Traumatic Intracranial Hypertension

Nino Stocchetti, M.D., and Andrew I.R. Maas, M.D., Ph.D.

AN ELEVATION IN INTRACRANIAL PRESSURE CAN BE A MEDICAL OR surgical emergency. There are many possible conditions that can lead to elevated intracranial pressure on either an acute or a chronic basis (Table 1). In this article, we focus on the increased intracranial pressure that occurs in patients after traumatic brain injury, since this is an area in which there are both physiological and clinical data.

Traumatic brain injury is a medical and social problem worldwide, with an estimated 10 million cases leading to hospitalization or death each year.¹ In low- and medium-income countries, in which the use of motor-powered transportation is increasing, the incidence of this condition is rising² and involves predominantly young men. In contrast, in richer countries, the epidemiology of traumatic brain injury is changing because of two main factors: the rate of traffic incidents is decreasing owing to successful enforcement of safety laws and preventive measures, whereas the aging of the population makes such injury in the elderly more frequent.²⁻⁴

Falls are a frequent cause of injury in older patients, often resulting in contusive brain injury. Elderly patients often have multiple coexisting illnesses and are frequently taking a number of medications, including anticoagulants and platelet aggregation inhibitors.⁴ These medications may contribute to the development of hematomas and hemorrhagic expansion of contusions. In the past, it was generally thought that traumatic brain injury in elderly persons was associated with a uniformly bad outcome, and as a consequence more aggressive treatment was often withheld.⁵ Although increasing age is unequivocally an independent predictor of a poor outcome,⁶ recent data suggest that favorable outcomes, at least in the short term, are no longer uncommon among elderly patients⁷; however, these patients require sustained, high-level medical care and rehabilitation.

PATHOPHYSIOLOGY

Normal intracranial pressure in adults is below 15 mm Hg, with transient increases due to coughing or sneezing. Intracranial-pressure values that are sustained above 20 mm Hg are considered to be pathologic in adults and an indication for intensifying treatment in patients with traumatic brain injury. Under normal conditions, the total volume within the skull remains constant and is determined by the sum of the cerebrospinal fluid, blood, and brain-tissue compartments. The volume of these compartments is tightly regulated, and cerebral blood flow is kept constant by autoregulation. When additional volume is added to the system, compensatory mechanisms (e.g., displacement of cerebrospinal fluid to the spinal subarachnoid space and compression of the cerebral venous bed) operate to keep intracranial pressure constant.

The relationship between intracranial volume and intracranial pressure is exponential. Initially, pressure increases only slightly with increasing volume, but when the buffering capabilities of the system are exceeded, intracranial pressure rises

† Craniosynostosis is associated with inadequate skull growth.

steeply. This explains the rapid deterioration that is frequently seen in patients with a traumatic intracranial hematoma.

Both intracranial and systemic events contribute to increased intracranial pressure after traumatic brain injury (Table 2). In the first hours after trauma, expansion of hematomas is the main threat,⁸ whereas in the following days, other mechanisms, including water accumulation, disrupted autoregulation, ischemia, and contusion expansion, lead to further increases in intracranial pressure.

The direct consequences of increased intracranial pressure on the brain can be broadly differentiated as mechanical or vascular. When a mass lesion develops, a pressure gradient originating from this area will cause distortion of brain tissue, midline shift, and displacement of the brain tissue in a medial or caudal direction (herniation) (Fig. 1). Herniation is a medical emergency, requiring prompt treatment to prevent irreversible and often fatal damage to the brain stem.

Vascular effects of increased intracranial pressure are caused by impaired cerebral perfusion pressure, which is defined as the mean arterial

blood pressure minus the intracranial pressure. The cerebral perfusion pressure is the driving force behind cerebral blood flow, but levels that are required for adequate flow vary among patients. As the cerebral perfusion pressure decreases, cerebral blood flow may become insufficient for adequate brain-tissue perfusion and oxygenation.^{9,10} Ischemia will induce further cytotoxic edema and result in even higher intracranial pressure. Adverse effects of increased intracranial pressure and low cerebral perfusion pressure on mortality and long-term outcome have been documented in many studies.¹¹⁻¹³ These insights, while providing a clear motivation for the monitoring and treatment of raised intracranial pressure, illustrate the complex interactions among pressure, flow, and metabolism.

