#### Abstract

The mechanism of the CO ligand dissociation of fac- $\left[\operatorname{Re}^{\mathrm{I}}(\mathrm{bpy})(\mathrm{CO})_{3} \mathrm{P}(\mathrm{OMe})_{3}\right]^{+}$has theoretically been investigated, as the dominant process of the photochemical ligand substitution (PLS) reactions of fac-[ $\left.\mathrm{Re}^{\mathrm{I}}(\mathrm{bpy})(\mathrm{CO})_{3} \mathrm{PR}_{3}\right]^{+}$, by using the (TD-)DFT method. The PLS reactivity can be determined by the topology of the $T_{1}$ potential energy surface, since the photoexcited complex is able to decay into the $\mathrm{T}_{1}$ state by internal conversions (through conical intersections) and intersystem crossings (via crossing seams) with sufficiently low energy barriers. The $\mathrm{T}_{1}$ state has a character of the metal-to-ligand charge-transfer ( ${ }^{3} \mathrm{MLCT}$ ) around the Franck-Condon region, and it changes to the metal-centered ( ${ }^{3} \mathrm{MC}$ ) state as the $\mathrm{Re}-\mathrm{CO}$ bond is elongated and bent. The equatorial CO ligand has a much higher energy barrier to leave than that of the axial CO, so that the axial CO ligand selectively dissociates in the PLS reaction. The single-component artificial force induced reaction (SC-AFIR) search reveals the CO dissociation pathway in photostable fac-[ $\left.\operatorname{Re}^{\mathrm{I}}(\mathrm{bpy})(\mathrm{CO})_{3} \mathrm{Cl}\right]$ as well, however, the dissociation barrier on the $\mathrm{T}_{1}$ state is substantially higher than that in $f a c-\left[\operatorname{Re}^{\mathrm{I}}(\mathrm{bpy})(\mathrm{CO})_{3} \mathrm{PR}_{3}\right]^{+}$and the minimum-energy seams of crossings (MESXs) are located before and below the barrier. The MESXs have also been searched in fac-[ $\left.\operatorname{Re}^{\mathrm{I}}(\mathrm{bpy})(\mathrm{CO})_{3} \mathrm{PR}_{3}\right]^{+}$and no MESXs were found before and below the barrier.

## 1. Introduction

The photochemistry and photophysics of the rhenium(I) diimine tricarbonyl complexes, fac-[ReI(bpy) $\left.(\mathrm{CO})_{3} \mathrm{~L}\right]^{n+}\left(\right.$ bpy $=2,2^{\prime}$-bipyridine, $\mathrm{L}=$ various monodentate ligands, $\left.n=0,1\right)$, have attracted a lot of interests since they show emissions in good quantum yields even in solution at ambient temperature ${ }^{1}$ and can play a role as a photocatalyst for $\mathrm{CO}_{2}$ reduction. ${ }^{2,3}$ The electronic states of these complexes are characterised by 5d orbitals of the rhenium atom ( $\mathrm{d}^{6}$ metal ion) and low-lyingandorb the charge-transfer (CT), ligand-centered (LC), and metal-centered (MC) states appear as low-lying electronic excited states in their photochemistry. Detailed understanding of their energetics and dynamics is important to design new photo-functional materials. Triplet metal-to-ligand charge-transfer ( ${ }^{3}$ MLCT) states have been mostly studied over the last three decades, because such emissions or photo-catalytic activities are closely related to the lowest ${ }^{3}$ MLCT state. ${ }^{4}$ The ${ }^{3}$ MLCT state cannot be optically accessed from the electronic ground state, which is a singlet state herein, while the initial photoactivation of the rhenium(I) complexes is of singlet metal-to-ligand charge-transfer ( ${ }^{1}$ MLCT) character. The ${ }^{3}$ MLCT state should be populated via the intersystem crossing (ISC) between the singlet and triplet states and the internal conversion (IC) of the singlet-singlet or triplet-triplet states. Such a decay process can be achieved in several hundreds of femtoseconds. ${ }^{5-7}$

The complex with a halide ligand, e.g. fac- $\left[\operatorname{Re}^{\mathrm{I}}(\mathrm{bpy})(\mathrm{CO})_{3} \mathrm{Cl}\right]$, is thermally and photochemically robust under low-energy ultraviolet (UV) light ( $\square>330 \mathrm{~nm}$ ). ${ }^{8-10}$ On the other hand, the complex with a phosphorus ligand, e.g. $f a c-\left[\mathrm{Re}^{\mathrm{I}}(\mathrm{bpy})(\mathrm{CO})_{3} \mathrm{P}(\mathrm{OEt})_{3}\right]^{+}(\mathrm{Et}=$ $\mathrm{CH}_{2} \mathrm{CH}_{3}$ ), is photoactive; it shows the photochemical ligand substitution (PLS) reactions (Scheme 1) in which the axial CO ligand is substituted by a solvent molecule, e.g. $\mathrm{CH}_{3} \mathrm{CN}$
(acetonitrile). ${ }^{11,12}$ The PLS is a typical reaction that proceeds via the ${ }^{3} \mathrm{MC}$ state of $\mathrm{d}^{6}$ metal complexes, which can be understandable qualitatively by the conventional ligand-field theory. ${ }^{13}$ Ishitani and co-workers have proposed the following mechanisms (Scheme 2) from their experimental results: ${ }^{11,14}$
a) Of the phosphorus complexes, the ${ }^{3} \mathrm{MC}$ state is energetically accessible from the ${ }^{3} \mathrm{MLCT}$ state and the potential energy surface of the ${ }^{3} \mathrm{MC}$ state is repulsive along the $\mathrm{Re}-\mathrm{CO}$ dissociation coordinate.
b) Of the halide complexes, the ${ }^{3} \mathrm{MC}$ state is also accessible from the ${ }^{3} \mathrm{MLCT}$ state, but there is an extra potential barrier which has a rather high activation energy for the Re-CO dissociation because of the trans effect of the ligand.

