DECLARATIONS

Competing interests

JHC is Director of QRESEARCH. JF was a statistician employed at QRESEARCH at the time the work was undertaken. AS gave evidence to the House of Commons Health Committee review on *The provision of allergy services* and the House of Lords inquiry, was part of the Department of Health Allergy Review Stakeholder Group and serves on the Scottish Executive's Review of Allergy Services in Scotland Working Group. He is PI on a Scottish Executive study investigating the epidemiology of allergic disorders in Scotland (Ref: CZG/2/252). JN was funded to provide epidemiological advice to the Department of Health during its

Summary

Background Analysis of primary healthcare datasets offers the possibility to increase understanding of the epidemiology of acute uncommon conditions such as anaphylaxis, but these datasets remain under-exploited.

Aim To investigate recent trends in the recorded incidence, lifetime prevalence and prescribing of adrenaline for anaphylaxis in England.

Methods QRESEARCH is one of the world's largest national aggregated health databases containing the records of over nine million patients. We extracted data on all patients with a recorded diagnosis of anaphylaxis and calculated annual age-sex standardized incidence and lifetime period prevalence rates for each year from 2001–2005. We also analysed trends in adrenaline prescribing in those with a recorded diagnosis of anaphylaxis. National population figures were used to estimate numbers of people in England that have experienced anaphylaxis at some point in their lives.

Results The age-sex standardized incidence of anaphylaxis was 6.7 per 100,000 person-years in 2001 and increased by 19% to 7.9 in 2005. Lifetime age-sex standardized prevalence of a recorded diagnosis of anaphylaxis was 50.0 per 100,000 in 2001 and increased by 51% to 75.5 in 2005. Prescribing of adrenaline increased by 97% over this period. By the end of 2005 there were an estimated 37,800 people that had experienced anaphylaxis at some point in their lives.

Conclusions Recorded incidence, lifetime prevalence and prescribing of adrenaline for anaphylaxis all showed substantial increases in recent years. An estimated 1 in 1,333 of the English population have at some point in their lives experienced anaphylaxis.

Introduction

The American College of Allergy, Asthma and Immunology Epidemiology Working Group on Anaphylaxis recent international literature review highlighted the substantial gaps in our understanding of the epidemiology of anaphylaxis, noting that: 'An improved epidemiologic understanding of this disorder would aid ongoing

efforts to reduce morbidity and mortality from anaphylaxis and could provide important clues for primary prevention.¹ Particularly important are gaps in relation to describing the actual numbers of people at high risk of experiencing anaphylaxis, disease trends over time and identifying those at greatest risk of severe outcomes. Challenges to answering these questions include the inherent difficulties of mounting serial cross-sectional and

review of services
for allergy.

prospective cohort studies of acute, short-lived
and uncommon conditions such as anaphylaxis.²

In the absence of such population-based studies,
exploitation of large national healthcare datasets,
with their key strengths of large numbers and rep-
resentative data, offers an important opportunity to
develop insights into the epidemiology of anaphy-
laxis.³ Work from England studying hospital admis-
sions for anaphylaxis has, for example, found rapid
and sustained increases in the numbers of hospital
admissions for anaphylaxis over the last decade,
these data suggesting an underlying increase in the
incidence of anaphylaxis.^{4–8}

There are, however, important inherent limita-
tions associated with extrapolating population
estimates from hospital admission data in the case
of anaphylaxis, as it seems likely that only a minor-
ity of those experiencing anaphylaxis in England
are actually admitted as in-patients. Evidence sug-
gests that the majority of cases of anaphylaxis are
sent home from accident and emergency depart-
ments.⁹ Understanding how the epidemiology of
anaphylaxis may be changing is also potentially
problematic because of the risk of changing admis-
sion thresholds affecting findings. There has, fur-
thermore, been the additional challenge posed by
the fact that, until recently, English hospital data at
national level have only provided measures of ad-
mission episodes rather than numbers of individ-
ual patients admitted, thereby rendering it
impossible to assess the impact of repeated admis-
sions of the same individual.⁸

Studying primary care databases, which are
more likely to reflect the overall population picture
of anaphylaxis than hospital in-patient episode
data, should help to overcome some of these limi-
tations. Building on our previous work using hospi-
tal datasets,^{4–8} we sought to describe trends in
recorded diagnosis of anaphylaxis and prescribing
for anaphylaxis in England during the five-year
period between 1 January 2001 and 31 December
2005. Future planned work will seek to identify
those at greatest risk of poor outcomes.

Methods

We used Version 10 of the QRESEARCH database,
which is a very large nationally representative
anonymized aggregated health dataset derived
from 525 general practices throughout the UK.¹⁰ It
contains data on over 30 million patient years of
observation, these being derived from over nine
million individual patients.

General practices were included in the analysis
if they were based in England, were using the

Egton Medical Information Systems (EMIS) soft-
ware and had transmitted complete data to the
central QRESEARCH repository for the period
from 1 January 1999 to 31 December 2005. This
stipulation for practices to be submitting data for a
full two years prior to our period of interest was to
ensure that practices had sufficient lead time to
become accustomed to using their computing
systems for routine work.

Four hundred and twenty-two (80%) of the
QRESEARCH practices had complete data for
England for the seven-year period in question
(1999–2005), these practices yielding a total of
2,958,366 patients. Contributing practices were
distributed throughout England and had an age-
sex structure that was found to be directly compar-
able to the age-sex structure of the English
population (data not shown).

Patients were included in the analysis year if
they were registered for the entire analysis year in
question. Patients who might have incomplete
data (i.e. temporary residents, newly registered
patients and those who joined, left or died
during the year) were therefore not eligible for
inclusion.

We considered patients to have anaphylaxis if
they had a computer-recorded diagnostic Read
code for anaphylaxis in their electronic health
record for the relevant time period.

