1. Introduction. This survey of selected computational aspects of linear algebra is addressed to members of SIAM who are not specialists in numerical analysis. The reader is assumed to have a general familiarity with the algebra and analysis of finite vectors and matrices, including norms, and to know the Gaussian elimination process. A completely adequate background is given in the first 72 pages of Faddeeva [9]. A much more complete background for practical matrix work is found in Bellman [3], Marcus and Minc [38], and Wilkinson [61].

Far more extensive expositions of the computational methods of linear algebra are to be found in Fox [14], Noble [42], Householder [28], and Wilkinson [61].

The author gratefully acknowledges conversations with Gene H. Golub, Richard Hamming, and William Kahan, and especially the opportunity to see a draft of Kahan [32]. He also acknowledges substantial debts to Cleve Moler for the use of material from Forsythe and Moler [12].
2. Computational problems of linear algebra. The ordinary computational problems of linear algebra are concerned with matrices of real numbers.
a. Let $A$ be an n-rowed, $n$-columned matrix of real numbers. Let $b$ be an n-rowed column vector of real numbers. The traditional linear-equations problem is to find an n-rowed column vector $x$ such that

$$
\mathrm{A} x=\mathrm{b}
$$

It is normally assumed that $A$ is a nonsingular matrix, since then and only then does a unique solution exist for all b.
b. With the same $A$ as in part a, another traditional problem is to find the inverse matrix $A^{-1}$.
c. Let $A$ be an n-rowed, n-columned matrix of real numbers which is symmetric. The third traditional problem is to find some or all of the (necessarily real) eigenvalues of $A$. Recall that an eigenvalue of $A$ is a number $\lambda$ for which
there exists a column vector $u$ such that

$$
A u=\lambda y
$$

Such a vector $u$ is called a (column) eigenvector of $A$ belongirig to $\lambda$, and often the computational problem includes finding a $u$ belonging to each eigenvalue computed. There exist $n$ orthonormal eigenvectors of $A$, one belonging to each eigenvalue of $A$.
d. Let $A$ be an unsymmetric n-rowed, n-columned matrix of real numbers. Another triditional problem of linear algebra is to find some or all of its eigenvalues, and sometimes also its corresponding column eigenvectors and row eigenvectors. Recall that a row eigenvector belonging to $\lambda$ is an $n$-columned row vector $v$ such that

$$
v A=\lambda v .
$$

When $A$ is not symmetric, the problem is complicated in many ways: First, some of the eigenvalues $\lambda$ are ordinarily complex numbers. Second, there may not exist $n$ linearly jindependent column eigenvectors, and those which exist are not usually orthogonal. . Indeed, they are likely to be nearly linearly dependent and the same holds for the row eigenvectors. Third, if an eigenvalue $\lambda$ is a root of multiplicity $k>1$ of the characteristic eauation $\operatorname{det}(A-\lambda I)=0$, then there may exist anywhere from 1 to $k$ linearly independent column eigenvectors belonging to $\lambda$. (If A were symmetric, there would always be k.) If the number is less than $k$, it corresponds to one or more nondiagonal blocks in the Jordan canonical form of $A$, or equivalently to so-called nonlinear elementary divisors of A. Fourth, multiple or nearly multiple eigenvalues of $A$ are likely to be very rapidly changing functions of the elements $a_{i, j}$ of $A$, so that computations are at best tricky.
e. For any column vector $y$, define the p-th power norm of $y$ to be (1)

$$
\|y\|_{p}=\left(\sum_{i=1}^{n}\left|y_{i}\right|^{p}\right)^{\frac{1}{p}}
$$

Here $p$ is a real number with $1 \leq p<\infty$, and $y_{1}, \ldots, y_{n}$ are the components of $y$ in a given coordinate system. We define the maximum norm as the limiting case $p \rightarrow \infty$ of (1);

$$
\begin{equation*}
\|y\|_{\infty}=\max _{1 \leq i \leq n}\left|y_{i}\right| \tag{2}
\end{equation*}
$$

The norms most used in numerical analysis are $p=1,2, \infty$, but statisticians are now giving attention to values of $p$ between 1 and 2 .

Let $A$ be an n-rowed, k-columned matrix of real numbers, and let $b$ be an n-rowed column vector. Given some p, a more recent computational problem is to find a $k$-rowed column vector $x$ such that

$$
\|A \times-b\|_{p} \quad \text { is minimized }
$$

When $p=2$, the usual case, this is the linear least-squares problem. For $p=2$ the unit sphere in the norm is very smooth, and methods of analysis work well. However, for $\mathrm{p}=1$ or $\infty$ the unit sphere has many corners, and methods of minimizing $\|A x-b\|_{p}$ become combinatorial or discrete.
f. For two n-rowed column vectors $x$ and $y$, we define $x \geq y$ to mean that $x_{i} \geq y_{i}$ for all components of $x$ and $y$.

Let $A$ and $b$ be as in part $e$ above. Then an important computational problem is to describe the set $S$ of $k$-rowed column vectors $x$ such that
$A x \geq b$ 。

Sometimes, as in linear programming problems, one looks for vectors $x$ in $S$ such that $c^{T} x$ is a minimum, where $c$ is a given $k$-rowed column vector.

So far we have spoken only of matrices of real numbers. Similar problems are posed occasionally for matrices of complex numbers. Many of the problems can also be phrased for matrices whose elements are expressions in indeterminates or letters. As methods of symbol manipulation on digital computers become more accessible to computer users, problems of linear algebra with matrices of letters will be studied more. Practical symbol manipulation will probably do more to interest mathematicians in computing than anything that has happened in the computer era to date.

The present discussion is limited to matrices of numbers, and moreover to problems $\underline{a}, \underline{b}, \underline{c}, \underline{d}$. For discussions of problem $\underline{e}$ with $p=2$, the reader is referred to Golub and Kahan [18]. For problem $f$ see presentations on linear programming like Dantzig [5].

Why do the linear problems $\underline{a}, \underline{b}, \underline{c}$, and $\underline{d}$ arise so often? Why are they important? The answer is that linear operators are the simplest ones in mathematics, and the only operators that are fully understood in principle. rience they are a natural model for an applied mathematician to use in attacking a problem. Even though linear operators in infinite-dimensional spaces will sccur in analysis of differential equations (for example), the realities of computing mean that only finite-dimensional spaces can be handled with digital somputers.

More realistic models of applied mathematics are usually nonlinear. But, whenever nonlinear operators are used, the actual solution of functional equations almost always involves the approximation of nonlinear operators by ? inear ones. A typical example of this is the use of Newton's method for solving
a system of nonlinear enuations, in which at every step a locnlly best-fitting linear equation system must be solved. Nonlinear problems usually are very hard In attacking them by linear methods, it is essential thrt our linenr tools be very sharp, so the they can be relied upon to work without failure. Only in this way can the analyst concentrate on the real difficulties of the nonlinear world. This point of view not only emphasizes the importance of being able to solve linear problems, but also the necessity of solving linear systems with extremely reliable methods.

Linear equation systems a arise directly mainly from two sources. One is from an approximation to linear functional equations, usually ordinary or partial differential equations. The other source is a problem of data fitting, interpolntion, or npproximation by linear families of functions.

Eigenvalue problems usually arise from studies of vibration or stability or resonance of linear physical systems (e.g., flutter of aircraft and criticnlity of reactors), or from factor analysis problems.

An excellent textbook by Noble [42] gives a number of physical examples of computational matrix problems.
3. A closer look at the problems. Since actual computers have finite storage capacity and a finite precision, we need to have a closer look at the nature of the matrices $A$ and the computntional problems.

Is the matrix $A$ dense (most elements $a_{i, j} \neq 0$ ), or is it sparse (most elements $\left.a_{i, j}=0\right)$ ? If $A$ is sparse, do the nonzero elements form a significant pattern? For example, is $A$ triangular $\left(a_{i, j}=0\right.$ for $i>j$ or for $i<j)$ ? Is it of Hessenberg form $\left(a_{i, j}=0\right.$ for $i>j+1$ or for $j>i+1)$ ? Is it a band matrix $\left(a_{i, j}:=0\right.$ for $|i-j|>m$, where $m \ll n$ ? Is it a t,ridiagonal matrix (i.e., a band matrix with $m=1$ )? All these special forms occur freauently, and can be given special consideration.

Is the matrix A symmetric? Pos.tive definite? If it is sparse, is the pattern associated with the adjacency matrix of same graph? Frequently matrice associated with structures or with partial difference equations are best understood in terms of the associated graph.

Are the elements $a_{i, j}$ stored in the computer memory, to be retrieved when needed, or are they regenerated from some algorithm, as needed? One might deffine the informational content of a matrix as the number of cells needed (on a certain computer) to store the data and program to obtain all the $a_{i, j}$. The author knows of no work on this concept, which is clearly relevant to matrix computation.

What is the size of the matrix $A$, relative to the memory size and speed of a given computer?