However, the mechanism of the PLS or the reason for the photostability of the halide complexes remain obscure because there are no theoretical investigations so far for the relationship between the ${ }^{3} \mathrm{MLCT}$ (or ${ }^{1} \mathrm{MLCT}$ ) and ${ }^{3} \mathrm{MC}$ states, and the potential barriers in the ${ }^{3} \mathrm{MC}$ state.

In this study, the CO ligand dissociation pathway of $f a c-\left[\operatorname{Re}^{\mathrm{I}}(\mathrm{bpy})(\mathrm{CO})_{3} \mathrm{P}(\mathrm{OMe})_{3}\right]^{+}(\mathrm{Me}=$ $\mathrm{CH}_{3}$ ) - as the dominant process in the PLS reactions - has been explored by $a b$ initio quantum chemistry calculations. Geometry optimisations were achieved, not only for the equilibrium structures (EQs) but also for the conical intersections (CIs) and the seams of crossing (SXs). Characterizing CI and SX is important since the IC or ISC efficiently occurs at the CI or SX, respectively. ${ }^{15}$ Generally speaking, the geometry optimisation for a CI (or a SX) requires a computation of the non-adiabatic coupling matrix elements (NACMEs) and the complete-active-space self-consistent-field (CASSCF) method ${ }^{16}$ or much higher levels of $a b$ initio electronic structure theory can only compute the NACMEs, but the CASSCF
calculation is demanding and costly so that it cannot be applied to $f a c-\left[\mathrm{Re}^{\mathrm{I}}(\mathrm{bpy})(\mathrm{CO})_{3} \mathrm{P}(\mathrm{OMe})_{3}\right]^{+}$. With a help of the branching-plane updating method, ${ }^{17}$ the CIs and SXs can be optimised ${ }^{18}$ by the TD-DFT level of theory ${ }^{19}$ which is less expensive than the CASSCF and affordable, without computing the NACMEs at all. Here we discuss the relaxation process into the ${ }^{3} \mathrm{MLCT}$ state inclusively, and then the ${ }^{3} \mathrm{MLCT} /{ }^{3} \mathrm{MC}$ transition, the barrier in the ${ }^{3} \mathrm{MC}$ state, the SXs to the ground state, as well. Hence, this is the first report on theoretically studied mechanisms of the PLS reactions of the rhenium(I) diimine tricarbonyl complex with a phosphorus ligand.

## 2. Computational details

The minima of the potential energy surfaces and the minimum energy conical intersections (MECIs) for $\mathrm{S}_{3} / \mathrm{S}_{2}, \mathrm{~S}_{2} / \mathrm{S}_{1}$, and $\mathrm{T}_{2} / \mathrm{T}_{1}$, and the minimum energy seams of crossings (MESXs) for $S_{1} / T_{2}$ and $T_{1} / S_{0}$ were explored by the single-component artificial force induced reaction (SC-AFIR) method ${ }^{20}$ associated with the seam model function (SMF). ${ }^{21}$ It should be noted that the MECIs and MESXs were optimised by the branching-plane updating method ${ }^{17}$ without computing the non-adiabatic coupling matrix element (NACME) vectors. The collision energy parameter $\square=150 \mathrm{~kJ} \mathrm{~mol}^{-1}$ was adopted in the automated search of the SC-AFIR method. The automated search was performed at the (TD-)B3LYP ${ }^{23} / 6-31 G(d) /$ SDD level of calculation; the 6-31G basis set ${ }^{24}$ was applied to $\mathrm{H}, \mathrm{C}, \mathrm{N}, \mathrm{O}$ atoms, the 6-31G(d) to P atom, ${ }^{25}$ and SDD (Stuttgart/Dresden) ECP basis set with quasi-relativistic effect corrections to Re atom. ${ }^{26}$ Solvent effects of acetonitrile were considered by the conductor-like polarizable continuum model (C-PCM). ${ }^{27}$ In this model the equilibrium solvation was taken into account. The obtained structures by the SC-AFIR search were refined at the
(TD-)B3LYP/cc-pVDZ ${ }^{28} /$ SDD level with the C-PCM. The TD-DFT method with the B3LYP functional and the C-PCM reproduced the experimental absorption peak well for fac-[ $\left.\operatorname{Re}^{\mathrm{I}}(\mathrm{bpy})(\mathrm{CO})_{3} \mathrm{X}\right](\mathrm{X}=\mathrm{Cl}, \mathrm{Br}, \mathrm{I}) .{ }^{6,22}$ This level of theory also works in the case with $f a c-\left[\mathrm{Re}^{\mathrm{I}}(\mathrm{bpy})(\mathrm{CO})_{3} \mathrm{P}(\mathrm{OMe})_{3}\right]^{+}$as shown below. All these calculations were computed using a developmental version of the GRRM program ${ }^{29}$ combined with the Gaussian 09 electronic structure calculation program. ${ }^{30}$ The spin-orbit coupling (SOC) constants were also computed by the linear response approach ${ }^{31}$ using the Dalton 2015.1 quantum chemistry program system. ${ }^{32}$

