

Tumor Necrosis Factor Alpha-induced Apoptosis in Cardiac Myocytes

Involvement of the Sphingolipid Signaling Cascade in Cardiac Cell Death

Abstract

In the present study, it was shown that physiologically relevant levels of the proinflammatory cytokine TNF α induced apoptosis in rat cardiomyocytes in vitro, as quantified by single cell microgel electrophoresis of nuclei (“cardiac comets”) as well as by morphological and biochemical criteria. It was also shown that TNF α stimulated production of the endogenous second messenger, sphingosine, suggesting sphingolipid involvement in TNF α -mediated cardiomyocyte apoptosis. Consistent with this hypothesis, sphingosine strongly induced cardiomyocyte apoptosis. The ability of the appropriate stimulus to drive cardiomyocytes into apoptosis indicated that these cells were primed for apoptosis and were susceptible to clinically relevant apoptotic triggers, such as TNF α . These findings suggest that the elevated TNF α levels seen in a variety of clinical conditions, including sepsis and ischemic myocardial disorders, may contribute to TNF α -induced cardiac cell death. Cardiomyocyte apoptosis is also discussed in terms of its potential beneficial role in limiting the area of cardiac cell involvement as a consequence of myocardial infarction, viral infection, and primary cardiac tumors. (*J. Clin. Invest.* 1996. 98:2854–2865) **Key words:** apoptosis • cardiomyocytes • tumor necrosis factor • sphingosine • comet assay

Introduction

Apoptosis is a mechanism by which cells respond to damage by triggering a program of cell death (1–4). Apoptosis has only recently been recognized as a component of many common cardiac pathologies, including chronic heart failure, cardiac sudden death, viral myocarditis, and ischemia (5–13). Since the triggers and cellular mechanisms leading to cardiac cell apoptosis are not known, an understanding of this recently discovered form of cardiac cell death may help elucidate many common types of heart disease.

Serum levels of TNF α are elevated in many human cardiac-related pathogenic conditions, including heart failure (14–17).

Because TNF α can trigger apoptosis in many cell types (18–20), it is possible that endogenous TNF α may contribute to apoptosis in cardiac cells. Since TNF α may be produced by cardiac cells themselves (21, 22), it is possible that local concentrations of TNF α are high in cardiac tissue relative to serum levels. Significantly, we and others have shown that TNF α receptors are expressed by cardiomyocytes (23, 24). The “death domain” of the prominent type I receptor (TNFR1)¹ present in cardiomyocytes has been linked to TNF α -mediated apoptosis in nonmuscle cells (25), suggesting that TNF α acting via the TNFR1 could also mediate myocardial cell apoptosis. Since the sphingomyelin signal transduction system has been linked to the TNFR1 in other cell types (26), we hypothesize that many of the actions of TNF α on cardiac cells, including apoptosis, could be mediated by TNF α -induced sphingolipid production.

We have taken the approach of using several techniques in parallel to evaluate apoptosis in cardiomyocytes in vitro, following treatment with TNF α and sphingolipids. These techniques include the in situ 3' nick-end labeling (TUNEL) assay, the “laddering” of extracted DNA after agarose gel electrophoresis, as well as morphological criteria. In addition, we have employed the microgel electrophoresis method (27) (often referred to as the “comet assay”) (28, 29), which is a relatively new technique for distinguishing apoptosis from necrosis. This technique can detect DNA damage earlier than other methods, and it can differentiate single from double-strand breaks and thus be specific for apoptosis (29–31). Moreover, the comet assay lends itself to the examination of a large number of cells. As a result of its utility, the comet assay has been employed by a number of laboratories to assess apoptosis in several cell types (27, 28, 32–36). This broad range of criteria to assess apoptosis in cultured rat cardiomyocytes has been used in this study to determine whether cardiomyocyte death triggered by TNF α and sphingolipids results from apoptosis or necrosis.

Methods

Neonatal rat ventricular cardiomyocytes were isolated as described previously and cultured in DMEM-F12/10% FCS (37). Adult ventricular myocardial cells were cultured after dissociation from adult rat hearts as previously described (38), with the following modification: after the last perfusion with collagenase (type II; Worthington Biochemicals Corp., Freehold, NJ), rat ventricles were diced and incubated for 30 additional min at 37°C in 10–15 ml of 0.52 mg/ml collagenase in oxygenated Tyrode's solution (140 mmol/liter NaCl, 5.4 mmol/liter KCl, 5.0 mmol/liter MgCl₂, 10 mmol/liter Hepes, 0.25 mmol/liter NaH₂PO₄, pH 7.3) in which the CaCl₂ concentration had been adjusted to 0.06 mmol/liter, before culturing cells in the physiological calcium levels present in the culture and incubation media (1.0

1. *Abbreviations used in this paper:* TNFR1, tumor necrosis factor type I receptor; TUNEL, TdT-mediated dUTP nick end labeling.

mmol/liter CaCl_2). The acutely dissociated myocardial cells were plated on laminin-coated (50 $\mu\text{g}/\text{ml}$) frosted microscope slides or on coverslips and cultured in DMEM-F12/10% FCS in the presence or absence of the test agent. These procedures result in a high percentage of viable cells, since necrotic cells supercontract in the presence of high calcium concentrations and do not adhere well to the substrate.