If we are solving a linear equation system $A x=b$, do we have many different right-hand sizes $b$, or just one? Do we have many different matrice that are close together, or do we have just one A? Are the elements of $A$ ar precise mathematical numbers (for example, integers), or are they physical numbers subject to uncertainty? Any uncertainty in $A$ and $b$ leads to uncertainty in the definition of $x$ as the solution of $A x=b$. What $x d o$ the problem's proposer want to see? Even when $A$ and $b$ are mathematical numbers, the solution $x$ is normally not representable as a finite-precision number in the computer's number base. Of the various approximate answers $x$ which might be obtained, what is the proposer's desire? For example, does he want $\left\|x-A^{-1} b\right\|$ to be small, where $A^{-1} b$ is the true answer? or would th: proposer settle for an $x$ such that $\|A x-b\|$ is small? For each case: whic: norm, and how small?

Most proposers of linear equation systems haven't considered these guestions, and look to the numerical analyst to explain the possibilities and Belect the options.

If a proposer requests the inverse matrix $A^{-1}$, it is usually worth finding out why. Frequently he merely wishes a convenient way to solve $A \dot{x}=c$ for an arbitrary vector $c$. Having $A^{-1}$ stored away, the proposer expects to obtain the solution $x$ in the form $A^{-1} c$, for any new $c$ that comes along. It should be pointed out that there are other ways to obtain $A^{-1} c$ for new vectors $c$, ways that require no more storage and take no longer for the same accuracy, than the miltiplication of $A^{-1}$ by $c$. Because of these facts, the computation of $A^{-1}$ may frequently be dispensed with. However, certain statistical applications really do require knowledge of at least the diagonal elements of $A^{-1}$.

The eigenvalue problem $\subseteq$ for symmetric matrices $A$ can require finding all the eigenvalues, or only a few. It matters a good deal whether or not the corresponding eigenvectors are needed. If a complete set of eigenvectors is needed, is it important that they be orthogonal to each other? Getting orthogonal eigenvectors corresponding to multiple eigenvalues is far more difficult than just getting eigenvalues.

In the eigenvalue problem $\underline{d}$ for nonsymmetric matrices $A$, one has similar choices: do we want all eigenvalues, or just some? Do we want column eigenvectors? Do we want row eigenvectors? Both? But then comes a new choice. If some eigenvalues are multiple and correspond to a nonlinear elementary divisor, what vectors does the proposer want to see? In monographs on algebra one learns about chains of principal vectors that with the eigenvector form a basis for the null space $N$ of $(A-\lambda I)^{k}$, where $\lambda$ is an eigenvalue of multiplicity $k$ with an elementary divisor of degree $k$. These principal vectors are associated with the Jordan canonical form of $A$. It is my impression that a proposer who has a good background in algebra will want to see a set of principal vectors (they are not unique). But these principal vectors are extremely hard to compute,
partly because they are discontinuous functions of the data. It is likely thot an orthogonal basis for the nullspace $N$ would be a more useful set of vectors. The matter seems to be poorly understood by problem proposers and numerical analysts.

Matrices with actual multiple eigenvalues are very rare, and a imall computational perturbation of these will normally destroy the equality of eigenvalues. One might therefore assume that we need not be concerned in practice with what to do about them. But, in fact, the bad behavior of nonlinear divisors carries over in practice to a surprisingly large set of neighboring matrices. These neighboring matrices have distinct eigenvalues, but the $k$ column eigenvectors are so nearly linearly dependent that they cannot be separated in a normal computation. So also here one faces the problem of what vectors to give the proposer.

In a least squares problem, say a search for $x$ to minimize $f(x)=\| A x-0_{i}^{i}$, does the proposer really want a minimum of $f(x)$, or does he merely wish an $x$ that gives a value of $f(x)$ fairly close to the minimum? In a curve-fitting problem, for example, one can often get a surprisingly good fit by a polynomial with coefficients very different, from those of the minimizing polynomial.

In all of the above computational problems, it is important to ascertain which of the following types of answers the probiem proposer is looking for:
a) a surmised answer, with no estimates of its correctness;
b) sorne answer, together with some sort of probabilistic assertions
about its correctness;
c) some answer, together with mathematically provable bounds for its error.

Normaily it is more expensive to obtain $b$ ) than a), and still more expensive to obtain c).

It is not obvious which of the above types of answer the problem proposer will want. Frequently a) is quite satisfactory. The physical scientist and engineer frequently have their own checks on the validity of an answer, and may neither need nor wish the mathematician's rigorous bounds. They may recognize, for example, that the mathematical model is such a rough approximation to reality that mathematical bounds would only be ludicrous. When mathematicians enter the practical world of engineering, the rules by which mathematics is played frequently have little relevance. Nunericel analysts frequently have trouble deciding when to play the game according to mathematician's rules and when to play it like engineers. It is, of course, extremely pleasant to encounter those occasional examples where mathematically provable bounds can be found that are just as accurate and cheap as surmised answers. One should never cease looking for such miracles, because they do occur: One has been just reported at this SIAM Symposium; see Fox, Henrici, and Moler [26].
4. Nature of computer hardware and software. The character of achievable solutions to the computational problems of linear algebra is greatly influenced by the nature of the computing systems available to us. It is customary to separate compiter systems along the foliowing lines:
a) Computer hardwarc--the nature of the electronic circuitry of a computer;
b) Computer languages--the languages in which are described algorithms for the solution of a given problem on a given computer;
c) Computer software--the programs which make it possible for a computer actually to perform the algorithms described in the computer language.

In looking at computer hardware for computations in linear algebra one wants to know what precision is available for computation--how many digits are
in the significand of the floating-point operands, and to what base? One is also interested in the cost and speed of double-precision operations. In matrix algebra work the critical operation is frequently the computation of a rounded single-precision approximation to the double-precision inner product of two vectors whose components are single-precision floating-point numbers. The speed and cost of this inner product are very important.

One wonders whether the hardware rounds the result of an aritnmetic operations, or whether it is chopped off. Best of all is a system that lets the programmer decide when to round and when to chop.

What happens when the result of an arithmetic operation exceeds the capacity of the flosting-point system? Are there "traps" which make it possible for the system to detect overflow or underflow? Can these traps be by-passed, (turned off) by the programmer? When an overflow or underflow is detected, is all essential information recoverable, so that the solution can continue? Or are vital bits of information irretrievabiy lost?

What is the exact nature of the arithmetic operations in the machine? I one is to prove theorems about the behavior of a computation, one needs certair. properties of the arithmetic. Because of the rounding of the machine, it is well known that addition and multiplication are net associative, nor are they distributive. Nevertheless, one can do surprisingly good analysis, provided only that the arithmetic is monotonic.

By multiplication being monotonic, we mean, for example, that if $0<a<b$ and $0<c$. then $a \times c \leq b \times c$. Such properties seem elementa., out they are extremely helpful. And they are surprisingly often absent.'

It must be noted that apparently minor changes in the hardware of the arithmetic circuitry can make surprisingly large differences in the behavior of the al.gorithms.

A great many computer languages have been devised for the description of scientific algorithms. These range from the very elementary codes for Turing machines, through the machine codes of computers, to various algebraic languages like the forms of Fortran, Algol, and PL/I. All these languages are equivalent, in the sense that the class of representable algorithms ia the same for all of them. The languages differ only in regard to human convenience and in the compilation problems they create. Can one conveniently represent such a data structure as a triangula: matrix in a certain language? In typical languages like Algol or Fortran, one must choose between representing it as part of a much larger square matrix, on the one hand, or as an artificially created one-dmensional array, on the other. The former choice is humanly convenient and wastes space; the latter choice saves the computer time and space, at the cost of confusing the human.

Most matrix algorithms have "inner loops" where most of the computing time is spent. If only this inner loop is programmed very efficiently in machine code, the program will run very rapidly. It scarcely matters how the rest of the algorithm is programmed. Hence a very important question for any algebraic language is whether it is : easy to incorporate pieces of machine code into them. Perhaps the question is more appropriately addressed to the software system that translates the algebraic language into machine code.

Another important property of a computer language is its readability by human beings. If the algorithm is correctly written, a computer will (practicaily always read it correctly. But the practical use of the algorithm depends on the ability of human beings to comprehend it, adapt it to other uses, improve it in the light of recent discoveries, and so on. The human readability of existins; languages differs a great deal.

The most important software programs for the scientific computer user are the monitors and the compilers. The compilers are vast symbol-manipuiatior programs that translate an algorithm from, say, Fortran to the machine code of a given computer. Compilers should be distinguished from the languages they translate, and yet of course compilers and languages influence each other. Compilers differ greatly in speed, in the optimality of the machine code produced in the translation, and in the diagnostic facilities offered.

As we noted above, it is important that compilers be able to accep pieces of algorithms written in machine code, and incorporate them into a program otherwise written in an algebraic language. For matrix work, the ability to compile fast codes for iterative loops (the for statment of Algol) is very important.