## 3. Results and Discussion

### 3.1 The Excited States and the Relaxation Pathway

Table 1 shows the relative energies of the low-lying singlet $\left(\mathrm{S}_{1}, \mathrm{~S}_{2}\right.$, and $\mathrm{S}_{3}$ ) and triplet ( $\mathrm{T}_{1}$, $\mathrm{T}_{2}, \mathrm{~T}_{3}$, and $\mathrm{T}_{4}$ ) electronic excited states of $f a c-\left[\mathrm{Re}^{\mathrm{I}}(\mathrm{bpy})(\mathrm{CO})_{3} \mathrm{P}(\mathrm{OMe})_{3}\right]^{+}$, and the oscillator strengths of the excitations from the ground $\left(\mathrm{S}_{0}\right)$ state as well. These electronic states are characterised by three 5 d orbitals of the rhenium atom and low-lying localised on the bpy ligand (Fig. 1) which is the same as fac-[ $\left.\operatorname{Re}^{\mathrm{I}}(\mathrm{bpy})(\mathrm{CO})_{3} \mathrm{X}\right](\mathrm{X}=\mathrm{Cl}, \mathrm{Br}$, I) complexes. ${ }^{6,7,22}$ Although the $\mathrm{T}_{1}$ and $\mathrm{T}_{3}$ states include the LC excitation, HOMO-3 (99a) $\rightarrow$ LUMO (103a), all of the low-lying states indicate the MLCT character between the rhenium atom and bpy moiety. It is well reported that the photoexcitation of the $\operatorname{Re}(\mathrm{I})$ diimine tricarbonyl complexes corresponds to the MLCT excitation. ${ }^{6,7}$ The $S_{3} \leftarrow S_{0}$ vertical excitation energy, 3.62 eV (which corresponds to 319 nm in wavelength), is in good agreement with the experimental absorption peak, ${ }^{33}$ and its oscillator strength $f=0.1044$ is sufficiently larger
than the $\mathrm{S}_{2} \leftarrow \mathrm{~S}_{0}$ or $\mathrm{S}_{1} \leftarrow \mathrm{~S}_{0}$ excitations. Then we assume the following relaxation pathway starts on the $\mathrm{S}_{3}$ state in the Franck-Condon (FC) region.

Several important structural parameters of $f a c-\left[\operatorname{Re}^{\mathrm{I}}(\mathrm{bpy})(\mathrm{CO})_{3} \mathrm{P}(\mathrm{OMe})_{3}\right]^{+}$optimised in the low-lying excited states are listed on Table 2 . Once the $S_{3} \leftarrow S_{0}$ photoexcitation occurs, the molecule starts moving towards the minimum ( $\mathrm{S}_{3}-\mathrm{min}$ ), since the potential energy surface is downhill in the FC region. In this system the minimum-energy CI between the $S_{3}$ and $S_{2}$ states $\left(\mathrm{S}_{3} / \mathrm{S}_{2}\right.$-MECI) is very close to the $\mathrm{S}_{3}$-min and there are almost no barriers, so that the system can be easily relaxed into the $S_{2}$ state. Similarly it goes into the $S_{1}$ state through the $\mathrm{S}_{2} / \mathrm{S}_{1}$-MECI, which exists near the $\mathrm{S}_{2}$-min, as well. Such a relaxation process has been practically understood as the Kasha's rule; ${ }^{34}$ however, here we can characterise the pathway by optimising the minima and MECIs. In the FC region, the spin-orbit couplings between singlet and triplet states are not large enough (the coupling constants are less than $10 \mathrm{~cm}^{-1}$ ), and internal conversions through MECIs into the $S_{1}$ state are preferable. Therefore only the intersystem crossing between the $S_{1}$ and triplet states are considered here. In the $S_{1}$ state, the spin-orbit coupling with the $\mathrm{T}_{2}$ or $\mathrm{T}_{3}$ state is relatively strong (the coupling constants of the $\mathrm{S}_{1}$ with the $\mathrm{T}_{1}, \mathrm{~T}_{2}, \mathrm{~T}_{3}$, and $\mathrm{T}_{4}$ states are $0.89,5.18,5.99$, and $2.55 \mathrm{~cm}^{-1}$, respectively). The minimum-energy $S X$ between the $S_{1}$ and $T_{2}$ states ( $S_{1} / T_{2}$-MESX) is located with a barrier of 0.03 eV from the $\mathrm{S}_{1}$-min. The $\mathrm{S}_{1} / \mathrm{T}_{3}$-MESX is also located at 0.09 eV above the $\mathrm{S}_{1}$-min, but, the main exit from the $S_{1}$ state would be the $S_{1} / T_{2}$-MESX energetically. At the $S_{1} / T_{2}$-MESX, the complex could undergo intersystem crossing to the $\mathrm{T}_{2}$ state requiring no thermal activation. Then, the system relaxes into the $\mathrm{T}_{1}$ state quickly, because the minimum of the $\mathrm{T}_{2}$ state corresponds to a $\mathrm{T}_{2} / \mathrm{T}_{1}$-MECI. The resulting $\mathrm{T}_{1}$ state is also the ${ }^{3}$ MLCT state ( $102 a \rightarrow$