Apoptosis in cardiomyocytes was quantified by the single-cell microgel electrophoresis (comet assay) (27, 28, 36, 39). The comet assay is a method of measuring DNA strand breaks and has been used to quantify apoptotic cells from other tissues (31). In comparison with other methods of detecting apoptosis, the comet assay is considered more sensitive and able to detect DNA cleavage earlier than other methods (29, 30). The comet assay was performed essentially as described (39) with the following modifications: cells were cultured on frosted microscope slides, treated with the test agent (e.g., $\text{TNF}\alpha$, sphingosine, H_2O_2 , ceramide, anti-TNFRI Ab), and then embedded in situ in 1% agarose (SeaKem Gold; FMC Bioproducts, Rockland, ME). Cardiomyocytes were then placed in refrigerated alkaline lysis buffer (2.5 M NaCl, 1% Na-lauryl sarcosinate, 100 mM EDTA, 10 mM Tris base, 1% peroxide, and carbonyl-free Triton X-100) for 30 min, followed by 15 min unwinding in electrophoresis buffer containing 300 mM NaOH, 10 mM EDTA, 0.1% hydroxyquinoline, 0.02% DMSO, pH 10.0. The nuclei were subsequently electrophoresed for 5 min at 2 V/cm, followed by staining with YOYO-1 (3 $\mu\text{mol}/\text{liter}$; Molecular Probes, Inc., Eugene, OR) and visualization with a fluorescence microscope equipped with an FITC filter cube (Olympus Corp., Lake Success, NY). For quantification and image analysis of comet fields, fluorescent images of the nuclei were captured by a PULNIX TN-745 CCD camera connected to an Olympus BA-2 fluorescence microscope and digitally processed by KOMET software (Kinetic Imaging, Ltd., Liverpool, UK). Between 450 and 500 comets per treatment were scored and assigned into type A, B, or C categories (see Results), based on their tail moments (Table I). The tail moment is defined as the product of the comet tail length (distance between the mean of DNA fluorescence for the comet head and the end of the tail) and the proportion of DNA in tail (proportion of total fluorescence found in the tail region) divided by 100 (30). The tail moment parameter has been used to distinguish nucleosomal DNA fragmentation of apoptotic cells from DNA damage of those undergoing necrosis, and is a better discriminator than assessing comet tail length (36). According to Olive et al. (30), classification of individual cells into the various types of comets (e.g., B vs. C) "by eye" is the most accurate means of analyzing and quantifying large numbers of apoptotic cells. This was substantiated in the present study by experiments in which the percentage of apoptotic nuclei (type C comets) scored by eye were compared with the same data quantified by image analysis

Table I. Categorization of Nuclei by Tail Moment (TM)

	Mean TM (μm)	TM range (μm)
Type A nuclei ($n = 49$)	0.47 ± 0.10	0–3
Type B comets ($n = 36$)	$5.43 \pm 0.26^*$	3–8
Type C comets ($n = 48$)	$13.6 \pm 0.59^*$	8–30

Tail moments \pm SEM were calculated from computerized image analyses using the KOMET software. The tail moment is defined as the product of the comet tail length (distance between the mean of DNA fluorescence for the comet head and end of the tail) and the proportion of DNA in the tail (proportion of total fluorescence) divided by 100. Data were taken from a set of experiments in which adult rat cardiomyocytes were treated with $\text{TNF}\alpha$ to generate type B and C comets. Type A nuclei used for this analysis came from control (untreated) cells and from $\text{TNF}\alpha$ -treated nuclei displaying tail moments in the 0–3- μm range. *Significant differences ($P < 0.001$) from mean type A tail moment as determined by ANOVA.

using the criteria of tail moment (see Table II in Results). Consequently, in many experiments, even though tail moments were calculated for numerous control and treated nuclei in the A, B, and C categories, the number of apoptotic cells in a particular experiment was commonly assessed by counting the number of nuclei exhibiting puffy tail type comets with pinhead nuclear remnants (type C comets, e.g., Fig. 3 C). Statistical analyses employed the Student's t test, Mantel-Haenszel Chi Square trend analysis, and ANOVA using Microsoft Excel and SPSS software.

In addition to the comet assay, double-stranded DNA breaks were assessed by agarose gel electrophoresis of extracted cellular DNA and the presence of characteristic 180–200-bp multiple oligonucleosomal fragmentation (40).

Terminal deoxynucleotidyl transfer-mediated end labeling of fragmented nuclei (TUNEL assay) was performed on cardiomyocytes that had been plated on laminin-coated coverslips and cultured in DMEM-F12/10% FCS in the presence or absence of the test agent. The in situ TUNEL assay was then performed in accordance with the manufacturer's protocol for cultured cells (Boehringer Mannheim Biochemicals, Indianapolis, IN) after fixing the cells in 4% paraformaldehyde for 30–60 min.

Morphological identification of apoptotic nuclei was assessed either by hematoxylin or ethidium bromide staining. For hematoxylin staining, cells were first treated with cold acetone (-20°C), rinsed in cold PBS, and then stained for 20 min. For ethidium bromide staining, cultured cells were fixed in 4% paraformaldehyde, treated with RNase A (0.1%) at 37°C for 30 min, followed by ethidium bromide treatment (50 $\mu\text{g}/\text{ml}$ for 15 min). Ethidium bromide-stained cells were viewed by fluorescence microscopy using a rhodamine filter cube.

HPLC analysis of $\text{TNF}\alpha$ -induced sphingolipid production by rat cardiac membranes was performed essentially as described previously (41). Cardiac membranes were isolated from adult rat ventricles as described (23). Freshly isolated membranes were incubated for 90 min in the absence (control) or presence of $\text{TNF}\alpha$. The membranes were then extracted for sphingolipids and processed for HPLC separation and quantification as previously described (41).