Most compilers are now imbedded in control programs variously called master control programs, monitor systems, or operating systems. These monitor systems generally retain ultimate control of a computer, preventing a possibly erroneous user program from consuming vast amount of unwanted time, or from damaging the monitor system or other persons' programs by illegal assignments Also, the monitor systems generally recover control of the machine in case of overflow or underflow. This is a point of much interest to writers of linear algebra programs. In case of overflow or underflow, what happens next? Can the linear algebra program recover control of the computer and repair the dampre done by the overflow or underflow? (This assumes that the hardware retains necessary information.) Or does the monitor system take over the machine and ruthlessly flush the offending program from the machine? If the latter occiurs, then extra time must be taken in each program to make sure that overflow or underflow cannot occur.
5. The state of the art, 1953 and now. It is safe to say that matrix computation has passed well beyond the stage where an amateur is likely to think of computing methods which can compete with the better known methods. Certainly one cannot learn theoretical linear algebra and an algebraic programming language, and nothing else, and start writing programs which will perform acceptably by today's standards. There is simply too much hard-earned experience behind the better algorithms, and yet this experience is hardly mentioned in mathematical textbooks of linear algebra.

The amount of literature on matrix computations is staggering. In 620 pages, Faddeev and Faddeeva [8] record a pretty complete account of computational methods up to around 1958. In 662 pages, Wilkinson [6j] gives most of what is known about computing eigenvalues of dense, stored matrices (both symmetric and unsymmetric), with error bounds for many algorithms. There is very little overlap between the two books, because Wilkinson and a few contemporaries created most of the material in his book in the years after 1958. No one could possibly start research in the numerical mathematics of linear algebra without a thorough knowledge of the relevant material in these books.

It is perhaps instructive to examine the state of matrix computation in 1953, when the author wrote a survey [10] of methods for solving linear systems at the Institute for Numerical Analysis of the National Bureau of Standards, Los Angeles. We were amateurs. For dense, stored matrices we knew Gaussian elimination, of course. We knew that i.t sometimes produced nuite poor resul.ts. We weren t always sure why. We debated endlessly about how to pick pivots for the elimination, without settling it. The debate still continues, but now mainly among persons who don't understand that the main lines of the answer have been settled. Because of misunderstood difficulties with Gaussian elimination, we searched for other methods which might do better.

The conjugate-gradient $m \in$ thod had been devised for sparse matrices by Lanczos [36], and Hestenes and Stiefel [27]. In [10] I guessed that it might also prevail for dense, stored matrices, despite the extra time it would require, because we understood how to use higher precision to make the conjugate-gradient method work well. We did not realize that the same higher precision and a proper pivotal strategy would make Gaussian elimination work. We were not quite aware of the extent of problems of ill conditioning of matrices.

The only analysis available to us was the monumental work of von Neumann and Goldstine $[41,20$ ]. They avoided the pivoting problem by reducing any regular linear equation system $A x=b$ to the positive definite system $A^{T} A x=A^{T} b$. We knew that this normalization of the problem was costly in time and worsened the condition of the problem. Von Neumann and Goldstine presented guaranteed error bounds for the solution; actually observed errors were found to be perhaps 100 times smaller in reasonable cases. The form of the error analysis was a direct comparison of machine arithmetic with exact operations. The nonassociativity and nondistributivity of machine arithmetic made the analysis extremely difficult. In any case, it could only handle scaled fixedpoint arithmetic. Because of the size of their error bounds, von Neumann and Goldstine were unnecessarily pessimistic about the possibility of inverting general matrices of orders over 15 on machines with the 27-bit precision of the IBM 7090 series.

For the eigenvalue problems, things were in much worse state. We had the power method with matrix deflation. While reasonabl: satisfactory for a few dominant roots, its general npplication requires intuition and luck, and defies a complete algorithmization. For dense, stored symmetric matrices we had the 1846 method of Jacobi [31], rediscovered and analyzed by Goldstine, Murray and von Neumann [19], and it was quite satisfactory. Givens was writing up
his newly discovered method, maybe 7 to 9 times faster than Jacobi's and a basic step toward currently used methods.

For nonsymmetric matrices, things were ghastly. If the power method wouldn't work, we had practically no alternatives. We could search for zeros of $\operatorname{det}(A-z I)$ in some manner or another. We bravely tried methods for determining the characteristic polynomial, as described in Faddeeva [9], and found them to be hopeless. It was almost unbelievable, how badly the standard methods for $n=4$ would perform for $n=10$. Lanczos was advocating his new method of finite iterations, which became the source of modern methods in a later line of development through the Stiefel and Rutishauser QD-algorithm, (see Rutishauser [50] and Henrici [25]), the LR-algorithm of Rutishauser [51], and the $Q R$ algorithm of Francis [15, 16] and Kublanovskaja [35]. However, the original Lanczos method needed careful management, because the raw results were often poor.
6. The linear equations problem. For large, sparse matrices, like those arising in finite-difference approximations to partial differential equations, there is a whole special literature. See Varga [57], Forsythe and Wasow [13], the work of David Young, Jim Douglas Jr., Stiefel, and many others. The methods seem to depend for their success on the nature of the continuous problem being approximated. Because the matrices are sparse, the prevailing methods are iterative. I shall omit further discussion of them, and confine attention to dense, stored matrices.

For a general matrix $A$, the solution of the linear system $A x=b$ by Gaussian elimination requires $n^{3 / 3}+\underline{O}\left(n^{2}\right)$ multiplications, and the same number of additions. Recently Klyuyev and Kokovkin-Shcherbak [34] proved that
no method using rationl operations for general. $A, b$ can take fower operaticris. This result had long been believed but not proved. The result has two consequences:
(i) Gaussian elimination is likely to remain the method of choice for solving dense linear systems, when it works, because it is as fast as any.
(ii) The solution of a linear system of large order $n$ is going to require a very substantial amount of computing time, at least for serial computers. For $n=1000$, we have $1 / 3 \times 10^{9}$ multiplications and adaitions. If we can multiply and add in 10 microseconds, we need 3333 seconds, or about an hour of computation. In fact, there is some overhead also, and on an IBM 7094 (Model II) the solution would take over 2 hours. However, the storage cf the million elements of data requires extensive use of some bulk storage like tapes or disks, as only some 20,000 elements or so can be kept in the current 32,000-word core stornge. The very numerous transfers of matrix elements fromi core to magnetic tapes sppear likely to wear out the tapes before the solution can be obtained, according to certain tests made at Stanford: I know of no comprabable experience with magnetic disks or other form of bulk storage.

As a result, we cannot consider order $n=1000$ to represent a practucal. lineur equations problem, but we will undoubtedly soon be able to do $\mathrm{i}^{+}$regular:v for perhaps \$500.

The case $n=100$ is now easy and costs around $\$ 1$ on an IBM 7094. The case $n=10,000$ is likely not to be accessible for a long time, and it. wold thice over 2000 hours now on an IBM 7094.

There is beginnıng to be serious consideration of computers with a substantial amount of parallel operation, so that perhaps much of the solution of : 1 linenr system could be done simultaneously. Preliminary studies make it. clear that the solution of a linear system could very easily make use of parall:
computation, if it should prove worth while. Apparently only $\underline{C}(n)$ operation times would be needed for solving a linear system, if one had a sufficiently large amount of prallel arithmetic circuitry.
7. Inherent inaccuracy in solutions of linear systems. Given a nonsingular matrix $A$ and a nonzero $b$, let $x$ be the solution of $A x=b$. Suppose $A$ and $b$ are subject to uncertainty. What is the resultant uncertainty in the solution $x$ ?

For any column vector $y$ of order $n$, define $\|y\|$ to be the euclidean length of $y$ :

$$
\|y\|=\|y\|_{2}=\sqrt{y_{1}^{2}+y_{2}^{2}+\cdots+y_{n}^{2}}
$$

For any n-by-n square matrix $A$, define the spectral norm $\|A\|$ by

$$
\|A\|=\max _{\|x\|=1}\|A x\|
$$

These functions $\|. .$.$\| give useful measures of the size of vectors and matrices,$ respectively.

For a nonsingular matrix $A$, define the condition of $A$, cond $(A)$ by the relation

$$
\operatorname{cond}(A)=\|A\| \cdot\left\|A^{-1}\right\|
$$

The concept of condition of a matrix sfems to have been introduced by Turing [55], nnd studied extensively by Todd ([53] and some later papers) and many others.