103a, Fig. 2). This relaxation process can be compared to those for $\left[\operatorname{Re}(\mathrm{bpy})(\mathrm{CO})_{3} \mathrm{X}\right](\mathrm{X}=$ $\mathrm{Cl}, \mathrm{Br}, \mathrm{I})$ complexes. Experimentally, both ${ }^{3} \mathrm{MLCT}$ and ${ }^{3} \mathrm{LC}$ states were shown to be involved in the relaxation dynamics in the case of $\left[\operatorname{Re}(\mathrm{bpy})(\mathrm{CO})_{3} \mathrm{Cl}\right] .{ }^{8}$ Consistently, it has been suggested theoretically that the ISC occurs to both $\mathrm{T}_{2}\left({ }^{3} \mathrm{MLCT}\right)$ and $\mathrm{T}_{3}\left({ }^{3} \mathrm{LC}\right)$ states. ${ }^{6,22}$ It has also been shown that the ISC to the $\mathrm{T}_{2}\left({ }^{3} \mathrm{MLCT}\right)$ state is the main path, and the system finally relaxes into the $\mathrm{T}_{1}\left({ }^{3} \mathrm{MLCT}\right)$ state by internal conversions. The PLS reaction therefore occurs on the $\mathrm{T}_{1}$ surface in both $\left[\mathrm{Re}^{\mathrm{I}}(\mathrm{bpy})(\mathrm{CO})_{3} \mathrm{P}(\mathrm{OMe})_{3}\right]^{+}$and $\left[\mathrm{Re}(\mathrm{bpy})(\mathrm{CO})_{3} \mathrm{Cl}\right]$.

In this relaxation pathway, the deformations of molecular geometry are very small. The elongations of the $\mathrm{Re}-\mathrm{P}, \mathrm{Re}-\mathrm{C}_{\mathrm{ax}}$, and $\mathrm{Re}-\mathrm{C}_{\mathrm{eq}}$ bond lengths do not exceed $0.078 \AA(\sim 3 \%)$, $0.052 \AA(\sim 3 \%)$, and $0.077 \AA(\sim 4 \%)$, respectively. The $\mathrm{C}_{\text {eq }}-$ Re- $\mathrm{C}_{\text {eq }}$ angle varies between $85.04^{\circ}$ and $95.65^{\circ}$, and this is the largest change among the bond angles. These features are quite similar to $\left[\operatorname{Re}(\mathrm{bpy})(\mathrm{CO})_{3} \mathrm{X}\right](\mathrm{X}=\mathrm{Cl}, \mathrm{Br}, \mathrm{I})$ complexes, ${ }^{6}$ although the XLCT (halide-to-ligand CT) character is absent. The XLCT character might contribute to lower energy levels of the excited states in $\left[\operatorname{Re}(\mathrm{bpy})(\mathrm{CO})_{3} \mathrm{Cl}\right]$ system by $0.2-0.5 \mathrm{eV}$.

### 3.2 Mechanism of the Photochemical Ligand Substitution (PLS) Reaction

After the photoexcitation and the ISC between the singlet and triplet states, the fac- $\left[\mathrm{Re}^{\mathrm{I}}(\mathrm{bpy})(\mathrm{CO})_{3} \mathrm{P}(\mathrm{OMe})_{3}\right]^{+}$relaxes to the $\mathrm{T}_{1}$ state, which is the ${ }^{3} \mathrm{MLCT}$. As described above, the PLS is a typical reaction that proceeds via the MC state of $\mathrm{d}^{6}$ metal complexes, but no crossings of MLCT/MC states appeared on the relaxation path. Ishitani and co-workers ${ }^{11}$ reported the $f a c-\left[\operatorname{Re}^{\mathrm{I}}(\mathrm{bpy})(\mathrm{CO})_{3} \mathrm{P}(\mathrm{OMe})_{3}\right]^{+}$shows an emission $\left(\square_{\text {max }}=543 \mathrm{~nm}\right.$, $\mathrm{m}^{=}$ 0.216 ) with $1 \square$ of lifetime, and also the PLS reaction ( $\square=0.118$ ) competes with the emission. Their experimental results strongly suggested 1) the PLS reaction occurs via a ${ }^{3} \mathrm{MC}$
state which is thermally accessible from the ${ }^{3}$ MLCT state, and 2$)$ the axial $\mathrm{CO}\left(\mathrm{CO}_{\mathrm{ax}}\right)$ is selectively dissociated but any equatorial $\mathrm{COs}\left(\mathrm{CO}_{\text {eq }}\right)$ are not. From these points of view, the reactivity for the PLS reaction can be characterised by the topology of the $T_{1}$ surface along the $\mathrm{Re}-\mathrm{CO}_{\mathrm{ax}}$ dissociation coordinate, and the character of the $\mathrm{T}_{1}$ state would change from ${ }^{3} \mathrm{MLCT}$ to ${ }^{3} \mathrm{MC}$.