MONITORING OF INTRACRANIAL PRESSURE

The practice of continuous monitoring of intracranial pressure started with the pioneering work of Guillaume and Janny in France¹⁴ and

Lundberg in Sweden.¹⁵ A catheter, usually referred to as an external ventricular drain, was placed in the lateral ventricle and connected, through a fluid-filled system, to a transducer. This method is still considered the standard of care for the measurement of intracranial pressure. Noninvasive monitors of intracranial pressure currently have insufficient validation for clinical practice, but other invasive methods (e.g., intraparenchymal probes, microstrain gauge transducers, and fiberoptic catheters) are gaining in popularity because of their ease of use.¹⁶ These techniques, however, do not allow for drainage of cerebrospinal fluid, which removes an effective means of reducing intracranial pressure. Catheters may also be placed in the subdural space (e.g., after evacuation of an epidural or subdural hematoma); such techniques permit monitoring of intracranial pressure, but they do not permit drainage of cerebrospinal fluid, and measurements are less reliable than those obtained with an external ventricular drain.

International guidelines recommend the monitoring of intracranial pressure in all patients with survivable severe traumatic brain injury and abnormalities on computed tomography (CT) obtained at the time of admission,^{17,18} as well as in selected patients (e.g., those who are over the age of 40 years with hypotension or abnormal flexion or extension in response to pain) with a normal CT scan. The insertion of intracranial catheters carries risks of hemorrhage and infection. Ventricular catheters, with deeper brain penetration, are more risky. Reported rates of hemorrhage are variable (1 to 7% for ventricular catheters; less than that for intraparenchymal probes),^{19,20} and only rarely do such hemorrhages require surgical evacuation.¹⁸ Placement of an intracerebral catheter is relatively contraindicated in patients with coagulopathy (i.e., increased prothrombin time, partial thromboplastin time, or international normalized ratio or a platelet count of <100,000 per microliter).²¹ Routine cultures of catheter tips of external ventricular drains may reveal bacterial colonization, but fortunately the rate of invasive infection is lower than that of colonization.²² The risk of infection is higher with ventricular catheters than with parenchymal probes, with reported rates of infection ranging from 1 to 27%. Risk factors include longer duration of monitoring, the presence of an open skull fracture with leakage of cerebrospinal fluid, and leakage around the ventriculostomy site.^{22,23}

TREATMENT

Guidelines advocate the early treatment of increased intracranial pressure, since increased severity and longer duration of raised intracranial pressure are associated with a poor outcome.^{11,12} The accepted threshold for treatment is an intracranial pressure of 20 mm Hg. In all patients with increased intracranial pressure, a repeat CT scan should be considered to exclude surgically treatable lesions. Before initiating therapy to reduce increased intracranial pressure, practitioners need to exclude erroneous measurements and systemic causes that can be

Table 2. Causes of and Possible Therapies for Increased Intracranial Pressure in Traumatic Brain Injury.

Variable	Possible Therapeutic Approach
Intracranial cause	
Hematoma	Surgical evacuation, decompressive craniectomy
Epidural	
Acute subdural	
Intracerebral	
Contusion	Surgical evacuation, decompressive craniectomy
Disturbance in cerebrospinal fluid	Drainage of cerebrospinal fluid
With ventricular enlargement	
Without ventricular enlargement	
Edema	Hyperosmolar fluids, decompressive craniectomy
Cytotoxic (intracellular)	
Vasogenic (extracellular)	
Vasodilatation (increased intravascular blood volume, causing swelling)	Mild hyperventilation, barbiturates
Seizures	Antiepileptic medication
Extracranial cause	
Airway obstruction	Airway clearance, possible tracheal intubation
Hypoxemia	Oxygenation and ventilation
Hypercarbia	Ventilation
Hypertension associated with pain	Analgesia and sedation
Coughing or straining	Sedation, paralysis
Jugular venous obstruction (pneumothorax, neck compression)	Draining of pneumothorax, correction of neck position
Abdominal distention	Nasogastric tube
Fever	Antipyretic drugs
Hypoosmolarity	Hyperosmolar fluids