One of the main uses of the concept of condition lies in answering the question posed at the start of this section. Suppose that $A$ is known exactly, but that $b$ is subject to uncertainty. Let $x+\delta x$ solve the system with matrix $A$ and right-hand side $b+d b$. Then

$$
\begin{aligned}
A(x+\delta x) & =b+d b ; \\
x+\delta x & =A^{-1} b+A^{-1} d b ;
\end{aligned}
$$

(3)

$$
\begin{aligned}
\delta x & =A^{-1} d b \\
\|\delta x\| & \leq\left\|A^{-1}\right\| \cdot\|d b\|
\end{aligned}
$$

Since $A x=b$, we have

$$
\begin{equation*}
\|b\|=\|A x \mid \leq\| A\|\cdot\| x \| . \tag{4}
\end{equation*}
$$

Dividing (3) by (4), we have

$$
\frac{\|\delta x\|}{\|x\|} \leq\|A\| \cdot\left\|A^{-1}\right\| \frac{\|c b\|}{\|b\|},
$$

or

$$
\begin{equation*}
\frac{\left\|\delta x^{\|}\right\|}{\|x\|} \leq \operatorname{cond}(A) \frac{\|d b\|}{\|b\|} . \tag{5}
\end{equation*}
$$

Inequality (5) shows that the relative uncertainty in $x$ is bounded by cond(1) times the relative uncertainty in $b$. The bound in (5) is attainable, for any nonsingular $A$ and nonzero $b$. This is easy tu see, if we perform a change of coordinates in which $A$ takes $n$ diagonal form.

A: a linear transformation, $A$ takes vectors $x$ into vectors $b$.
A fandmentaliy important, but too little known theorem states that by a certain orthomonn change of coordinates in the space of $x$, and by another orthogonal chance of coordinates in the space of $b$, the matrix $A$ can be put in the diagonal form

$$
A=\left[\begin{array}{llllll}
\mu_{1} & & & & \\
& \mu_{2} & & & \\
& & \cdot & & \\
& & & & \\
& & & & \mu_{n}
\end{array}\right]
$$

Here the positive numbers $\mu_{1} \geq \mu_{2} \geq \ldots \geq \mu_{n}$ are called the singular values of A. Moreover,

$$
\|A\|=\mu_{1} ; \quad\left\|A^{-1}\right\|=\mu_{n}^{-1} .
$$

Finally, the orthogonal transformations do not change the norms of $x$ and $b$. We have

$$
A^{-1}=\left[\begin{array}{ccccc}
\mu_{1}^{-1} & & & O \\
& \mu_{2}^{-1} & & \\
& & \cdot & & \\
& O & & & \mu_{n}^{-1}
\end{array}\right]
$$

If $\quad \mathrm{b}=\left(\begin{array}{c}1 \\ 0 \\ \dot{0} \\ \dot{0}\end{array}\right) \quad, \quad$ and $\quad \mathrm{db}=\left(\begin{array}{c}0 \\ \dot{0} \\ \dot{0} \\ \epsilon\end{array}\right)$,
then

$$
x=A^{-1} b=\left(\begin{array}{c}
\mu_{1}^{-1} \\
0 \\
\vdots \\
0 \\
0
\end{array}\right), \text { and } \quad \delta x=A^{-1} d b=\left(\begin{array}{c}
0 \\
\vdots \\
\vdots \\
0 \\
\epsilon_{n}^{-1}
\end{array}\right)
$$

For these vectors,

$$
\frac{\|\delta x\|}{\|x\|}=\frac{\epsilon \mu_{1}}{\mu_{n}}=\frac{\|d b\|}{\|b\|} \frac{\mu_{1}}{\mu_{n}}=\operatorname{cond}(A) \frac{\|d b\|}{\|b\|} .
$$

The last line shows that (5) is an equality in this case, as we promised to prove.

Although (5) is only an exact equality under exceptional conditions, it is usually rather close to equality, and in the following we assume approximate equality.

If $\operatorname{cond}(A)=10^{p}$, and if $b$ is known to be correct only to 10 decimals, then $x$ can be known only to 10 - $p$ decimals. Now $p$ can range anywhere from 0 to $\infty$. The only hope of having any significance to $x$ in a 10-decimal computing system is that, roughly,

$$
\operatorname{cond}(\mathrm{A}) \cdot 10^{-10}<\frac{1}{2} .
$$

In a base - $B$ computer with $t$ significant digits, we rot ghly need

$$
\operatorname{cond}(A) B^{-t}<\frac{1}{2}
$$

in order to have any significance to a solution.
Remember that all statements in this section are independent of any method of :solving a system $A x=b$. They are statements about errors in $x$ which ire inherent in the uncertainty in the data.
I. A is subject to a change $d A$, and $b$ is known exactly, then an in utility analogous to (5) is the following:

$$
\frac{\|\delta x\|}{\|x+\delta x\|} \leq \operatorname{cond}(A) \cdot \frac{\|\alpha A\|}{\|A\|}
$$

If $\|\subset\|$ is small, compared with $\|x\|_{\text {, }}$ then we may safely consider the left-hand si e of (1) us a relative error in $x$.
8. Accuracy achievable with Gaussian elimination. I assume that the reader knows what Gaussian elimination is, as a method of solving linear enuation systems. The main strategic decision facing the designer of the algorithm is the choice of a unique pivot element for each of the $n$-l stages in which a variable is eliminated from the remaining equations. There are two main strategies discussed:
(i) complete pivoting, in which at each stage one selects as a pivot some element $a_{i, j}$ of maximum absolute value among all the remaining elements of the matrix.
(ii) partial pivoting, in which at each stage one selects as a pivot some element $a_{i, j}$ of maximum absolute value among the first column of the remainin: elements of the matrix.

Thus, in the first stage complete pivoting would search the whole matrix A for an element raximal in absolute value, whereas partial pivoting would search only the first column.

Some special classes of matrices permit elimination to proceed successfully without any search for pivoting--for example, positive definite symmetric matrices. But generally, pivotal searching is essential to guarantee success. The following simple example illustrates the disaster possible in not searching for a pivot. Consider a 3-digit floating-decimal machine.

The system is

$$
\left\{\begin{array}{l}
.0001 x+1.00 y=1.00 \\
1.00 x+1.00 y=2.00
\end{array}\right.
$$

The true solution, rounded to five decimals, is $x=1.00010, \mathrm{y}=.99990$.
If one accepts the element . 0001 as a pivot, the elimination of $x$ from the second equation yields the equation

$$
-10000 \mathrm{y}=-10000
$$

Backsolving, we find that $y=1.00$, whence $x=\underline{0.00}$, a clear disaster.

On the other hand, partial pivoting would select the element $a_{2,1}=1.00$ as the pivot. Elimination of $x$ from the first equation yields the equation

$$
1.00 \mathrm{y}=1.00
$$

Backsolving, we get $y=1.00$ and then $x=1.00$, with obvious success.
We shall now assume that we are dealing with a t-digit base -2 floatingpoint computer. Rather than discuss the solution of a linear system, we shall consider the computation of the inverse $A^{-1}$ of a given matrix. We wish to state the rounding error bounds that have been proved for Gaussian elimination.

Wilkinson [58] assumes a complete pivotal strategy, and that the matrix $A$ is reasonably scaled at the start and at all intermediate stages (see Sec. 10 for more about scaling). Then, if all $\left.\right|_{i, j} \mid \leq 1$, o certain Gaussian algorithm yields a matrix $X$ such that

$$
\begin{equation*}
\frac{\left\|X-A^{-1}\right\|}{\left\|A^{-1}\right\|} \leq(0.8) 2^{-t} n^{7 / 2} g(n)\left\|A^{-1}\right\| \tag{7}
\end{equation*}
$$

Here $g(n)$ is the maximum of all elements of the successive matrices found during the elimination.

To express the result (7) in a form to be comped with those of Sec. 7, we note that $1 \leq\|A\| \leq n$, so that we expect that $\|A\| \doteq n^{1 / 2}$. Then we have roughly

$$
\begin{equation*}
\frac{\left\|X-A^{-1}\right\|}{\left\|A^{-1}\right\|} \leq n^{3} \cdot 2^{-t} \operatorname{cond}(A) g(n) \tag{8}
\end{equation*}
$$

What kind of bound can we give for $g(n)$ ? This turns out to be an open question. The best known result is approximately

$$
\begin{equation*}
g(n) \leq 1.8 n^{(1 / 4) \log n} \tag{9}
\end{equation*}
$$

On the other hand, for ill equ mutruers ower yamed it has always been observed that

$$
g(n) \leq n
$$

The last bound is attained for unboundedly large $n$ by matrices related to the Hodamard matrices. For most matrices one even observes that

$$
\begin{equation*}
g(n) \leq 8 \tag{10}
\end{equation*}
$$

Tornheim [54] has found complex matrices A of unboundedly large $n$ for aich

$$
g(n) \div 3.1 n .
$$

It would be most desirable to have a good bound for $g(n)$, so that (7) could be turned into a good a priori error bound for the computation of $A^{-1}$. Naturally, for any particular matrix $A, g(n)$ is easily observed in iie course of the elimination, so that in any event (7) becomes an a posteriori $\therefore$ ror bound. However, still better error bounds can be given a posteriori, as rill be shown in Sec. 9.