In this study a local minimum on the $T_{1}$ potential energy surface, at which the $\mathrm{Re}-\mathrm{C}_{\mathrm{ax}}$ is lengthened by $0.177 \AA$ and the $R e-C_{a x}-\mathrm{O}_{\mathrm{ax}}$ angle is bent by $49.30^{\circ}$, was found $\left(\mathrm{T}_{1}-\mathrm{min}\right.$ (bent)). At the $\mathrm{T}_{1}$-min (bent) the singly occupied molecular orbitals (SOMOs) consist mostly of the 5 d orbitals (Fig. 3), so that the character of the $\mathrm{T}_{1}$ state changes from the ${ }^{3}$ MLCT to the ${ }^{3} \mathrm{MC}$. Also the transition state (TS) between the $\mathrm{T}_{1}$-min (global) and $\mathrm{T}_{1}$-min (bent) was optimised. It corresponds to a critical point of the ${ }^{3} \mathrm{MLCT} /{ }^{3} \mathrm{MC}$ states. The TD-DFT calculation supports that this is an avoided crossing between the $T_{1}$ and $T_{2}$ states. On the ${ }^{3} \mathrm{MC}$ state the low-energy barrier, $0.17 \mathrm{eV}\left(16.08 \mathrm{~kJ} \mathrm{~mol}^{-1}\right)$ above the $\mathrm{T}_{1}$-min (bent), exists as a TS along the $\mathrm{Re}-\mathrm{CO}_{\mathrm{ax}}$ dissociation coordinate ( $\mathrm{T}_{1}-\mathrm{TS}$ (dissociation)). Some of the structural parameters are summarised in Table 3, and the energy profile is depicted in Fig. 4 (a).

To evaluate whether the B3LYP functional and C-PCM model describes the relative energy between the MLCT and MC states properly, the kinetic data is calculated and it is compared with the experimental data. ${ }^{11}$ The overall PLS reaction rate constant $k_{r}^{\prime}$ can be written by the rate constants for elementary steps, $k_{\text {th }}\left(\mathrm{T}_{1}-\right.$ min (global) $\rightarrow \mathrm{T}_{1}-\mathrm{TS}$ (bent)), $k_{\text {-th }}\left(\mathrm{T}_{1}-\mathrm{TS}\right.$ (bent) $\rightarrow$ $\mathrm{T}_{1}$-min (global)), and $k_{\mathrm{r}}\left(\mathrm{T}_{1}-\mathrm{TS}\right.$ (bent) $\rightarrow \mathrm{T}_{1}-\mathrm{TS}$ (dissociation)). Once the CO ligand leaves it is assumed that no CO ligand returns to the $\mathrm{T}_{1}$-min (bent), so that $k_{-\mathrm{r}}\left(\mathrm{T}_{1}-\mathrm{TS}\right.$ (dissociation) $\rightarrow$
$\mathrm{T}_{1}-\mathrm{TS}$ (bent)) to be zero. Then the overall PLS reaction rate constant $k_{\mathrm{r}}^{\prime}$ based on the steady state approximation is

$$
\begin{equation*}
k_{r}^{\prime}=\left(k_{t h} \cdot k_{r}\right) /\left(k_{t h}+k_{-t h}+k_{r}\right) \tag{1}
\end{equation*}
$$

and the overall free energy barrier ( $\square G^{\prime}$ ) can be calculated as

$$
\begin{equation*}
\Delta G_{r}^{\prime} \approx-\ln k_{r}^{\prime} \cdot R T \tag{2}
\end{equation*}
$$

where $R$ is the gas constant and $T$ is the temperature. The calculated relative free energies at 298 K at the $\mathrm{T}_{1}$-min (global), $\mathrm{T}_{1}-\mathrm{TS}$ (bent), $\mathrm{T}_{1}$-min (bent), and $\mathrm{T}_{1}-\mathrm{TS}$ (dissociation) are $2.619,2.945,2.915$, and 2.970 eV , respectively. So that the rate constants $k_{\mathrm{th}}, k_{\text {-th }}$, and $k_{\mathrm{r}}$ are $1.22 \times 10^{8}, 1.26 \times 10^{14}$, and $4.52 \times 10^{12} \mathrm{~s}^{-1}$, respectively. Consequently the overall reaction rate constant $k_{r}^{\prime}$ and the free energy barrier $\Delta G_{r}{ }^{\prime}$ can be calculated as $4.23 \times 10^{6} \mathrm{~s}^{-1}$ and 3323 $\mathrm{cm}^{-1}$. The experimentally reported free energy barrier at $298 \mathrm{~K}\left(\Delta G^{\ddagger} 298\right)$ is $3740 \pm 760 \mathrm{~cm}^{-1}$. Here, the B3LYP functional was successful in describing these MLCT and MC states.

