisure as a residual after deducting working time from total available time may introduce a specification error (Abbott & Ashenfelter 1976). Following their approach, we modify the system of equations by substituting $(t - \bar{\gamma})$ for γ_1 in the equation (a1). This yield:

$$-ws = -\bar{\gamma}w + \beta_1(b + w'\bar{\gamma} - p_{fd}\gamma_2 - p_{ofd}\gamma_3 - q\gamma_4)$$

(a2)

and

$$p_{fd}c_{fd} = \gamma_2 p_{fd} + \beta_2(b + w'\bar{\gamma} - p_{fd}\gamma_2 - p_{ofd}\gamma_3 - q\gamma_4) \quad\quad\quad\quad (b2)$$

$$p_{ofd}c_{ofd} = \gamma_3 p_{nfd} + \beta_3(b + w'\bar{\gamma} - p_{fd}\gamma_2 - p_{ofd}\gamma_3 - q\gamma_4) \quad\quad\quad (c2)$$

$$qm = \gamma_4 q + \beta_4(b + w'\bar{\gamma} - p_{fd}\gamma_2 - p_{ofd}\gamma_3 - q\gamma_4) \quad\quad\quad\quad (d2)$$

where $b = w's + p_{fd}c_{fd} + p_{ofd}c_{ofd} + qm = -kws + p_{fd}c_{fd} + p_{ofd}c_{ofd} + qm$