Wilkinson's proof of (7) in [58] is reasonably short. It makes use of : Iverse rounding error analysis, which we shall mention agein in Sec. ll. It is $\therefore$ istructive to compare (8) with (6), even though one deals with inverses and one $\therefore$ n linear systems. The factor $2^{-t}$ is essentially the inherent uncertointy 'evel of the data, and should be equat.ed to $\|d A\| /\|A\|$. Then the bound in (8) i.; larger than that in (6) by the foctor $n^{3} g(n)$. Taking into account the empirseal result (10) that $g(n) \leq 8$ for most real matrices, we then interpret (8) - s saying that the computed matrix $X$ generally differs from the true inverse $A^{-i}$ in relative terms by no more than $8 n^{3}$ times the error inherent in the roblem. Thus simple Gaussian elimination is reasonably good at keeping the rounding error bound under control, for modest values of $n$. Much better results
can be achieved with some devices to be mentioned in Sec. 9 .
The bound corresponding to (7) given by von Neumann and Goldstine [41]
was

$$
\begin{align*}
\frac{\left\|x-A^{-1}\right\|}{\left\|A^{-1}\right\|} \leq & \left(5.3+14.6\|A\|^{2}\right) 2^{-t} n^{2}\left\|A^{-1}\right\|^{2}  \tag{11}\\
& \sim 15 n^{2} 2^{-t}[\operatorname{cond}(A)]^{2}
\end{align*}
$$

The factor $[\operatorname{cond}(A)]^{2}$ arose from solving $A^{T} A x=A^{T} b$, rather than $A x=b$. The proof of (11) was an order of magnitude more difficult and tedious than the proof of (7).
9. More accurate solutions. Suppose that $A$ is given as singleprecision data, and that we wish to get solutions guaranteed to be more accurate than the above bounds would indicate. How shall we proceed? The most obvious choice is to perform all calculations in double-precision. Roughly speaking, then $t$ is replaced by $2 t$ in the above error bounds, and, since $2^{-2 t}$ is so very much smaller than $2^{-t}$, we gain many orders of magnitude in accuracy. The cost in computing time varies among different machines, but is only a factor of four on the IBM 7094. The cost in storage is greater, since we mus double the storage reserved for the developing matrix.

Where the time and storage costs are too high to justify comple devole precision, it is possible to make a very substantial gain by a mach more limited ase of double precision. Most of the operations in Gaussian elimination car be phrased as inner products of vectors of single-precision numbers. On many machines it is possible to accumulate such an inner product in double precision, and then round it off to single precision before storing away the result. The result of this accumulation is to reduce the maximum rounding error of an
inner product by a factor of $n$. The total effect turns out to be to reduce the round-off error bound by a factor of $n^{5 / 2}$. Thus, instead of the result (7), an elimination with pivoting and accumulation produces an approximate inverse $X$ such that

$$
\begin{equation*}
\frac{\left\|X-A^{-1}\right\|}{\left\|A^{-1}\right\|} \leq 3.3 n 2^{-t}\left\|A^{-1}\right\| g(n) \tag{12}
\end{equation*}
$$

under certain additional hypotheses. See Wilkinson [61, p. 253]. The gain of the factor $n^{5 / 2}$ is very substantial, although experience shows that the actual errors in single-precision computation are usually rather less than the bounds. One theoretical disadvantage of the complete pivoting strategy is that it does not mix well with the accumulation of inner products. When products are accumulated, one almost always uses a partial pivotal strategy, and accepts the theoretical possibility that pivots can grow very large.

A third and the most successful approach to increasing the accuracy of solutions of dense, stored linear systems is the so-called method of iterative improvement. By this method, if the matrix $A$ is not too ill-conditioned, one in practice gets solutions which are the correctly rounded approximations to the trui answers. We will now describe this development.

Suppose that by Gaussian elimination one has achieved a first approximate solution $x_{0}$ of the linear system $A x=b$. The next step is to form the residual vector $r_{0}=b-A x_{0}$. If $x_{0}$ were the exact solution of the system, we would have $r_{0}=\theta$, the null vector. If not, we solve the new linear system $A y=r_{0}$, to obtain a vector $y_{1}$. Let $x_{1}=x_{0}+y_{1}$.

The process is repeated iteratively. I.e., for $k=0,1,2, \ldots$ we form the residual $r_{k}=b-A x_{k}$, solve the system $A y=r_{k}$ to obtain a vector $y_{k+1}$, and then form $x_{k+1}=x_{k}+y_{k+1}$.

Under suitable hypotheses to be specified below, the sequence $x_{k}$ converges to the true solution $A^{-1} b$ of the system $A x=b$.

Several matters need to be clarified in this algorithm. First, it appears to involve a great deal of work to solve systems of the form $A y=r_{k}$ for many values of $k$. In fact, this is not so. Gaussian elimination to solve a. system $A x=b$ involves three distinguishable stages:
(i) Triangularization of the matrix $A$ by elementary row irarsforma :ons
(ii) Application of the same row transformations to 'he right-hend sidr os
(iii) Solution of the triangular system by back-substitution.

It turns out that stage (i) requires approximateiy $n / 3$ multipilications and additions, but that stages (ii) and (iii) together reqiure unly approxima'ely $n^{2}$ multiplicntions and additions. Stage (i) need be done oniy once for a $a \neq$ the systems $A y=r_{k}$. If the multipliers defining the row transformations are saved, stages (ii) and (iij) can be done rapidly for each new system Ay $r_{k}$ In turn. As a result, it is found that a sufficiently iong sequence of reciors $x_{k}$ can usually be computed in something like only 20 per cert more time han the computation of the first solution $x_{0}$.

```
..t is absolutely essfntial that each residini vectur ry be comp.ed . =
```

nigh precision. This is normally done by a double-precisior necumaiat on of inner prod,cts, followed by rounding of the answer to single-precision ilea*ing. poin. form. If $r_{k}$ is computed with merely a singıe-precisicn inner pr d.ct.

 tells us that $x_{k}$ will de wrong by several times cond(A) in its leas: sagnific:ant dirat. Since cond $(A)$ may well be $10^{4}$ or $10^{5}$, the resultan. accuracy in $x_{k}$ is very low and, in fact, $x_{0}$ is itseif aimost as acc..r.te as iny sicceeding $X_{k}$.
"he foliuwing theursii. Eires $n$ pasis f the above me hod of iterative improvement:

Tneorem Le: the ratrix A iave he property inat

$$
\begin{equation*}
(0,8) 2^{-\cdot} n^{7,2} \varrho\left(n_{1}\right)\| \|^{-1} \|<\frac{1}{2} \tag{13}
\end{equation*}
$$

-et the abcve algorithm be carried ou'., win each system $A y=r_{k}$ being sotved -n single-precision base-2 floating. Ecint aritnretic, but with computat:ons of ${ }^{r}{ }_{K} \quad b-A x_{k}$ and $x_{k+1} \because x_{k}+y_{k+1}$ carried 0.1 withoni, ronding error nen

$$
\left\|x_{k}-A^{-1} b\right\| \rightarrow 0, \text { as } k \rightarrow \infty
$$

If the solution of the systems $A y=r_{k}$ were done with accurlalations of r.ner-products in double precision, then the left hari sade of (13) could be replaced by the right.hand side of (i2)

In practice, of course, $r_{k}$ is computid oy a double-precision
Cimulation of irner products, and $x_{k \cdot i}$ is comp ited as the floating-Fo.nt $\therefore$ of $x_{k}$ and $y_{k+i}$ As a resil, the searence $x_{k}$ does not converge to ${ }^{-} \mathrm{i}$ in the mathematical sense. Instead, $X_{k}$ is observed to pecone constant i valie which is normally the cur rectly rcunded single-precisior: approximation $A^{-I_{b}}$

In the actual use of iterative mprovemert, on does not sually know : ndvance whether or not hypothesis (13) is sa.1sfied, and it cannot be con. hed afterwards either, Normal practice as there:cre to rely on the follcwing $\because . r: s t i c$ result:

Almost-theorem. Let the aioore algorilnm be carried out, with each : $\because$ em Ay $r_{k}$ being solved by $h \in$ same version of Gaussian elimination, with $\because 2 r_{\text {is }}$ being computed by a do, bit-precision accan. la ion of inner prod.cts, ain with $x_{k+i}$ being complited as the flcating-pciri s.miof $x_{k}$ and $y_{k+1}$.

If for $k \geq k_{0}$, all vectors $x_{k}$ are equal to some single-precision vector $x^{*}$, then $x^{*}$ is the correctly rounded single-precision approximation to $A^{-1} b$.

This almost-theorem cannot be proved, and, indeed, Kahan [32] has an extremely ingenious counter-example. However, most computers would bet their life on the applicability of the above almost-theorem in any practical example, unless Kahan were furnishing the problem:

Normally, when cond(A) gets near $2^{t}$, the vectors $x_{k}$ obviously diverge. Then there is no cure except to increase the precision with which the elimination is carried out, unless scaling $A$ will help.