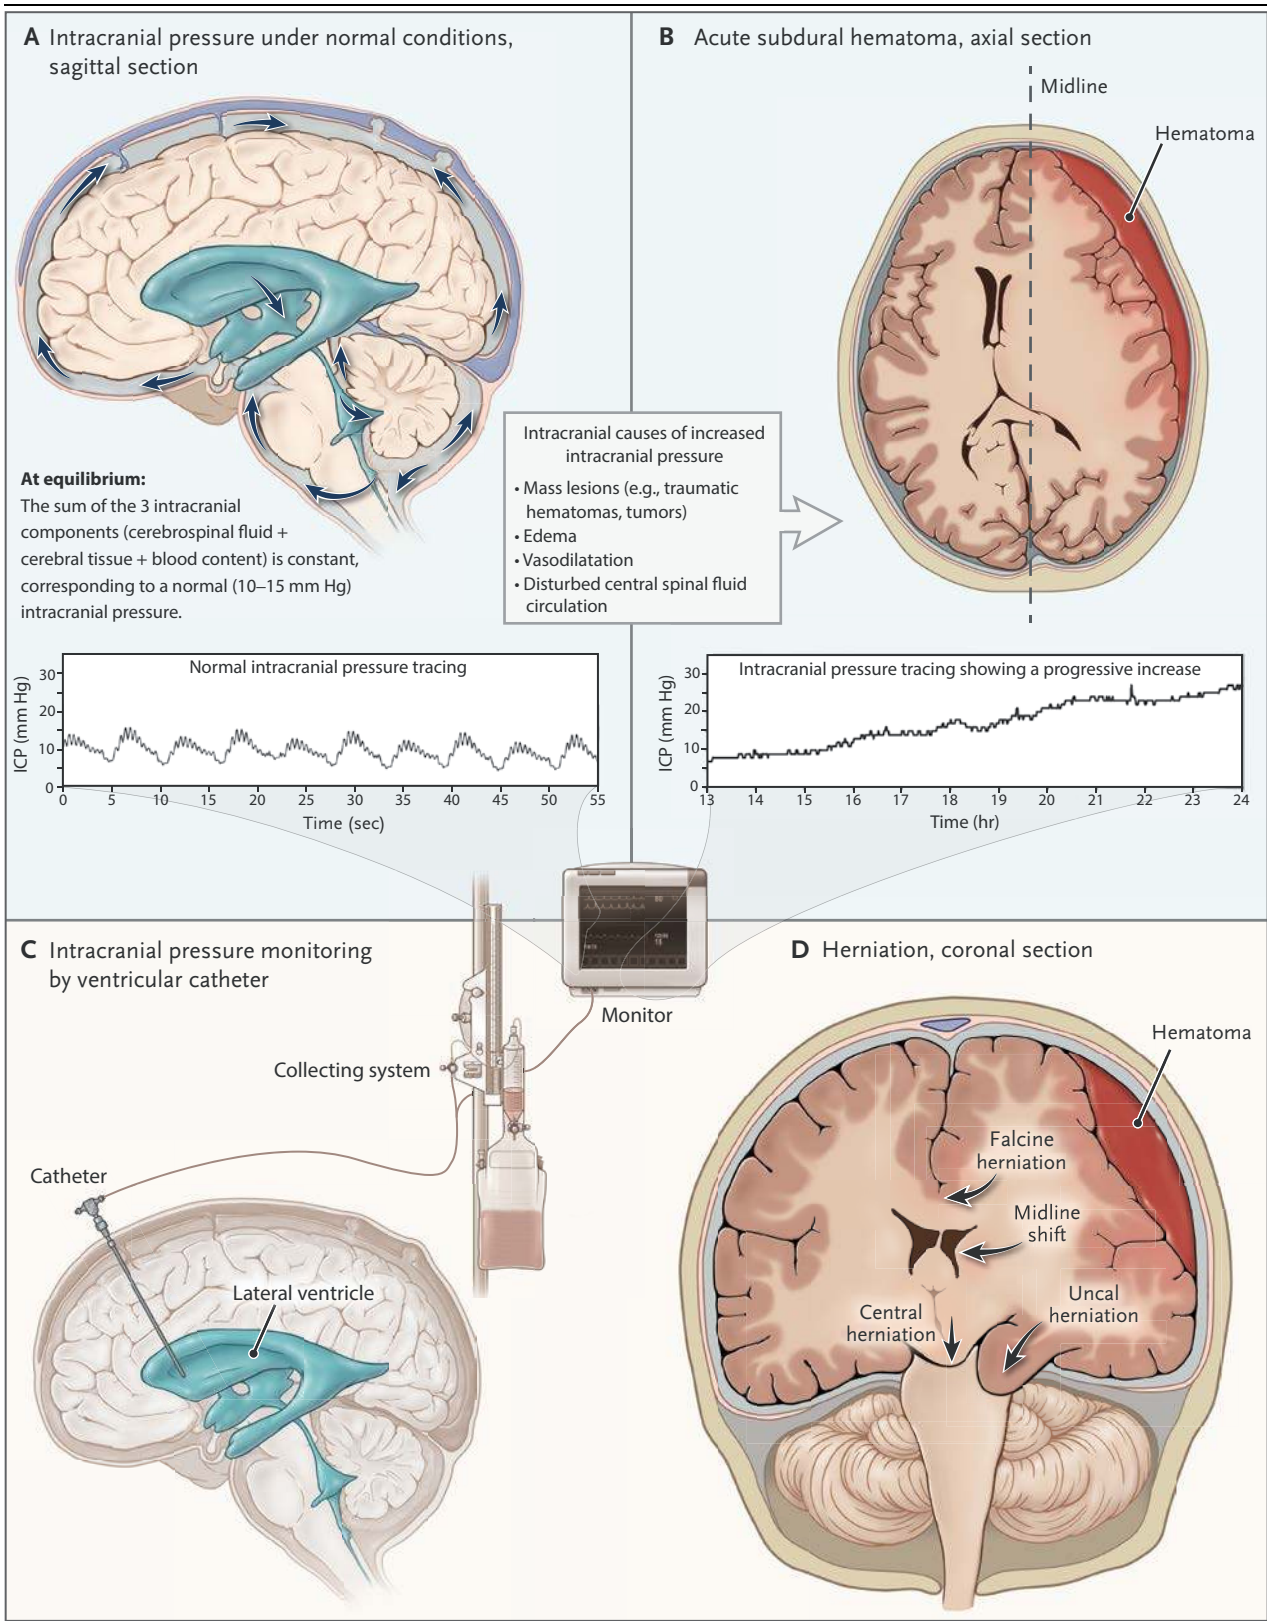

Figure 1 (facing page). Intracranial Pressure under Normal and Abnormal Conditions.

Under normal conditions, the intracranial pressure (ICP) remains constant at 10 to 15 mm Hg, fluctuating with cardiac and respiratory cycles, as shown in the normal trace recording (Panel A). Since the cranium is a rigid container, the sum of the various intracranial volumes (brain tissue, cerebrospinal fluid, and blood) must remain constant. Cerebrospinal fluid is continuously formed and reabsorbed, with the circulation indicated by blue arrows. Several intracranial and systemic causes may alter the intracranial components and cause pathologic increases in intracranial pressure — for example, a traumatic left subdural hematoma that compresses the brain and shifts the lateral ventricles to the right, as shown on computed tomography (Panel B). The hematoma volume cannot be compensated by buffering systems, and there is a corresponding increase in intracranial pressure, which can be recorded through a catheter inserted in a lateral ventricle (also allowing the withdrawal of cerebrospinal fluid) (Panel C). The catheter is connected to a collecting system, to which cerebrospinal fluid can be drained, and to a monitor, where the trace recording of intracranial pressure is displayed. Intracranial hypertension may cause compression and displacement of the cerebral tissue from areas of higher pressure toward areas of lower resistance (Panel D). Brain herniation occurs in three main ways. First, a hemisphere is displaced medially against the falx, resulting in falcine herniation. Second, a monolateral pressure gradient pushes the medial edge of the temporal lobe (uncus) through the tentorial foramen, resulting in uncal herniation. In this syndrome, the third cranial nerve and the posterior cerebral artery are compressed, causing unilateral pupillary dilation, a lack of reactivity to light, and infarction. The brain stem is distorted and compressed, with early impairment of consciousness. Third, a bilateral, homogeneous increase in intracranial pressure in the supratentorial space displaces the brain downward through the tentorial foramen, resulting in central transtentorial herniation. The brain stem is compressed and displaced downward without signs of lateralization and with bilateral pupillary abnormalities.