Reverse transcriptase PCR of TNFRI in adult and neonatal rat ventricular cells was performed essentially as described previously by us (23). Briefly, DNase-treated poly (A+) RNA obtained from total RNA was reverse transcribed and the resultant cDNA amplified (30 cycles) by PCR using a programmable thermal cycler (PTC-100; MJ Research, Watertown, MA). Sense and antisense primers for rat TNFRI were 5'-GCTCCTGGCTCTGCTGAT-3' and 5'-AACAT-TCTTTCCGACAT-3', respectively. Primers for atrial natriuretic factor, 5'-AGCGGGGGCGGCACTTAG-3' (sense), and 5'-CTC-CAATCTGTCAATCC-3' were included as a positive control for myocardial gene expression. Primers were synthesized in the San Diego State University Microchemical Core Facility. The reverse transcriptase PCR product was separated on a 2% agarose gel. The sizes of the amplification products for rat TNFRI and atrial natriuretic factor were 288 and 212 bp, respectively.

Results

We hypothesize that $\text{TNF}\alpha$ and sphingolipids are capable of driving rat cardiomyocytes into apoptosis. We present results from in vitro studies using cultured cardiomyocytes exposed to $\text{TNF}\alpha$ and to the lipid second messengers, sphingosine, sphingosine-1-phosphate, and ceramide. To assess apoptosis in cardiomyocytes, we employed a multiplicity of techniques, including single-cell microgel electrophoresis (comet assay), the in situ TUNEL assay, and laddering of extracted DNA after agarose gel electrophoresis in addition to conventional cytological methods. Trypan blue exclusion and other criteria were also used to determine if cardiomyocytes succumb by necrosis

Figure 1. Single cell microgel electrophoresis (the comet assay) can distinguish single-stranded from double-stranded DNA fragmentation in rat cardiomyocytes. Adult cardiomyocytes were treated for 20 min with 100 $\mu\text{mol/liter}$ H_2O_2 to induce necrosis (*A*) or with 10 $\mu\text{mol/liter}$ C2 ceramide (18 h) to induce apoptosis (*B*), and then were subjected to the comet assay. Nuclei were visualized by YOYO-1 staining under fluorescence microscopy. The comets displayed in both *A* and *B* were not digitally enhanced. Bar represents 50 μm .

rather than by the apoptotic process when subjected to $\text{TNF}\alpha$ and sphingolipid triggers. Hydrogen peroxide was employed as a positive control for induction of single strand breaks.

Assessment of apoptosis in cardiomyocytes using single-cell microgel electrophoresis (the comet assay). The sphingolipid, ceramide, was chosen for our initial evaluation of sphingolipid-induced apoptosis in cardiac myocytes since ceramide is a well established inducer of apoptosis in nonmuscle cells and is thought to be a significant second messenger mediating apoptosis triggered by cytokines such as $\text{TNF}\alpha$ and by other agents (42). To measure apoptosis in cardiomyocytes, a very sensitive and relatively new method, the comet assay, was used in these studies. The comet assay has been employed by many laboratories as a sensitive method of assessing DNA fragmentation (27, 28, 32–36), but has not been applied to cardiomyocyte cell death. In this report, the comet assay was used to evaluate apoptosis in both adult and neonatal rat cardiomyocytes. Cultured cardiomyocytes were embedded in agarose, lysed, and electrophoresed (see Methods). As a result of conditions that promote unwinding, DNA fragments are free to migrate in the agarose away from the nucleus forming an image that resembles a comet tail (Fig. 1). The pattern of DNA fragmentation detected by the comet assay has been used to distinguish the double-stranded DNA cleavage commonly accompanying apoptosis from the random breaks often seen in necrosis or produced by genotoxic agents (29–31). To compare putative

apoptosis produced by sphingolipids to genotoxic/necrotic damage, we incubated cardiomyocytes for 20 min with 100 $\mu\text{mol/liter}$ H_2O_2 , a treatment that is often used to induce random single-strand DNA breaks (36, 43) (Fig. 1 *A*). This treatment produced comets with small tails, with most of the DNA unfragmented and remaining in the nucleus. Incubation of cardiomyocytes with the sphingolipid C2 ceramide produced a distinct comet pattern characterized by a puffy comet tail disconnected from the remnant nucleus (Fig. 1 *B*), a pattern of DNA fragmentation that is characteristic of apoptosis exhibited by other cell types and has been attributed to double-strand breaks (29–31).

Fig. 2 *A* shows a field of control (untreated) myocardial cells and Fig. 2 *B* shows a field of C2 ceramide-treated cells, demonstrating that the comet assay can be used to evaluate the effects of apoptotic-inducing agents on large numbers of cells. One can readily see from the density of nuclei in Fig. 2 *A* vs. 2 *B* that approximately the same number of cells survived the ceramide treatment and thus direct quantitative comparisons can be made between treatment conditions. Nuclei from untreated, non-apoptotic cells (Fig. 2 *A*) appeared as spheroids after electrophoresis. On the other hand, fields of C2 ceramide-treated cells displayed a full range of comet types (Fig. 2 *B*). The amount and type of DNA damage in each nucleus was assessed by image analysis and “by eye,” as discussed in Methods. Nuclei from untreated, nonapoptotic cells had no tails and consequently most cells displayed negligible tail moments (mean 0.47 μm in these experiments). Electrophoresed nuclei classified by us as type A nuclei displayed little damage and had tail moments in the range of 0–3 μm (Fig. 3 *A* and Table I). The nuclei resembling comets resulting from ceramide or other apoptosis inducers (see below) were of two general types that could be distinguished visually and quantitatively by their tail moments and are referred to as types B and C comets. Type B comets were those nuclei that had a developing tail but with a substantial amount of unfragmented DNA present in the “head” of the comet (mean tail moments of 5.43 μm , range 3–8 μm , Fig. 3 *B* and Table I). Type C comets were those nuclei with the apoptotic-associated pattern previously observed (29–31), a characteristic puffy tail separated by a space from the pinhead remnant of the head (e.g., Fig. 3 *C*), and having tail moments in the 8–30 μm range with mean values of 13.6 μm (Table I). Table I gives a comparison of image analysis-derived tail moment measurements in our system for types A, B, and C nuclei.