The usual value of $k_{0}$ is 3 or 4 .
10. Scaling of matrices. One matter that was glossed over in Sec. 8 was the scaling of the matrix $A$ before solving a system $A x=b$. Alternate terms for scaling are preconditioning and equilibration. Suppose that the 2-by-2 numerical example of Sec. 8 were altered by multiplying the first equation by $10^{6}$. Then the system would be

$$
\left\{\begin{array}{c}
10.0 x+100000 y=100000  \tag{14}\\
1.00 x+1.00 y=2.00
\end{array}\right.
$$

The effect of the scaling is to make 10.0 the larger pivot in the first column. Then elimination of $x$ from the second equation of (14) in 3-digit floatingdecimal arithmetic will result in a new second equation

$$
-10000 y=-10000
$$

Back solution leads to $y=1.00$ and the awful result $x=0.00$.

We see thet pror scol.ng viti: a good pivoral sumtegy torces ins into the same enormous rounding error thet we cotained in Sec 8 from the origingl set of equations and a bad pivotal strntegy

The conclusion of this is tha: a good pivotal strategy is only good when the matrix is properly scaled in adv nce. However, it must be admitted that so far we do not know guaranteed algorithms for scaling motrices well.

It is normn to scale matrices by simply mult.aplying rows and column by factors. In effect, one chooses nonsingliar diagonal matrices $D_{1}$ and $J_{2}$, nd then scaips $A$ by the transformation

$$
\mathrm{A} \rightarrow \mathrm{D}_{1}^{-1} \quad \mathrm{~A} D_{2}
$$

Becruse cond(A) is an ingredient of all our error bounds and convergence theorems, it is natural to wish to seiec: $D_{1}$ and $D_{2}$ so as tu reduce cond ( $D_{1}^{-1} A D_{2}$ ) t.c as low a value as is reasonabiy possible.

One usually ises powers of the floating-peint base for scnle factors, to avoid the introduction of rounding prrors in the scaing. Or, alternativeiy, one may use the scaling only implicitly, without nct.wily altering the element.s of $A$.

Theorem (F.I. Bauer) If the crdered set of pivotal elements is selecter in advance, scaling of a matrix $A$ by powers of the fioating-point base does no. change a single digit. of the sigrificand of any intermediate or final number in the solution of $A x-b$ by Gaussian elimination.

The theorem was presented in Ba, er [1]. Thus the oniy pussible effec: of the scaling of $A$ on the rounding eyrors mus occur through changing the order of pivots. Our example showed that the change in pivots can indeed make a great deal of difference.

One is sometimes advised to pick $D_{1}$ and $I_{2}$ so that the resulting
matrix $D_{1}^{-1} A D_{2}$ has its maximum element in each row ond colum (in ausoin a volue) in the intervel $[, l, 1$ ), in whatever number bn e one is using, howerer, Richard Hamming has showed (unpublished) that this advice does not always iead to good scaling. If

$$
A=\left[\begin{array}{ccc}
1 & 1 & 2 \times 10^{9} \\
2 & -1 & 10^{9} \\
1 & 2 & 0
\end{array}\right]
$$

Then both of the following matrices are decimally scaled equivaisnts of $A$ :

$$
\begin{aligned}
& A_{C}=\left[\begin{array}{ccc}
.1 & .1 & .2 \\
.2 & -.1 & .1 \\
.1 & .2 & 0
\end{array}\right] ; \\
& A_{R}=\left[\begin{array}{ccc}
10^{-10} & 10^{-10} & 2 \\
2 \times 10^{-10} & -10^{-10} & \cdots 1 \\
. i & .2 & 0
\end{array}\right]
\end{aligned}
$$

However, $\hat{A}_{C}$ is a well-conditioned matrix that offers no diffici-tics in one solution of an equation syster., whereas $A_{R}$ is most. $: 21$-condit.sred and provides vast troubles for elimanation.
zauer [2] has studied the problem of finding $\mathcal{I}_{1}$ and $I_{2}$ to minimiat cond $\left(D_{2}^{-3}\right.$ i $\left.D_{2}\right)$. It turns oit that the solution deperds on cer ain properties of the nonnegative matraces $|A| \cdot \mid A^{-1}$ and $\mid A^{-i}$ : $|A|$. (Here $|B|$ denotes the matrix of absclite values $\left.\left|b_{1, j}\right|.\right)$ Cleariy, ve car nardly nope $o$ compute $A^{-1}$ in order tc find a reasonable scaling, so that we can compute $A^{-1}$ :

So, it is $n$ open question, how to find a $d \in$ mons $\dagger$, $r$ ably good and convenient scaling algorithm. Existing algorithms are either very superficial or potentially very slow.

The only cheerful side of the scaling question is that it seems to be a rare matrix which good scaling changes from untract,able to tractable!
11. Analysis of rounding errors. We poirted out in Sec. 5 that the direct rounding error analysis of von Neumann and Goldstine was extremely -edious to apply. Givens [17] introduced the idea of inverse rounding errors. Wilkinson has developed this into a very powerful tool for bounding the rounding errors in matrix computations. The error bounds of Secs. 8 and 9 were obtained from inverse analysis. The basic idea is to change the nonassociative, nondistributive floating-point arathmetic system into an associative, distributive number system, by throwing the errors back onto the data of the computation.

For example, let $f l(u \times v)$ stand for the floating-point product (number base $\beta$ ) of the floating-point numbers $u$ and $v$. The direct error analysis uses statements of the form

$$
w=f l(u \times v)=u v+\epsilon, \text { where }\left|=\left|<\frac{1}{2}\right| u v\right| \beta^{i-t}
$$

Firther operations on $w$ irtroduce new errors, ard one has to keep account of the cumulation of all the old and new rounding errors. Eventually, one bounds ine difference between the cumpited final arswer and the mathematically correct inswer corresponding to the given data.

In inverse analysis, one makes statements of the form

$$
w=f l(\sim X v)=u v(1+\delta), \text { where }|\delta|<\frac{1}{2} \beta^{1-t}
$$

Thus the computed product is considered the true mathematical product of (for example) the real numbers $u$ and $v(l+\delta)$, which differ slightly from $u$ and $v$. Further floating-point operations on $w$ produce numbers which are always treated as the results of exact operations on other slight,ly more perturbed approximations to the original data. The final answer is considered as the exact solution of an original problem with data which are perturbed by amounts for which bounds are given.

If desired, these inverse error bounds can be converted to crdinary error bounds, by normal mathematical methods.

Inverse error analysis turns out to be extremely well adapted to the analysis of algorithms of a marching type which continally introduce new data. Both the solution of linear equations and the evaluation of polynomials are of this type. Inverse error andysis is not at all well suited for problems of an iterative nature-for example, the Newton process for evaluating the snuare root of a number.

The reader is referred to Wilkinson $[60,62]$ for further study of inverse round-off analysis.

A second approach to round-off analysis is the interval analysis, extenaively developed by Moore [40], but based on the idea of "range numbers" presented earlier by Dwyer [6]. In its orıginal form, interval analysis is poorly adapted to matrix comp,tations, but Hansen [23] has modified it inger.ıcusly for majrix work.
extensive a treatment of the eigenvalue problem as that given for the linear equations problem. We can only mention a few highlights of today's methods The reader is referred to Wilkinson's treatise [61] for an almost complete presentation of the state of the art.

As with the linear equations problem, the computation of eigenvalues of matrices divides into two methods, according to the nature of the matrices. For large, sparse matrices the methods are mostly infinite iterations, and will not be considered here. For dense, stored matrices, most methods are finite algorithms.

If a matrix $A$ is symmetric, its eigenvalues are very well determined by the data. In fact, let the symmetric matrix $B=A+E$ have eigenvalues $B_{i}$, and let $A$ (also symmetric) have eigenvalues $\alpha_{i}$. Then the eigenvalues can be so numbered that

$$
\begin{equation*}
\left|\alpha_{i}-\beta_{j}\right| \leq\|E\|, \quad j^{\prime} \circ r a_{i} i \tag{15}
\end{equation*}
$$

Now inverse error analysis refers the computed eigenvalues of a matrix $A$ back to a matrix $B=A+E$. If $E$ can be proved to de small (as it can), then (15: shows how small the eigenvalue errors are. In fact, today "s met nods can yield eigenvalues that are in error by only a few digits in the least significant digits of the large eigenvalues.

The method of Jacob: [31; is an infinite iteration for dense, stored matrices. It produces a sequence of matrices orthogonally congruent to A :

$$
A_{k}=U_{k}^{T} A U_{k}
$$

Moreover, $A_{k}$ converges to a diagonal matrix $D$ whose diagonal entries are, of
course, the eigenvalues of $A$. In fact, each $A_{k+1}$ is computed from the previous $A_{k}$ by a rotation in the coordinate 2 -space of some two indices $i$ and $j$, a rotation chosen so that $\underset{a, j}{(k+1)}=0$.

For any $k$ such that $A_{k}$ is almost diagonal, the columns of the corresponding orthogonal matrix $U_{k}$ are approximately column eigenvectors of $i$ Moreover, the columns are themselves orthogonal. Thus the Jacobi method yle!ds approximate eigenvectors of fine quality as a by-product of the basic iter $\cdot 1$. The whole program is easy to write, and it is difficult for it to be dore bady. There are some theoretical problems about how good the eigenvectors are, and whether the $U_{k}$ actually converge .