rapidly corrected. A practical algorithm is presented in Figure 2.

MEDICAL THERAPY

During the past 10 years, management of increased intracranial pressure has evolved toward standardized strategies that use a “staircase” approach with an escalating treatment intensity (Fig. 3).^{24,25} Sedation and analgesia are used to treat pain and agitation²⁶ and to prevent arterial hypertension and patient–ventilator dyssynchrony. Sedation increases the risk of arterial hypotension

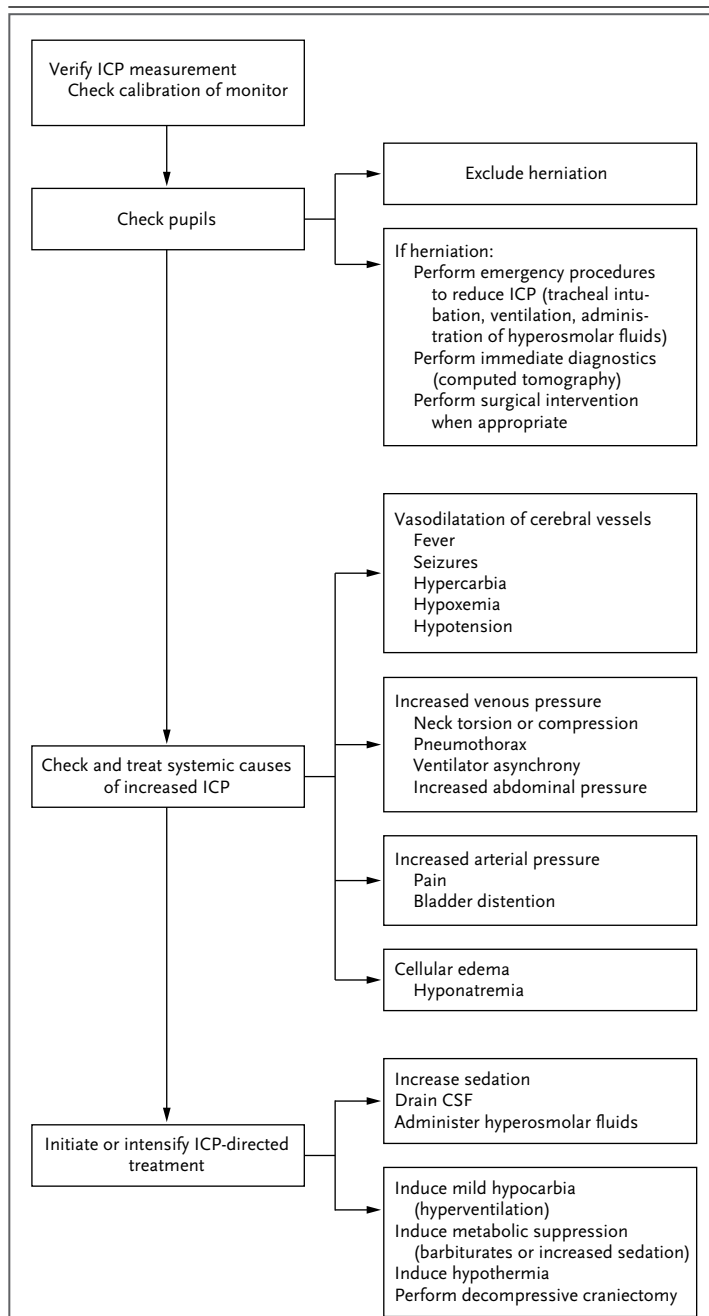

Figure 2. Algorithm for the Treatment of Increased Intracranial Pressure (ICP). CSF denotes cerebrospinal fluid.