Based on this data, we concluded that, with the extensive amount of DNA fragmentation observed in our studies after treatment of cardiac myocytes with C2 ceramide (Fig. 3 *D*), use of the comet assay was a rapid and effective method of evaluating apoptosis. Moreover, this first demonstration of ceramide-triggered apoptosis in cardiomyocytes suggested that the heart might be susceptible to other well characterized apoptotic triggers, such as $\text{TNF}\alpha$ or other cytokines.

$\text{TNF}\alpha$ induces apoptosis but not necrosis in adult rat cardiomyocytes. When primary rat cardiomyocytes were analyzed by the comet assay after an 18-h incubation with 4 nmol/liter $\text{TNF}\alpha$ (recombinant rat $\text{TNF}\alpha$ from Biosource, Camarillo, CA), substantial apoptosis was evident (Fig. 3 *D*). For control (untreated) cells, nearly 80% of the nuclei appeared as spheroids, categorized as type A (Fig. 3 *D*). In contrast, over 60% of nuclei in $\text{TNF}\alpha$ -treated cells yielded comets typical of apoptosis (type C) with pinhead nuclear remnants, and puffy tails

Figure 2. Ceramide drives large numbers of rat cardiomyocytes into apoptosis. Nuclei of adult cardiomyocytes were electrophoresed according to the comet procedure (see Methods). Cells were either untreated for 18 h (A) or incubated for 18 h with 10 $\mu\text{mol/liter}$ C2 ceramide (B) before cell lysis and electrophoresis of nuclei. Nuclei were visualized by YOYO-1 and digitally enhanced (see Methods). Bar represents 50 μm .

and tail moments in the 8–30 μm range. The cardiomyocyte DNA fragmentation pattern we observed was likely due in large part to double-strand DNA breaks typical of apoptosis, since extensive comet formation was observed using the double-strand break-specific neutral comet assay (30) (data not shown). The percentage of type C comets was linearly depen-

dent on the concentration of TNF α in the 1–4 nmol/liter range (Fig. 4), reaching a maximum effect (61% apoptotic cells) at 4 nmol/liter TNF α (3,500 U/ml, 68 pg/ml), and then declining somewhat at 5 nmol/liter (4,250 U/ml, 85 pg/ml). The half-maximal concentration of TNF α required to induce apoptosis in our cardiomyocytes was 2.2 nmol/liter (1,870 U/ml, 37.4

Figure 3. TNF α and sphingolipids drive significant numbers of adult rat cardiomyocytes into apoptosis. Adult cardiomyocytes were treated for 18 h in culture with media alone (*control*), 4 nmol/liter (3,500 U/ml, 68 pg/ml) TNF α (recombinant rat TNF α), 10 $\mu\text{mol/liter}$ sphingosine (*SPH*), or 10 $\mu\text{mol/liter}$ C2 ceramide (*C2*), followed by the comet assay. (A–C) Representative nuclei of the various categories, types A (nonapoptotic), B (intermediate and nonapoptotic DNA damage), and C (characteristic of apoptosis). (D) Cumulative results displayed as a bar graph. In D, values

D

are means of three separate experiments (\pm SEM) with each treatment performed on $> 6,000$ cells. Between 450 and 500 comets per treatment point were scored and assigned into type A, B, or C categories. Bar represents 50 μm .

Figure 4. Dose dependence of TNF α -induced apoptosis in adult cardiomyocytes. Adult rat cardiomyocytes were treated for 18 h with varying concentrations of TNF α as shown. The percentage of apoptotic-type (type C) nuclei is plotted as a function of TNF α concentration in nanomoles per liter. Results are means \pm SEM of 10,733 nuclei counted from four separate experiments. ANOVA and Mantel-Haenszel Chi Square trend analysis revealed a significant ($P < 0.001$) dose-dependent effect of TNF α in its ability to induce apoptosis.

pg/ml). The reason for the statistically significant ($P < 0.001$, Student's t test) decline in the ability of TNF α to induce apoptosis at 5 nM TNF α is unknown, but may result from down-regulation of the receptor by receptor-mediated endocytosis, which would reduce cell responsiveness to TNF α . The percentage of type C comets shown in Fig. 4 was determined by eye (see Methods), and comparison measurements of tail moment were made using a subset of the same cells. This comparison is displayed in Table II and shows that the percent apoptotic nuclei determined by characterizing the cells by eye was nearly identical to determinations characterizing the cells using the

Table II. Comparison of Percentage of Apoptotic Cells Determined by Image Analysis of Tail Moment (TM) vs. Visual Determination

TNF α concentration nmol/liter	Percent apoptotic cells (percent type C comets) \pm SEM	
	By TM	By visual
1	20.6 \pm 9.01	18.3 \pm 3.58
2	24.3 \pm 9.50	24.4 \pm 6.24
3	27.8 \pm 16.3	42.5 \pm 7.40
4	61.2 \pm 5.70	61.0 \pm 1.45

The percentage of apoptotic cells (percent type C comets) scored by computerized image analysis of tail moment were compared with the percentage of apoptotic cells scored by visual inspection of individual cells (data taken from Fig. 4). The two methods of scoring comets were not significantly different (t test of differences, comparison of slopes).