Incidence was defined as the number of new cases
of disease diagnosed in a specific year, with the
denominator of number of patient years of obser-
vation (this being calculated as a product of the
number of patients registered with practices and
their length of registration) being used to calculate
incidence rates. Lifetime prevalence was defined as
the numbers of people with a diagnosis of anaphy-
laxis recorded in the GP records on at least one
occasion at any point in their lives; the denominator
used to calculate the lifetime prevalence rate was
the number of patients registered with the study
practices.

Because of the known age and sex variations, we
standardized rates by sex and five-year age bands
using the estimated mid-year population estimates
for England in each year as our reference popu-
lation. These results were then scaled up to
estimate the actual numbers of people with ana-
phylaxis in England. In order to better estimate the
actual numbers of people affected by anaphylaxis,
we calculated 95% confidence intervals around
these estimates of lifetime prevalence and absolute
numbers of people affected in 2005.¹¹

In order to describe trends in prescribing of
self-administered adrenaline, we extracted linked

prescribing data in those with a recorded diagnosis of anaphylaxis and estimated numbers of prescriptions prescribed (which may or may not equate with the numbers of prescriptions dispensed) nationally for each of the five years.

Results

Age-sex standardization of rates

Figure 1 reveals how the lifetime prevalence of anaphylaxis varied very markedly by age and sex. In the pre-pubertal period, lifetime prevalence was highest in males, but then increased very rapidly in females, peaking during the fifth decade. These findings underscore the importance of age-sex standardization of data.

Incidence rate of anaphylaxis and changes over time

Table 1 details the incidence rate of anaphylaxis for each of the five years of interest, these data showing an overall 19% increase during the period 2001–2005.

Lifetime prevalence rate of anaphylaxis and changes over time

Table 2 details the age-sex standardized lifetime prevalence rate of anaphylaxis for each of the five years of interest, these data revealing a 51%

Table 1
Incidence rate of anaphylaxis per 100,000 patient-years, 2001–2005

Year	Age-sex standardized incidence rate/100,000 person-years	95% CI
2001	6.7	5.7–7.7
2002	6.6	5.7–7.6
2003	6.8	5.9–7.9
2004	8.5	7.5–9.6
2005	7.9	7.0–9.0

increase in recorded lifetime prevalence of anaphylaxis over this time period.

Trends in adrenaline prescribing

Table 3 details the estimated numbers of community prescriptions in patients with anaphylaxis throughout England for each of the five years, these revealing a 97% increase in prescribing of adrenaline over the study period.

Numbers of people with a history of anaphylaxis

The estimated numbers of people who have had anaphylaxis at some point in their lives increased from 24,700 (95%CI 23,500–26,000) in 2001 to 37,800 (95% CI 36,300–39,400), this 2005 estimate indicating that 1 in 1,333 of the English population had a lifetime prevalence of anaphylaxis.

Age-sex variations in lifetime prevalence of anaphylaxis per 100,000 registered patients for 2001 and 2005

Discussion

There has been a marked recent increase in recorded incidence and lifetime prevalence of anaphylaxis and prescribing of adrenaline in these patients.

Considering findings in relation to the published literature

The age-sex variations described in Figure 1 are in keeping with described patterns showing an interaction between age and gender.^{1,12} The American College of Allergy, Asthma and Immunology Epidemiology Working Group on Anaphylaxis found that the reported lifetime frequency of anaphylaxis varies internationally between 0.02–0.5% and our estimate of 75.5 per 100,000 or 0.08% in 2005 is comparable to these data.¹ These esti-

Table 2
Lifetime prevalence of anaphylaxis per 100,000 registered patients, 2001–2005

Year	Age-sex standardized prevalence rate/100,000	95% CI
2001	50.0	47.5–52.7
2002	55.9	53.3–58.7
2003	61.8	59.0–64.7
2004	68.5	65.6–71.6
2005	75.5	72.4–78.7

mates are furthermore very comparable to the limited available data from other primary care datasets.^{13,14}

Main strengths and limitations of this work

The main strengths of this study include our interrogation of an extremely large nationally representative dataset, the fact that all contributing practices used the same computing systems for electronically recording clinical data and the approach used to ensure that all contributing practices were accustomed to electronically recording routine data. The study design means that it was not subject to selection bias due to non-responders or recall bias. As recommended by the American College of Allergy, Asthma and Immunology Epidemiology Working Group on Anaphylaxis,¹ our attempt to obtain various estimates of disease frequency is allowing a comprehensive picture of the epidemiology of anaphylaxis in England to emerge.^{4–8}

There are a number of limitations that need to be considered when using databases of routinely collected data and these all potentially apply to this work. Most importantly, we were dependant on physician-recorded diagnosis of anaphylaxis and there may have been improvements in anaphylaxis recording over this time period. The rela-

Table 3
Estimated numbers of prescriptions for adrenaline in patients with a history of anaphylaxis in England, 2001–2005

Year	Estimated number of prescriptions in England	95% CI
2001	10,700	9,900–11,600
2002	12,600	11,700–13,600
2003	13,300	12,400–14,300
2004	16,200	15,200–17,300
2005	21,100	19,900–22,300

tively short time window over which trends were studied is another limitation, but this does also have the advantage of confining analysis to a period during which there were no changes in disease definition or classification.

Conclusions and implications for future research

This large national study reveals that the recorded incidence and lifetime prevalence of anaphylaxis increased in England during the first half of this decade. Further work is now needed to explore why these increases occurred and determine which of the increasing numbers of individuals with a history of anaphylaxis are at greatest risk of recurrent anaphylaxis and severe outcomes should a further episode occur.¹⁵ The changes in disease patterns described highlight the need for ongoing surveillance of the epidemiology of anaphylaxis.