resulting from vasodilatation, making maintenance of normovolemia a prerequisite. An additional advantage of sedation is to minimize the risk of seizures.^{27,28}

Hyperosmolar agents reduce brain volume

Therapy Steps	Levels of Evidence	Treatment	Risk
8	Not reported	Decompressive craniectomy	Infection or delayed hematoma Subdural effusion Hydrocephalus and syndrome of the trephined
7	Level II	Metabolic suppression (barbiturates)	Hypotension and increased number of infections
6	Level III	Hypothermia	Fluid and electrolyte disturbances and infection
5	Level III	Induced hypocapnia	Excessive vasoconstriction and ischemia
4	Level II	Hyperosmolar therapy Mannitol or hypertonic saline	Negative fluid balance Hypernatremia Kidney failure
3	Not reported	Ventricular CSF drainage	Infection
2	Level III	Increased sedation	Hypotension
1	Not reported	Intubation Normocarbic ventilation	Coughing, ventilator asynchrony, ventilator-associated pneumonia

Figure 3. Staircase Approach to the Treatment of Increased Intracranial Pressure.

The level of therapy in patients with raised intracranial pressure is increased step by step, with more aggressive interventions when there is no response. The sequence of interventions may vary among different institutions; every intervention is associated with adverse effects. Shown are the levels of evidence that underpin various approaches to treatment. Levels of evidence are based on the criteria for classification of evidence, as used in international guidelines.²⁴ The revised guidelines for the management of severe traumatic brain injury and the surgical guidelines for the management of such injury do not contain any evidence on ventricular drainage of cerebrospinal fluid (CSF) or the use of decompressive craniectomy. Level I evidence²⁵ shows that decompressive craniectomy is effective in reducing intracranial pressure but may worsen the long-term outcome and is associated with several complications. Among them is the syndrome of the trephined, in which a sunken skull flap develops with a (poorly understood) neurologic deterioration.

and intracranial pressure through multiple mechanisms. In the first minutes of infusion, mannitol and hypertonic saline expand the plasma volume, decrease blood viscosity, and reduce the cerebral blood volume.²⁹ Once plasma osmolarity increases, a gradient across the blood–brain barrier is established, and water is extracted from the brain. This effect may last for up to several hours, until the osmotic equilibrium is reestablished. The integrity of the blood–brain barrier is a prerequisite for the efficacy of hyperosmolar agents. Mannitol is an osmotic diuretic and may cause dehydration and hypovolemia. Hypertonic saline may cause abrupt increases in the sodium

plasma concentration. Comparisons between mannitol and hypertonic saline for the treatment of increased intracranial pressure have not shown a clear superiority of one option over the other.²⁹

Induced arterial blood hypocarbia (hyperventilation) reduces intracranial pressure at the expense of decreasing cerebral blood flow as a result of vasoconstriction.³⁰ Hyperventilation carries a serious risk of cerebral ischemia. For this reason, current guidelines recommend additional monitoring for cerebral ischemia (e.g., by the monitoring of oxygen saturation in the jugular bulb and of brain-tissue oxygenation) when hyperventilation is used.³¹

Barbiturates depress the cerebral metabolism and reduce cerebral blood flow, causing a proportional decrease in cerebral blood volume and a decrease in intracranial pressure. Initial enthusiasm for barbiturate therapy has been tempered by the recognition of serious side effects, including cardiac depression, arterial hypotension, and an increased risk of infection.³² The administration of barbiturates is generally reserved for refractory intracranial hypertension, after other therapies have been tried and have failed.¹²

Mild hypothermia (32 to 34°C) is effective in decreasing intracranial pressure,³³ but studies on the clinical benefit are contradictory, and current evidence does not support its general use in patients with traumatic brain injury.^{34,35} The effects of hypothermia are complex, and adverse effects are a particular problem in patients with traumatic brain injury who may require cooling for many days to control refractory intracranial hypertension.