In contrast to $f a c-\left[\mathrm{Re}^{\mathrm{I}}(\mathrm{bpy})(\mathrm{CO})_{3} \mathrm{P}(\mathrm{OMe})_{3}\right]^{+}$, the rhenium diimine tricarbonyl complex with halide ligand fac-[ $\left.\operatorname{Re}^{\mathrm{I}}(\mathrm{bpy})(\mathrm{CO})_{3} \mathrm{Cl}\right]$ is photostable and no PLS reaction is observed. ${ }^{11,12}$ What does control reactivity for the PLS reaction? We have explored the $\mathrm{Re}-\mathrm{CO}_{\mathrm{ax}}$ dissociation pathway of $f a c-\left[\mathrm{Re}^{\mathrm{I}}(\mathrm{bpy})(\mathrm{CO})_{3} \mathrm{Cl}\right]$ and the structural parameters are summarised in Table 4, and the energy profile is depicted in Fig. 4 (b). As well as fac-[ $\left.\mathrm{Re}^{\mathrm{I}}(\mathrm{bpy})(\mathrm{CO})_{3} \mathrm{P}(\mathrm{OMe})_{3}\right]^{+}$, the minimum in the ${ }^{3} \mathrm{MC}$ state, at which the $\mathrm{Re}-\mathrm{C}_{\mathrm{ax}}$ is lengthened by $0.127 \AA$ and the $\mathrm{Re}-\mathrm{C}_{\mathrm{ax}}-\mathrm{O}_{\mathrm{ax}}$ angle is bent by $50.69^{\circ}$, was found. There is a barrier of $0.378 \mathrm{eV}\left(36.47 \mathrm{~kJ} \mathrm{~mol}^{-1}\right)$ to the $\mathrm{Re}-\mathrm{CO}_{\mathrm{ax}}$ dissociation. The barrier is substantially higher than that in the case of $f a c-\left[\mathrm{Re}^{\mathrm{I}}(\mathrm{bpy})(\mathrm{CO})_{3} \mathrm{P}(\mathrm{OMe})_{3}\right]^{+}\left(16.08 \mathrm{~kJ} \mathrm{~mol}^{-1}\right)$. Mixing of the XLCT (halide-to-ligand CT) character might contribute to lower energy levels of the MLCT
state. In contrast, there is no mixing of the XLCT character to the MC state, so that the barrier becomes rather large. This would be one reason of the low PLS reactivity of $f a c-\left[\operatorname{Re}^{\mathrm{I}}(\mathrm{bpy})(\mathrm{CO}){ }_{3} \mathrm{Cl}\right]$.

Another important factor determining the PLS reactivity would be the efficiency of the ISC to the $\mathrm{S}_{0}$ state. The $\mathrm{T}_{1} / \mathrm{S}_{0}$-MESXs were therefore searched by the SC-AFIR method. The search found 11 independent $T_{1} / S_{0}-M E S X s$ for fac-[ $\left.\operatorname{Re}^{\mathrm{I}}(b p y)(C O)_{3} C l\right]$. Fig. 5 shows the four lowest $\mathrm{T}_{1} / \mathrm{S}_{0}$-MESXs. All of these MESXs have lower energy than 3.20 eV , the $\mathrm{T}_{1}$-TS (dissociation). The second and third lowest-energy $\mathrm{T}_{1} / \mathrm{S}_{0}$-MESXs, especially, are located at 3.05 and 3.06 eV (Fig. 5 (ii) and (iii)) respectively on the way from $\mathrm{T}_{1}$-min (global) to $\mathrm{T}_{1}$-min (bent), so that these MESXs are important for the reaction mechanism. Therefore fac-[ $\left.\mathrm{Re}^{\mathrm{I}}(\mathrm{bpy})(\mathrm{CO})_{3} \mathrm{Cl}\right]$ would prefer to relax into the $\mathrm{S}_{0}$ state in the FC region than overcoming the barrier for the PLS reaction energetically. The $T_{1} / S_{0}$-MESXs, in which the bipyridine ring is distorted, are located above 3.70 eV (see Electronic Supplementary Information for details) and rather higher than the barriers.