Figure 5. Time dependence of TNF α -induced apoptosis in adult rat cardiomyocytes. Cultured adult cardiomyocytes were incubated with 4 nmol/liter TNF α for various time periods as indicated. The percent apoptotic-type (type C) nuclei are plotted as a function of TNF α exposure, with the percentage of type A and B comets also listed. Results are means \pm SEM of 36 fields of cardiomyocyte nuclei. The percentage of type C comets significantly increased with time ($P < 0.001$ ANOVA and Mantel-Haenszel Chi Square trend analysis) from control cells incubated with media alone for 18 h.

tail moment calculated by computerized image analysis. Fig. 4 also shows that \sim 5% of untreated cells in culture display apoptotic type comets. This basal level of apoptosis in control cell cultures likely results from the harsh manner in which cells are prepared for culture (i.e., collagenase treatment of Langendorff-perfused hearts). The data in Fig. 5 indicate that the extent of apoptosis produced by TNF α was dependent on the exposure time of cells to the cytokine. This figure shows that from 12 to 18 h, 4 nmol/liter TNF α progressively drove an increasing number of cells into apoptosis as judged by the steady increase in type C comets and the concomitant decrease in type A undamaged nuclei. ANOVA performed on these data showed that there was a significant ($P < 0.001$) time-dependent effect of TNF α on the adult cardiomyocytes. Since 12 h of incubation was needed for TNF α to induce significant apoptosis ($P < 0.001$), it is likely that some protein synthesis was required to complete the death program.

To demonstrate that the TNF α -induced apoptosis was mediated by the TNFR1, which we have recently identified as the prominent receptor subtype found on rat cardiomyocytes (23), we incubated adult rat cardiomyocytes overnight with 2.5 μ g/ml anti-sTNFR1 (mAb clone 16803.1 supplied by R & D Systems Inc., Minneapolis, MN), and then subjected the cells to the comet assay. As seen by the data presented in Table III, the anti-TNF α receptor antibody, when added alone, was capable of driving a significant ($P < 0.0001$, Student's t test) number of adult cardiomyocytes into apoptosis (51.9%). The extent of apoptosis produced by antibody interaction with the receptor was comparable with that produced by TNF α (47.6%), and no significant additive effect was seen when cells were incubated

Table III. Effects of Anti-TNFR1 Antibodies

	Percent apoptotic nuclei
No treatment	13.7±2.66
TNF α	47.6±4.97*
Anti-sTNFR1	51.9±3.53*
TNF α + anti-sTNFR1	42.9±4.00*

Adult rat cardiomyocytes were incubated overnight with TNF α , (3,500 U/ml), 02.5 μ g/ml anti-sTNFR1 (mAb clone 16803), or a combination of both, and then subjected to the comet assay. Type C comets were taken as indicators of the percentage of apoptotic nuclei. 279 fields of comets from two separate experiments were scored for type C comets. Values are means±SEM. * Antibody produced significantly more ($P < 0.0001$, Student's t test) apoptotic comets than did control cells. No significant differences were seen among the three treatment groups.

with TNF α and the antibody in combination (42.9% apoptotic cells).

Evidence for TNF α -induced apoptosis demonstrated by the comet assay was further substantiated by in situ terminal deoxynucleotide transfer-mediated labeling of TNF α -treated cardiomyocytes (Fig. 6 A), although this method cannot distinguish random single- from double-strand DNA cleavage, as does the comet assay. In one experiment, we directly compared the TUNEL assay performed on a duplicate set of cultured cells processed for the comet assay after treatment with TNF α . The TUNEL assay showed that 32.5% of the TNF α -treated cells had strong enough fluorescent signals to be counted as apoptotic, compared with > 60% apoptotic nuclei determined by the comet assay using similar conditions of TNF α treatment (Fig. 3 D). Thus, the TUNEL assay appears to be somewhat less sensitive than the comet in assessing apoptosis in cardiomyocytes.

Figure 6. In situ morphological assessment of apoptosis in adult cardiomyocytes. (A) An adult rat cardiomyocyte was treated with 300 U/ml TNF α followed by staining for DNA damage by in situ terminal deoxynucleotidyl transfer-mediated end labeling of fragmented nuclei (TUNEL assay). The myocyte was visualized under bright field illumination (to show the rod-shaped outline of the cell) and under fluorescence (to visualize the damaged nucleus, which appears green). The inset is the fluorescent image (i.e., TUNEL) alone. Non-apoptotic cardiomyocytes have nuclei that do not fluoresce (data not shown). (B-C) Hematoxylin staining of adult cardiomyocytes cultured in the absence (B) and presence (C) of 10 μ mol/liter sphingosine. The low magnification (200 \times) image of untreated myocytes (B) shows both mononucleated and binucleated cells that exhibit the typical rod shape and elongated nuclei, while the apoptotic cell seen in C is somewhat crenated with prominent membrane blebbing and condensed chromatin in its nucleus. Bars represent 50 μ m.