SURGICAL THERAPY

The surgical therapy of raised intracranial pressure includes the evacuation of mass lesions, drainage of cerebrospinal fluid, and decompressive craniectomy. Rapid detection and timely evacuation of an intracranial hematoma is a cornerstone in the management of traumatic brain injury. Guidelines on the surgical management of epidural or acute subdural hemorrhage and of brain contusions have been published, but all of them are based on class III evidence and are heavily focused on volumetric criteria.³⁶ However, the surgical evacuation of an intracerebral or subdural hematoma may be motivated not only by volume or mass effect but also by mitigation of a toxic effect. In a study of experimental rodent models of cerebral contusions, Tanaka et al.³⁷ found metabolic disturbances, with a massive increase in the production of excitatory amino acids and subsequent ischemic damage, in the cortex underlying blood clots. Possible benefits of surgical excision in the clinical situation are suggested by an analysis of 182 patients with cerebral contusions registered in the Japan Neurotrauma Databank.³⁸ Currently, there are no data from randomized, controlled trials to support this approach.

Drainage of cerebrospinal fluid is a simple and effective approach to reducing increased intracranial pressure. During withdrawal of cerebrospinal fluid, the pressure reading is determined more by

the outflow pressure than by actual brain pressure, so that accurate monitoring of intracranial pressure is not possible with continuous drainage of cerebrospinal fluid.³⁹ New ventricular catheters, including those with a miniature pressure transducer at the tip, may offer more accurate reading during drainage but at a higher monetary cost. Intermittent drainage when the intracranial pressure exceeds 20 mm Hg should be performed against a pressure gradient of approximately 10 cm of water. Drainage of cerebrospinal fluid through lumbar catheters is not recommended in patients with increased intracranial pressure because of the risk of herniation.⁴⁰

Much interest has focused on decompressive craniectomy. The concept of decompressive craniectomy is to provide a larger reserve to compensate for increased intracranial volume. The actual volume that is gained depends on the diameter of the craniectomy. The presumed benefits of decompressive craniectomy have been challenged by the results of the Decompressive Craniectomy (DECRA) trial.²⁵ In this study, which compared decompressive craniectomy performed within 72 hours after traumatic brain injury with maximal medical therapy in patients with diffuse brain injury whose intracranial pressure exceeded 20 mm Hg for 15 minutes or longer in a 1-hour period, mortality was similar in the two groups. However, the rate of unfavorable neurologic outcomes was significantly higher among patients undergoing decompressive craniectomy. After adjustment for baseline data, such as the reactivity of pupils, the between-group difference in outcome was not significant. The generalizability of these results is limited because of the highly selected patient population and because the study examined the effect only in patients with diffuse injuries.

Decompressive craniectomy is not without risk, and adverse effects are common.⁴¹ In the ongoing Randomized Evaluation of Surgery with Craniectomy for Uncontrollable Elevation of Intracranial Pressure (RESCUEicp) study (Current Controlled Trials number, ISRCTN66202560),⁴² which is comparing medical therapy with decompressive craniectomy, patients with a sustained elevation in intracranial pressure (>25 mm Hg for more than 1 hour and up to 12 hours) that is resistant to initial medical therapy are randomly assigned to undergo surgery or intensive medical therapy, including the use of barbiturates. The results of this trial will

provide further evidence to define the role of decompressive craniectomy in traumatic brain injury.