The SC-AFIR search for the $\mathrm{T}_{1} / \mathrm{S}_{0}-\mathrm{MESXs}$ of fac- $\left[\operatorname{Re}^{\mathrm{I}}(\mathrm{bpy})(\mathrm{CO})_{3} \mathrm{P}(\mathrm{OMe})_{3}\right]^{+}$was also performed. In our search 23 independent structures of the $T_{1} / S_{0}$-MESXs were obtained. The lowest four $\mathrm{T}_{1} / \mathrm{S}_{0}$-MESXs are depicted in Fig. 6 and they are very similar to those of $f a c-\left[\mathrm{Re}^{\mathrm{I}}(\mathrm{bpy})(\mathrm{CO})_{3} \mathrm{Cl}\right]$ (Fig. 5), except the MESX after the $\mathrm{CO}_{\text {eq }}$ dissociation (at 3.34 eV ). However, all of these MESXs are located at higher energy than 3.22 eV of the $\mathrm{T}_{1}-\mathrm{TS}$ (dissociation). On the Re-CO ${ }_{\mathrm{ax}}$ dissociation coordinate the MESXs at 3.45 and 3.50 eV (Fig. 6 (iii) and (iv)) would be most effective, but the TS for the PLS reaction has much lower energy, then the PLS reaction is energetically preferred. In addition, the spin-orbit coupling (SOC) constant at the $\mathrm{T}_{1} / \mathrm{S}_{0}$-MESX computed by the linear response theory ${ }^{31}$ is $2.55 \mathrm{~cm}^{-1}$
(Fig. 6(iii)), and that of $f a c-\left[\mathrm{Re}^{\mathrm{I}}(\mathrm{bpy})(\mathrm{CO})_{3} \mathrm{Cl}\right]$ is $47.8 \mathrm{~cm}^{-1}$ (Fig. 5(ii)). This supports fac-[ $\left.\mathrm{Re}^{\mathrm{I}}(\mathrm{bpy})(\mathrm{CO})_{3} \mathrm{P}(\mathrm{OMe})_{3}\right]^{+}$relaxes much slower than $f a c-\left[\mathrm{Re}^{\mathrm{I}}(\mathrm{bpy})(\mathrm{CO})_{3} \mathrm{Cl}\right]$ through the $\mathrm{T}_{1} / \mathrm{S}_{0}$-MESX, so that more probabilities of the PLS reaction are expected in $f a c-\left[\mathrm{Re}^{\mathrm{I}}(\mathrm{bpy})(\mathrm{CO})_{3} \mathrm{P}(\mathrm{OMe})_{3}\right]^{+}$. From the viewpoint of the efficiencies of the dissociation on the $T_{1}$ and of the decay to the $S_{0}$, the reactivity is explained successfully.

### 3.3 Selectivity of CO Position on the PLS Reaction

The rhenium tricarbonyl complex has three carbonyl ligands, an axial and two equatorial COs. Only the dissociation pathway for $\mathrm{CO}_{\mathrm{ax}}$ has been discussed above since the ${ }^{13} \mathrm{C}$-NMR study has revealed that any $\mathrm{CO}_{\text {eq }}$ are not dissociated. ${ }^{11}$ In this study, however, the transition state structures towards the PLS reaction have been searched by the SC-AFIR method, not only for $\mathrm{CO}_{\mathrm{ax}}$ but also for $\mathrm{CO}_{\mathrm{eq}}$.

The important points in the $\mathrm{Re}-\mathrm{CO}_{\text {eq }}$ dissociation pathways of $f a c-\left[\mathrm{Re}^{\mathrm{I}}(\mathrm{bpy})(\mathrm{CO})_{3} \mathrm{P}(\mathrm{OMe})_{3}\right]^{+}$and $f a c-\left[\mathrm{Re}^{\mathrm{I}}(\mathrm{bpy})(\mathrm{CO})_{3} \mathrm{Cl}\right]$ are depicted in Figure 4 as well as that of the Re-CO ${ }_{a x}$. The structural parameters are also summarised in Table 5 and Table 6. In the same way as the $\mathrm{Re}-\mathrm{CO}_{\mathrm{ax}}$ dissociation pathway, it is characterised by bending of the $\mathrm{CO}_{\text {eq }}$. However, the $\left(\mathrm{T}_{1}-\mathrm{TS} \text { (dissociation) }\right)_{\text {eq }}$ is located at much higher energy than the ( $\mathrm{T}_{1}-\mathrm{TS}$ (dissociation)) $)_{\mathrm{ax}}$ and the $\mathrm{S}_{0} / \mathrm{T}_{1}$-MESXs, so that the $\mathrm{Re}-\mathrm{CO}_{\mathrm{ax}}$ dissociation is energetically preferable. Note that the $\mathrm{T}_{1}-\mathrm{TS}$ (bent) would exist as a $\mathrm{T}_{2} / \mathrm{T}_{1}$-MECI because the character of the state is interchanged between the ${ }^{3} \mathrm{MLCT}$ and ${ }^{3} \mathrm{MC}$. In this study, the $\left(\mathrm{T}_{1}-\mathrm{TS} \text { (bent) }\right)_{\text {eq }}$ is obtained as the $\mathrm{T}_{2} / \mathrm{T}_{1}$-MECI.