An important feature of apoptosis that distinguishes apoptosis from necrosis is maintenance of plasma membrane integrity (1–3). Apoptotic adult cardiomyocytes such as those displayed in Fig. 6 A demonstrated substantial DNA fragmentation, but often retained their rod-shaped appearance indicative of intact plasma membranes. In this experiment, a TUNEL-positive cell was examined under bright field to confirm that DNA damage had occurred in a rod-shaped cell. The otherwise normal appearance of the cell not only confirmed that this cardiomyocyte underwent apoptosis while maintaining the integrity of its plasma membrane, but also suggested that the rod-shaped cardiomyocytes displaying apoptotic signs were not necrotic. Over 50% of such cells retained their rod-shaped appearance and were not “supercontracted” in the presence of millimolar Ca^{2+} , as would be the case for permeabilized necrotic cells. Supercontracture results from the cardiomyocyte’s unique sensitivity to changes in plasmalemma Ca^{2+} permeability and can be used as an additional discriminator between apoptosis and necrosis. In the necrotic myocyte, characterized by loss of membrane integrity, the uncontrolled influx of Ca^{2+} down a steep electrochemical gradient results in supercontracture of the cell. The subsequent “balled-up” morphology and loss of defined cell structure can be clearly distinguished from the normal rod-shaped myocyte seen in Fig. 6 A. Apoptotic cells such as the one displayed in Fig 6 A are not easily distinguished morphologically from untreated rod-shaped cells such as the hemotoxylin and eosin–stained cells shown in Fig. 6 B. While rod-shaped apoptotic cells are common, occasionally apoptotic cells appear shrunken with evidence of membrane blebbing more characteristic of apoptotic cells from nonmuscle tissue (Fig. 6 C). A comparison of panels

A, B, and C illustrates that apoptotic cardiomyocytes can appear either rod-shaped or crenated (also see Fig. 6, legend), and these morphological variations may reflect different stages of the apoptotic process. While the cell shown in Fig. 6 C was clearly apoptotic, as judged by the presence of membrane blebbing, this appearance was not a common feature of adult cardiomyocytes driven into apoptosis by $\text{TNF}\alpha$ or other triggers, and likely represents a cell in an advanced stage of apoptosis. Additionally, cells such as this one were found to exclude trypan blue and to respond to Ca^{2+} ionophores, providing further evidence that they were not necrotic. In general, > 80% of cells induced into apoptosis were found to supercontract after challenge with the Ca^{2+} ionophore, A23187, suggesting that the cell membranes were intact and not permeable to Ca^{2+} before ionophore addition. As a further check of cell membrane integrity a subset of cell fields was examined for indo-1 fluorescence. Cells are permeable to indo-1 AM, which is subsequently de-esterified in the cell to an impermeant Ca^{2+} -sensitive species. Without exception, the same cells that excluded trypan blue and responded to the ionophore also retained and fluoresced the Ca^{2+} -sensitive fluorescent dye, indo-1 AM.

TNF α activates the sphingomyelin signal transduction cascade. Because it has been demonstrated that $\text{TNF}\alpha$ may produce apoptosis in a variety of cell types, principally through ceramide production (18, 19) or via ceramide’s conversion product, sphingosine (20), it is possible that $\text{TNF}\alpha$ -mediated cardiac apoptosis may result from enhanced sphingolipid production. When cardiac membranes were exposed to $\text{TNF}\alpha$, substantial (1.57-fold) sphingosine production was observed (Fig. 7), suggesting that this lipid may be an important mediator of the effects of $\text{TNF}\alpha$ in cardiac tissue. Consistent with this hypothesis, treatment of primary cardiomyocytes with sphingosine (10 $\mu\text{mol/liter}$) for 18 h resulted in characteristic apoptotic-type comets in almost all (95%) of the cardiomyocytes observed (Fig. 3 D). The cell permeant ceramide analog, C2 ceramide (10 $\mu\text{mol/liter}$), was somewhat less effective in stimulating cardiomyocytes to undergo apoptosis, with only 32% apoptotic-type comets produced (Fig. 3 D). Sphingosine also produced the characteristic morphological changes that are hallmarks of apoptosis, including nuclear condensation and membrane blebbing (Fig. 6 C). In neonatal cardiomyocytes, sphingosine produced oligonucleosomal DNA laddering and prominent pyknotic nuclear fragmentation patterns characteristic of apoptosis (see below).

To confirm that the adult cardiomyocytes treated with sphingosine were not necrotic, trypan blue exclusion was employed as an indicator of plasma membrane permeability (Table IV). Over 80% of sphingosine-treated cells excluded trypan

Figure 7. Analysis of $\text{TNF}\alpha$ -induced sphingosine production by adult rat cardiac membranes. Membranes were incubated for 90 min in the absence (Control) or presence of $\text{TNF}\alpha$, followed by extraction of sphingolipids and their separation by HPLC. Values are means (picomoles per milligram of cardiac membranes) \pm SEM of eight extractions performed on two separate membrane preparations. Data were analyzed by Student’s *t* test. * $\text{TNF}\alpha$ significantly ($P < 0.005$) stimulated sphingosine production.

Table IV. Percent Necrotic Cardiomyocytes

Control myocytes ($n = 153$) [‡]	21.0 \pm 1.27*
Sphingosine 18 h ($n = 162$)	17.2 \pm 2.80

Trypan blue (0.1%) exclusion was one criterion used to identify necrotic cardiomyocytes. Values represent means \pm SEM of cells that did not exclude the dye and were considered necrotic. The remainder of the cells excluded trypan blue and were thus taken to be viable. See text for other tests used for necrosis (supercontraction when challenged with the Ca^{2+} ionophore, A23187, and retention and fluorescence of the Ca^{2+} -sensitive fluorescent dye, indo-1 AM). *No significant difference as determined by Student’s *t* test. [‡] n = number of cells counted from four different fields of cells.

blue after 18 h in culture. Since these same conditions caused more than 95% of the cells to become apoptotic as judged by the comet assay (Fig. 3 D), sphingosine must induce apoptosis without appreciable signs of necrosis. This conclusion is supported by the finding that after sphingosine treatment, 50.5% of the apoptotic cells retained their rod-shaped appearance and did not supercontract in the presence of millimolar Ca^{2+} .