Goldstine, Murray, and von Neumann [19] analyzed the rounding errors in a fixed-point version of the Jacobi method.

The original Jrcobi algorithm chose $i$ and $j$ to maximize the absolute value of the element $a_{i, j}^{(k)}$ of $A_{k}$. Modern algorithms modify this craterion in one of two ways:
(i) In the cyclic Jacobi methods, the off-diagonal elements $a_{i, j}$ are zeroed in some cyclic order. Forsythe and Henrici [11] proved the convergence of a common cyclic method. See also Hansen [22].
(1i) In threshold Jacobi methods, an element ${ }^{\circ}$ :,j is selerted for annihilation only when its absolute value is above a certan threshoid suze, which gets smaller us the iteration progresses. See Fope nd Tompkins [49j rii sorneil! 4].
lt has been proved only recently that the cyclic dacobi methud converges :indratically for any matrix A. See Schönhage [52] and Wilkinson [59]. "ne work was based on that of Henrici [24].

Givens [17] observed that, although it takes on infinite senuence of
rotations to bring $A_{k}$ to diagonal form, a mere $\frac{1}{2}(n-1)(n-2)$ rotations can bring $A_{k}$ to tridiagonal form. This reduced the problem to that of finding eigenvalues of tridiagonal matrices, and the latter problem has been a subject of research ever since. See Ortega [43], Ortega nd Kaiser [45], and recent work of Kahan and Varah [33]. In any case, the Givens Idea cut the practical time of finding eigenvalues by a factor of about 9 in practice (Wilkinson [61, p. 3351.. A few years later Householder (see Householder and Bauer [29]) introduced a new method of tridiagonalizing a symmetric matrix, using $n-2$ reflections instead of $\frac{1}{2}(n-1)(n-2)$ rotations. This cut the time down by another factor of two, and effectively put the Givens method out of business. An error analysis is given by Ortega [44]. Most contemporary programs use the Householder method, but differ widely in how eigenvalues of tridiagonal matrices are found. Getting the eigenvectors is surprisingly tricky, and lack of knowledge of how to do it is one reason for the occasional continued use of the Jacobi methods.
13. Eigenvalues of unsymmetric matrices. The area of greatest activity in the past decade of research on computational linear algebra $h$ :s been the eigenvalue problem for unsymmetric matrices. Only one method from before the computer era is still in use--the power method--and it has only limited applications today. Most methods in use today were unheard of 15 years ago.

It is essential to realize tne instability inherent in the eigenvalue problem for unsymmetric metrices. In contrast to the close bound (15), for unsymmetric matrices the corresponding rescilt, due to Ostrowski [46], is

$$
\begin{equation*}
\left|\alpha_{i}-\beta_{i}\right| \leq(\text { polynomial in } n) \times\|E\|^{1 / n} \quad(\text { all i }) . \tag{16}
\end{equation*}
$$

The above result is very weak, and yet is the best possible general result of 1 ts kind. For the matrix

$$
\left[\begin{array}{llllll}
0 & & & & & \epsilon \\
1 & 0 & & 0 & & \\
& 1 & 0 & & & \\
& & 1 & \cdots & & \\
& & & \cdots & \cdots & \\
& & & & \cdots & 0
\end{array}\right]
$$

of order $n$ has all eigenvalues 0 for $t=0$, but all eigenvalies : $\quad \mathrm{distac}$ a mat $\therefore$ ve modulus $|\epsilon|^{l / n}$ for $\epsilon \neq 0$. Thus, if $n=40$ and $r=10^{-40}$, $n$, eqgenv: in have modulus 0.1 (:).

Fortunately, eigenvalues are not usually so sensituve in fait, anferen: eigenvalues of a matrix $A \quad c^{n} n$ differ enormously in their sensitivity $t=$ perturbations in A. Chapter 2 of Wilkinson [61] is full of useful resilts. They are generally a posteriori results, giving bound for the changes ir eigen. values as functions of perturbations in a matrix and information about the other eigenvalues and eigenvectors.

The great power of the Jacobi method for symmetric mitrices, ind ine axtremely pleasant rounding characteristics of unitary miraces led t. $:$ desure to use them for the unsymmetric eigenvalue problem. Tne b. sic theorer is dum - o Schur:

Theorem. For an arbitrary matrix A, there exists itunttry m:r.x $\because$ sich thot

$$
T=U^{H} A U
$$

1strianglar. (Here $U^{H}$ denotes the conjigate transpose of l.)
Since the elgenvalies of $A$ are the diagonal elements of $m$, the hope has been to find unitary matrices which bring $A$ nearly into a triangular for: , and then let the diagonal elements serve as approximate eigenvalues of $A$.

Investigations by Grefnstadt [21], Lot,kin [37], and Eberlein [7] offer some hope, but no real promise of success

For most methods of at tacking the elgenvalue problem, the first step is to condense the data, to save time and storage in further work. The now universally accepted condensed form is the Hessenberg matrix, in which $a_{i, j}=0$ for $i-j>1$ (or its transpose) It $1 s$ pcssible to transform $A$ by orthogonnl congruences of the Householder type into • Hessenberg form witn only very small rounding errors. Any further condensatıon (say, into tridiagonal form) is subject to serious losses of digits. A transformation to the companionmatrix form is particularly disastrous in practice, and it normilly requires ver.j substantial increases in precision to successfully yield the eigenvalues of $A$.

As on alternative, one can transform A :o Hessenberg form by Gaissian elamination with partial plvoting, a simılarity transformation

The next stage in the insymmetric eagenvilue problem is to get the eigenvalues of a Hessenberg matrix $H$. A vriety of methods $h$ ve been used.
(i) One can search for zeros of det (H. z !) by root-finding methods, for complex $z$. The most satisfactory method appears to be that proposed by Hyman [30j and developed by Farlett [47; in a naper of programs. He makes is se of the method of Laguerre tc find the zerus of $f(z)$, following by a form of zero suppression Very satisfactory recurrences are usedto evailate f(z), $f^{\prime}(z)$, and $f^{\prime \prime}(z)$, as needed by the Lag, erre process. After the eigenvalues $\wedge_{1}, \ldots . \lambda_{r}$ have been found, they are suppressed by applying the jaguerre process to

$$
f(z) / \prod_{i=?}^{r}\left(\lambda-\lambda_{j}\right)
$$

(ii) The LR-algorithm of Rutishauser $\lceil 58$, was an 1 mportant. development.

Sunce it has now been pretty weil supplanted by the $Q R$-aigorithrm, we cmit mention of it.
(1ii) Francis [15, 16 l in England, and Kublanovskaja [35] in the Soviet Union devised the very interesting QR-algorithm. This is now widely considered the most satisfactory eigenvalue algorithm for dense, stored unsymmetric matraces.

The basic theorem is that an arbitrary real square matrix $A$ can be factored in the form $A=Q R$, where $Q$ is orthogons1, and where $R$ is an upper-triangular matrix with all diagonal elements $r_{i, i}$ nonnegative. If $A$ is nonsingular, then both $Q$ and $R$ are unique.

In fact, the computation is done by building up an orthogonal matri: $Q^{T}$ such that $Q^{T} A=R$, where $R$ has the above properties.

As an aside, for nonsingular $A$, the reader will be more fomilar with the stepwise determination of an uper-triangular matrix $R$ with positive $r_{1,1}$ such that $A R^{-1}$ is an orthogonal matrix $Q$. This is the mitrix expression of the familiar Gram-Schmidt process of analysis. It will perhaps surprise the reader that the matrix $Q$ resulting from the Gram-Schmidt algorithm is normaliy far from orthogonal, because of rounding errors. On the other hand, if the same $Q$ is determined so that $Q^{T} A=R$, the rounding errors are very small.

The basic QR-algorithm proceeds as follows. Let $H=H_{0}$ be a Hessenderg matrix. For $k=0,1,2, \ldots$, factor $H_{k}$ in the fort

$$
H_{k}=G_{k} R_{k},
$$

and then form

$$
H_{k+1}=F_{k} Q_{k} .
$$

It is etsily shown that $H_{k+1}$ is also a Hessenberg min. rix.
The basic theorem is the following.
Tneorem, Let $H$ have eigenvalues $\lambda_{1}, \lambda_{2}, \ldots, \lambda_{n}$ with

$$
\left|\lambda_{1}\right|<\left|\lambda_{2}\right|<\ldots<\left|\lambda_{n}\right| .
$$

## Then the matrices $H_{k}$ converge to an upper-tri-ngular matrix whose diagona]

## elements are the eigenvalues of $H$

In the more usual case where (17) is not s=tisfied, we find that $H_{k}$ converges in shape to a blockwise triangular matrix. (This means that outsıde 2. blockwise triangular matrix all elements of $H_{k}$ tend to zerc, as $k \rightarrow \infty$, but thet some elements of the blockwise triangular form may not converge.) Moreover the 2-by-2 and l-by-1 diagonal blocks of the matrix $H_{k}$ have eigenvolues which in their totality converge to the eigenvalues of $H$.