RETHINKING OF MONITORING

Despite the strong motivational reasons for monitoring intracranial pressure, the concept of such monitoring in patients with traumatic brain injury has been challenged. In a comparison of two approaches to the monitoring of patients with traumatic brain injury at two Dutch centers — one that used frequent monitoring of intracranial pressure and the other that did not use such monitoring — patients in the two institutions who survived beyond 24 hours after injury had similar outcomes at 1 year.⁴³ On the basis of a large trauma database, Shafi et al.⁴⁴ found an association between monitoring of intracranial pressure and a worse outcome. The two studies have substantial methodologic limitations because of study design, selection bias, and inadequate adjustment for confounders. In contrast to these trials, two other studies — one a historical comparison⁴⁵ and the other an analysis of a large database⁴⁶ — show a reduced rate of death associated with monitoring of intracranial pressure.

Chesnut et al.⁴⁷ recently reported the results of a clinical trial aimed at determining the potential benefit of monitoring intracranial pressure. Patients with severe traumatic brain injury were randomly assigned to a therapeutic protocol driven by monitoring of intracranial pressure or to a therapy that was determined on the basis of clinical and radiologic findings. No significant between-group difference in outcome was shown. Although the study provided the first randomized comparison of the treatment of patients with traumatic brain injury with or without monitoring of intracranial pressure, we do not consider the findings to be conclusive evidence against the use of such monitoring. Conceptually, any improvement in outcome must result from differences in treatment as a result of monitoring of intracranial pressure and not from the monitoring alone. The question then becomes how the monitoring influenced treatment, a question that is difficult to answer since the two groups received aggressive therapy to lower the intracranial pressure. It is also likely that the trial had an inadequate sample size. In clinical practice, at most 50 to 60% of patients with traumatic brain injury who are undergoing

monitoring of intracranial pressure have persistently increased intracranial pressure.¹² In this trial, the median and mean percentages of recordings of intracranial pressure that were 20 mm Hg or higher were only 7% and 20%, respectively. This low incidence confounds sample-size calculations and probably renders the trial underpowered.

A major asset of the study by Chesnut et al. is that it forms an incentive to rethink our concepts of the monitoring of intracranial pressure and the treatment of intracranial hypertension. The main intent of such monitoring is to better target early and specific therapy to the patients who may benefit most while not exposing others to unnecessary risks. This intent is in line with the concept that improved disease characterization will facilitate targeted management and individualized approaches.⁴⁸ Furthermore, we should recognize that current treatments that are initiated in response to intracranial hypertension are simplistic and often ill-focused. Current protocol-driven approaches use a “one size fits all,” staircase approach with an escalating intensity of therapy, regardless of the underlying pathophysiological features. More individualized approaches may be preferable, but we are not yet able to identify specific causes of increased intracranial pressure with sufficient reliability. The only study in the literature reporting a targeted approach is based on findings in 17 patients.⁴⁹ Since the outcomes for patients with severe traumatic brain injury have not improved substantially during the past 20 to 30 years, developing and advocating a new approach may be considered to be long overdue.

CONCLUSIONS

After traumatic injury, the brain is vulnerable to a range of threats that may be successfully treated if they are recognized promptly and therapy is started early. Among such threats is the rapid development of increased intracranial pressure, which is especially relevant, since it is associated with increased morbidity and mortality and is amenable to treatment. In the absence of evidence to the contrary, increased intracranial pressure should be detected and treated promptly (e.g., with surgical removal of intracranial hematomas) and, whenever possible, should be prevented with appropriate intensive care.

Currently, invasive monitoring is the only reli-

able method for detecting and monitoring raised intracranial pressure in daily practice. The technique is controversial, since it clearly carries risks and side effects and its usefulness has not been conclusively shown. Further uncertainty remains concerning specific medical and surgical therapies for intracranial hypertension. Ongoing trials^{42,50} will provide important new data, but more re-

search will be needed to reduce the massive and growing burden of traumatic brain injury.

AN NEJM APP FOR IPHONE

The NEJM Image Challenge app brings a popular online feature to the smartphone. Optimized for viewing on the iPhone and iPod Touch, the Image Challenge app lets you test your diagnostic skills anytime, anywhere. The Image Challenge app randomly selects from 300 challenging clinical photos published in NEJM, with a new image added each week. View an image, choose your answer, get immediate feedback, and see how others answered. The Image Challenge app is available at the iTunes App Store.