Apoptosis in neonatal cardiomyocytes. Sphingolipids can also drive neonatal cardiomyocytes into apoptosis (Figs. 8 and 9). When cells were cultured for 18 h with 10 $\mu\text{mol/liter}$ C2 ceramide, sphingosine-1-phosphate, or sphingosine, the cells showed extensive DNA fragmentation with discernible $\sim 200\text{-bp}$ oligonucleosomal laddering characteristic of apoptosis (Fig. 8). Control cells cultured in DMEM/F12 with 10% FCS did not show any discernible laddering or other features of apoptosis. In comparison with sphingosine, C2 ceramide was less effective in producing oligonucleosomal ladders. The lower effectiveness of ceramide in inducing neonatal cells into apoptosis is in agreement with the comet data of Fig. 3 D, showing that in adult cells, sphingosine produced a higher yield of apoptotic type cells than did ceramide. When neonatal cardiomyocytes were cultured overnight with sphingosine, $72.2 \pm 12.8\%$ of the cells exhibited type C apoptotic-type comets (data from five fields of neonatal cells) compared with 0.0% type C comets exhibited by control (untreated) cells (data from four fields of neonatal cells). Treatment of neonatal cardiomyocytes with the sphingosine conversion product, sphingosine-1-phosphate, showed extensive oligonucleosomal DNA fragmentation, suggesting that this metabolite may be physiologically relevant in the signaling pathway for apoptosis in cardiomyocytes. Curiously, $\text{TNF}\alpha$ did not produce detectable apoptosis in neonatal cardiomyocytes as evidenced by absence of significant laddering, or by comet and TUNEL analyses (data not shown).

In agreement with the presence of double-stranded DNA cleavage on agarose gels, neonatal cells displayed TUNEL staining in response to sphingosine (Fig. 9). Untreated (control) cardiomyocytes were largely unstained (Fig. 9 A), while most of the cells treated with sphingosine (Fig. 9 B) were apoptotic as judged by nick-end labeling of fragmented DNA. Many of the nick-end-labeled nuclei in Fig. 9 B showed evidence of pyknotic bodies. Ethidium bromide-stained neonatal cardiomyocytes also more clearly demonstrated that sphingosine produced the characteristic morphological changes that are hallmarks of apoptosis, including substantial chromatin fragmentation and the formation of pyknotic nuclei (Fig. 9 C). These results, taken together, suggest that both developing (neonatal) and terminally differentiated (adult) cardiomyocytes are susceptible to apoptosis, although possibly to different degrees and in response to different triggers.

Discussion

This study provides the first evidence that $\text{TNF}\alpha$ and its sphingolipid second messenger molecules, including ceramide, sphingosine, and sphingosine-1-phosphate, can induce apoptosis in cardiomyocytes. Moreover, the resulting cardiomyocyte cell death is not associated with appreciable necrosis as evidenced not only by cell viability assays but also by the preponderance of apoptotic-like nuclei in the single cell gel electrophoresis (comet) assay and the presence of pyknotic nuclear fragmentation patterns characteristic of apoptosis.

Figure 8. Oligonucleosomal DNA laddering of apoptotic rat cardiomyocytes. Neonatal cardiomyocytes were cultured for 18 h either in control conditions (DMEM/F12 with 10% FCS) or in the presence of 10 $\mu\text{mol/liter}$ sphingolipid. Total DNA was then extracted (see Methods) and fractionated on agarose (1%) gels. Lanes a–d represent electrophoresed DNA extracted from neonatal cardiomyocytes treated either with C2 ceramide (lane a), sphingosine-1-phosphate (lane b), sphingosine (lane c), or control (lane d). On the right (lane e) is a 100-bp ladder.

Apoptosis and programmed cell death are often inappropriately equated with necrotic cell death. However, important distinctions can and must be made, since apoptosis and necrosis have different consequences and they present distinct histopathological features in the clinical setting. Some widely used techniques for assessing apoptosis have been criticized for their inability to distinguish apoptotic cells from the DNA fragmentation associated with necrosis unless other criteria are applied (44). Neither nick-end labeling nor flow cytometry can differentiate the double-strand breaks commonly associated with apoptotic cell death from the more random breaks characteristic of necrosis. The presence of oligonucleosomal DNA ladders is often used to identify double-stranded DNA breaks. However, according to Collins et al. (44), evidence of DNA laddering is not a definitive hallmark of apoptosis and should not be used as the sole criterion for apoptosis, since internucleosomal fragmentation can occur as a result of necrosis and many nuclei must be caught in synchronous fragmentation patterns to get a result. Using a variety of standard techniques and a newly developed technique for assessing DNA damage in nuclei, the comet assay, we have demonstrated the induction of apoptosis in cardiomyocytes.