For simplicity, consider a mitrix $H$ with eigenvalues

$$
0<\lambda_{1}<\lambda_{2}<\cdots<\lambda_{n}
$$

The $\Omega$ R method for such a matrix converges with an error which is

$$
\underline{o}\left[\left(\lambda_{1} / \lambda_{2}\right)^{k}\right]
$$

The convergence would be more rapid if, instead of $H$, we dealt with the matrix $H-p I$, where $0<p<\lambda_{1}$. If $p$ were practically equal to $\lambda_{1}$, the convergence would be extremely rapid. Modificatıons of the QF-algorithm have been devised that simulate this so-cailed orign shift which introduces . $p$ near $\lambda_{i}$. After one eigenvalue $\lambda_{1}$ has been isolated, the QR method can thon be applied to an $n-1$ by $n-1$ matrix with eigenvalues $\lambda_{2}, \ldots, \lambda_{n}$. New origin shifts are then introduced to bring out $\lambda_{2}$ as rapidly as possible. $\Xi$. With well devised origin shifts, the whole process has been observed to convery with an average of less than two iterative steps per eigenvalue.

Most research goes into the invention of crigin shifts when some of ine eigenvaiues are compiex and of equal modulus. We shall not attempt to give tan ideas.

A more recent convergence proof has been given by Wilkinson [62], but. like the Francis proof, is given for an arbitrary matrix $A$. If one limits himself to matrices of Hessenberg form. easier proofs can be giver, see Kahan (unpublished).

Normally, the eigenvalues are obtained in order of increasing modulus.
farlett [48] has given theorems stating precisely when this cccurs.
If H is a symmetric band matrix, then the $Q R$-algoritim preserves the band width during the iteration, and is very satisfactory. In particular, $Q R$ is a possible algorithm for computing eigenvalues of a symmetric tridiagonal matrix.

If $H$ is an unsymetric band matrix, the QR-algorithm loses the zero bard: above the diagonal.

So far, we have not mentioned getting the eigenvectors of a fiessennere matrix $H$. This is the most difficult problem we shall mention. The previnlins method is that of inverse iteration . The eigenvai,es are assumed already known. For any fixed eigenvalue $\lambda$, one selects a vector $x_{0}$ arbitrarsiy. Then one carries out an iteration of the following form:

For each $k=0,1,2, \ldots$, find $x_{k+1}$ by solving the system

$$
\begin{equation*}
(H-\lambda I) x_{k+1}=x_{k} \tag{18}
\end{equation*}
$$

One continues until $x_{k}$ is quite large. In easy cases, $x_{k}$ is nearly an eigenvector belongıng to $\lambda$. Wilkinson [61, Chap. 9j discusses variants of this process. Varah [56] hes written several algor:thms

If $H$ is a real Hessenberg matrix, but $\lambda$ is a complex aervalwe, onf has to choose between doing complex arithmetic, or sme judicions y selected process with real arithmetic.

Finally, one transforms $x_{k}$ back to the oraginal coordinate systen cif $A$ by undoing the orthogonal transformations from $A * O H$.

If some of the eigenvalues of $H$ are very close, the real problems begin. A pair of close eigenvalues may in fortunate cases have distinct coiumn eigenvecto: that are far from perallel; this represents an approximation $t o$ a doubie eigenvalue
with a linear elementary divisor. It is far more likely that, a pair of close eigenvnlues will have column eigenvectors that are almost parallel This represents an anproximation to the infinitely more probable case of a double eigenvalue with nonlinear divisors.

In the former case, it is not difficult to compute two eigenvectors that are far from parallel. It is only necessary to carry out the iteration (18) with different $x_{0}$, or with two slightly different values of $\lambda$.

In the latter case, it appears difficult to obtajn much from the it.eration but a single eigenvector belonging to $\lambda$, What should be done next? In part one doesn't know what the problem proposer would like. In part one doesn't know what is possible. Varah is carrying out research on the problem. He is attempting to find an orthogonal basis for the invariant subspace of dimension 2 (in this case) belonging to $\lambda$.

For a "nice" matrix, Varah is also getting giaranteed error bounds for all eigenvalues and all eigenvectors, using Gerschgorin theorems, as Wilkinson recommends.
14. Conclusion and moral. The computational methods of linear algebra are moving into stage where we have reasonabiy satısfactory methods for dense, stored matrices $A$. The main exception is the problem of getting eigenvectors with error bounds, for unsymmetric matrices. The algorithms have been refined several times, and are being published, particularly in Numerische Mathematik. Casual users of matrix algebre will do no better thrn to take such algorithms "off the shelf" for their problems. The best algorithms are mainly written in Algol 60. Even though the reader may use another language, it is unquestionably worthwhile for him to learn to read Algol 60, just in order to be able to read these algorithms and adapt them to his own problems.

No method of solving a computational problem is re"lly nviste a a wiser untilit is completely described in algebric computing lang.epge anci made completely reliable. Before that, there are indeterminate spects in every rlgorithm. Frequent,ly the entire advantage of a certain computing rocess ies : $n$ the treatment of certain fine points which can hardly be suspered unt.i : ney are completely programmed. This is the renson why the mateur shoud eitaer consult an expert, or take great p"ins to pick up foolprof "lgoritan is the reason why professionals should concentrate very hra on compledey foolproofing the algorithms they devise, before patting them on the aelf :l. widespread use.

19. ABSTRACT

This is a survey of selected computational aspects of linear algebra, addressed to the nonspecialist in numerical analysis. Some current methods of solving systems of linear equations, and computing eigenvalues of symmetric and unsymmetric matrices are outlined. There is a bibliography of 62 titles.

4. DEECNIPTIVE MOTEA: IS eppropriate, enter the type of report, eife, interim, procesess, cummary, ansual, or final. Give the lacluelve dates when a apecific reporting period is covered
5. AUTHOR(B): Enter the namo(o) of author(a) as ahown on or ta the report. Enter leat name, firct name, middil Initial. If milltary, show sank and branch of servica. The name of the priscipal author is an absolute minimum requirement.
6. REPORT DATE: Entor the dete of the report an day, month year, or mouth, yean if more than one date appears on the repert, uee date of publication
7a. TOTAL NUNGER OF PAOES: The total page count should follow sormal pagination procedures, i. e., enter the mumber of pages contaiaing information
7b. NUIBER OF REFERENCE: Entor the total number of references cltod in the report.
8a. CONTRACT OR GRANT NUMEER: If mpropriate, ontor the applicable number of the contract or erant under which the report wae writton
et, min ed. PROJECT NUMBER: Enter the appropriate milltary departmens identification, wuch as project numbet, subproject mumber, syatem numbers, task number, etc.
9. ORIGINATOR'S REPORT NUMBER(8): Enter the offclal report number by which the document will be idendified and controlled by the oricinating activity. This number muet be unlque to thile report.
9b. OTHER REPORT NUMBER(8): It the report has boen easigned any other seport numbers (elthor by the oritinator or by the eponeor), alco enter this number(a).
10. AVALLABILITY/LEITATION NOTICE\& Enter any IIm itations ca furtber diasemination of the report, other than those
lmposed by eocurity classification, using etandard etatemente
(1) "Qualifiod requegtore may obtain coples of thle report from DDC"
(2) "Forelgn announcoment and diesgalaation of thite report by DDC is not authorised"
(3) "U. S. Government ageacles may obtain coples of this report directly from DDC. Other quallified DDC users thall request throush
(4) "U. 8. military agencies may obsala copies of this report directly from DDC. Other qualified uewre shall request through Ifled DDC users shall sequest through
$\qquad$ . 10
If the report has been furnithod to the Office of Tectraical Services, Department of Commerce, for eale to the publle, ladicate this fect end enter the price, if known
1L. SUPPLEMENTARY NOTES: Use for additional expleastory notes.
12. SPONSORING MILITARY ACTIVITY: Enter the name of the departmental project offlce or laboratory eponcoring (pay ine for) the research and development Include edrese.
13. ABSTRACT: Enter an abatract giving abriof and factual aummary of the document indicative of the report, evea though It may also appear eleewhere in the body of the techalcal report. If addillonal apace is required, a continuation abeet ahall be attached.

It is hichly desirable that the abetract of clacaified moporte be unclassified. Each paragraph of the abetract shall ead with an indication of the military aecurity clasaification of the information in the paragraph, represented as (TS), (S), (C), or (U).

There is no Limitetion on the length of the abetract. How--ver, the suggented length is from 150 to 225 words.
14. KEY WORDS: Key worda are technically moanalagful torme or short phrases that charsctertse a report and may bo used as Index entries for cataloging the report. Key worde muat be selected so that no security clageification is required. Edeatdfiere, such as equipment model desiemation, trade name, fllitary project code nanie. geographic location, may be used as koy words but will be followed by an indication of technicel comtoxt. The aseignment of links, reles, and weighte it optional.