## Conclusions

In this article, the mechanism of the CO ligand dissociation of
$f a c-\left[\mathrm{Re}^{\mathrm{I}}(\mathrm{bpy})(\mathrm{CO})_{3} \mathrm{P}(\mathrm{OMe})_{3}\right]^{+}$has theoretically been investi-gated, as the dominant process of the photochemical ligand substitution (PLS) reactions of $f a c-\left[\operatorname{Re}^{1}(b p y)(C O){ }_{3} \mathrm{PR}_{3}\right]^{+}$. The excited states have been calculated by the TD-DFT method with the B3LYP functional. The experimentally observed absorption peak was assigned to the $\mathrm{S}_{3}$ ( $\left.{ }^{1} \mathrm{MLCT}\right) \leftarrow \mathrm{S}_{0}$ (ground) photoexcitation. Once the photoexcitation occurrs, the system is able to decay into the $S_{1}$ and $\mathrm{T}_{1}$ states through conical intersections and seam of crossings with sufficiently low energy barriers, and the molecular geometry does not change so much. The relaxation is achievable within the Franck-Condon (FC) region. Such a fast decay process of fac-[Re ${ }^{\mathrm{I}}(\mathrm{bpy})(\mathrm{CO})_{3}$ $\left.\mathrm{P}(\mathrm{OMe})_{3}\right]^{+}$is quite similar to that of photostable fac- $\left[\mathrm{Re}^{\mathrm{I}}(\mathrm{bpy})(\mathrm{CO})_{3} \mathrm{Cl}\right]$. The PLS reactivity can be determined by the topology of the $\mathrm{T}_{1}$ potential energy surface. Around the FC region the $\mathrm{T}_{1}$ state has a character of the metal-to-ligand charge-transfer ( ${ }^{3} \mathrm{MLCT}$ ), and it changes to the triplet metal-centered $\left({ }^{3} \mathrm{MC}\right)$ state as the Re-CO bond is elongated and bent. Equatorial CO ligands have a much higher energy barrier to dissociate than that of the axial CO, so that the axial CO ligand selectively dissociates in the PLS reaction. Whereas both of fac-[ $\left.\mathrm{Re}^{\mathrm{I}}(\mathrm{bpy})(\mathrm{CO})_{3} \mathrm{P}(\mathrm{OMe})_{3}\right]^{+}$and $f a c-\left[\mathrm{Re}^{\mathrm{I}}(\mathrm{bpy})(\mathrm{CO})_{3} \mathrm{Cl}\right]$ have similar energy profiles along the coordinate of the $\mathrm{Re}-\mathrm{CO}$ dissociation, $f a c-\left[\mathrm{Re}^{\mathrm{I}}(\mathrm{bpy})(\mathrm{CO})_{3} \mathrm{Cl}\right]$ is photostable and it shows no PLS reactivity. It is shown that the axial CO dissociation barrier on the $\mathrm{T}_{1}$ state is substantially higher in $f a c-\left[\operatorname{Re}^{\mathrm{I}}(\mathrm{bpy})(\mathrm{CO})_{3} \mathrm{Cl}\right]$ than that in $f a c-\left[\operatorname{Re}^{\mathrm{I}}(\mathrm{bpy})(\mathrm{CO})_{3} \mathrm{P}(\mathrm{OMe})_{3}\right]^{+}$. Furthermore, the single-component artificial force induced reaction (SC-AFIR) search reveals that the minimum-energy seam of crossings between the $T_{1}$ and $S_{0}$ states ( $\mathrm{T}_{1} / \mathrm{S}_{0}$-MESXs) exist before and below the barrier in the $f a c-\left[\mathrm{Re}^{\mathrm{I}}(\mathrm{bpy})(\mathrm{CO})_{3} \mathrm{Cl}\right]$ system, while all $\mathrm{T}_{1} / \mathrm{S}_{0}$-MESXs exist before and above the barrier in fac- $\left[\operatorname{Re}^{\mathrm{I}}(\mathrm{bpy})(\mathrm{CO})_{3} \mathrm{P}(\mathrm{OMe})_{3}\right]^{+}$ (Scheme 3). Therefore fac-[ $\left.\operatorname{Re}^{\mathrm{I}}(\mathrm{bpy})(\mathrm{CO})_{3} \mathrm{Cl}\right]$ can decay into the $\mathrm{S}_{0}$ state and it shows no

PLS reactions.

## Acknowledgements

The authors would like to thank Dr. Chantal Daniel of Université de Strasbourg for stimulating discussions. This work is supported by a grant from Japan Science and Technology Agency with a Core Research for Evolutional Science and Technology (CREST) in the Area of "Establishment of Molecular Technology towards the Creation of New Functions". In this work we used the supercomputer of ACCMS, Kyoto University, Japan.

[^0]Table 2. Optimised structural parameters of $f a c-\left[\mathrm{Re}^{\mathrm{I}}(\mathrm{bpy})(\mathrm{CO})_{3} \mathrm{P}(\mathrm{OMe})_{3}\right]^{+}$. The optimised parameters at the $\mathrm{S}_{0}$-min (global minimum) are listed as that of the $\mathrm{S}_{3}$ state in the Franck-Condon (FC) region. The B3LYP/cc-pVDZ/SDD level of calculation was used to optimise the $\mathrm{S}_{0}$-min, and the other minima were optimised by the TD-B3LYP calculation. Due to mixing of the electronic states, the $S_{3}$-min and $T_{2}$-min exist in the $S_{3} / S_{2}$ or $T_{2} / T_{1}$ conical intersections respectively.