The observation that $\text{TNF}\alpha$ is a trigger for apoptosis in the heart suggests that the cardiotoxicity of $\text{TNF}\alpha$ observed in a variety of clinical conditions, including heart disease and sepsis, are not only due to $\text{TNF}\alpha$'s acute negative inotropic effects (23), but may also be complicated by $\text{TNF}\alpha$ -induced cell death

Figure 9. Apoptosis in neonatal rat cardiomyocytes. (A) TUNEL staining of untreated neonatal rat cardiomyocytes cultured for 2 d in DMEM/F12 with 10% FCS, showing only an occasional TUNEL-positive nucleus. (B) TUNEL staining of the same preparation of neonatal cells shown in A, but treated for 18 h in culture with 10 $\mu\text{mol/liter}$ sphingosine. (C) Ethidium bromide-stained neonatal cardiomyocytes treated with 10 $\mu\text{mol/liter}$ sphingosine for 18 h. Note the crenated apoptotic cell with a very prominent pyknotic nucleus. Non-apoptotic cells appear larger and their nuclei are also larger with no evidence of DNA condensation or pyknotic apoptotic bodies. Bar represents 50 μm .

by apoptosis. The levels of TNF α capable of producing apoptosis in our cultured rat cardiomyocytes are within the range found in serum of patients experiencing severe acute myocardial infarction (16, 45), suggesting that TNF α may contribute to cell death by apoptosis during ischemia. It has been shown that apoptosis occurs in experimental models of ischemia/reperfusion injury (5, 6, 13) and, importantly, that apoptosis is a feature of human ischemic myocardial damage (7, 8). Moreover, it has recently been shown that apoptosis rather than necrosis determines the size of myocardial infarcts (10). Since cardiac cells themselves may produce TNF α (21, 22), local concentrations of the cytokine are expected to be higher than reported serum values, complicating our ability to estimate the extent of apoptosis that may be caused by TNF α during acute ischemia, heart failure, or other conditions in which TNF α may play a role in cardiac cell death. Since the true concentration of TNF α in heart tissue is unknown, one cannot know exactly the extent of TNF α -induced apoptosis. Importantly, the data in Fig. 4 also demonstrate that appreciable apoptosis in rat cardiomyocytes does not occur unless the concentration of TNF α is in the nmol/liter range. This is in the range that just exceeds the K_d for TNF α binding to type I TNF α receptors (~ 500 pmol/liter) (25), suggesting that TNF α -induced apoptosis is mediated by the TNF α receptors present on rat cardiomyocytes (23) and that apoptosis is unlikely to occur in the heart unless the K_d for the receptor is approached. Since normal human serum TNF α levels (1.2 pg/ml or 70 pmol/liter, reference 46) are far below this value, our data predict that apoptosis in the human heart would not occur in the absence of pathology and then only if the pathology is severe enough to raise local TNF α levels to approximate the K_d for its receptor (8.5 pg/ml or 500 pmol/liter).

Significantly, receptor-specific anti-TNFR1 antibodies induced appreciable apoptosis in cardiomyocytes (Table III). These findings strongly implicate the type I p60 receptor in mediating TNF α -triggered apoptosis and are similar to observations made by others in which anti-TNFR1 antibodies were shown to induce apoptosis (47, 48). It is possible that antibody cross-linking of the trimeric receptor activates the signal transduction cascade and accounts for the ability of anti-TNFR1 antibodies to mimic TNF α action.

Data presented here demonstrate that TNF α activates the sphingomyelin signal transduction pathway, resulting in the production of the intracellular signaling molecule, sphingosine. Since sphingosine is a very effective inducer of apoptosis in cardiomyocytes, it is possible that TNF α 's ability to trigger apoptosis may result from TNF α -induced sphingosine production, similar to the finding that TNF α -induced sphingosine production is responsible for apoptosis in HL-60 cells (20). Significantly, we have demonstrated that the TNFR1 is the predominant receptor for TNF α in adult rat cardiomyocytes (23). Since it is well established that the TNFR1 is the receptor linked to membrane-bound sphingomyelinase (26) and to sphingosine production (49), we speculate that TNF α -induced apoptosis may be mediated by the TNFR1 coupled to the sphingomyelin signal transduction cascade.

The mechanism of sphingosine-induced apoptosis has not yet been determined. One possibility is that sphingosine down-regulates the expression of the cell death repressor, bcl-2, as it does in other cells (50). Since protein kinase C (PKC) may protect cells from apoptotic cell death (18, 51, 52) and since sphingosine is a potent inhibitor of PKC (53), it is also possible

that sphingosine could promote apoptosis through PKC inhibition, possibly by changing the level of bcl-2 phosphorylation (51, 52). It is curious that while TNF α triggered apoptosis in adult cardiomyocytes, apoptosis could not be detected in the TNF α -treated neonatal cells. In experiments employing reverse transcriptase PCR (see Methods), we have determined that, in contrast with adult rat cardiomyocytes, neonatal cardiomyocytes in culture do not possess detectable transcript levels for the TNFRI (data not shown). This relative absence of receptor in neonatal cells can account for the observed lack of responsiveness to TNF α .

The surprising ease with which adult cardiomyocytes can be driven into apoptosis by sphingolipids and TNF α may be due to the presence of a preexisting death program that can be readily activated with the appropriate trigger. Apoptosis is often equated with programmed cell death and as such can also be distinguished from necrosis in that it is critically dependent upon the expression of the bcl family of protooncogenes, including bcl-2 itself, which normally protects cells from apoptotic triggers (54, 55). Low bcl-2 expression has been reported in adult rat and chicken cardiac muscle (10, 56). Thus it is possible that cardiac muscle is not well protected from apoptotic triggers. This may explain, in part, why cardiomyocytes are readily driven into apoptosis by physiologically relevant triggers of the death program, such as TNF α and sphingolipid second messengers.

The present study suggests that cardiac cells could be driven into apoptosis by other triggers, such as infection, injury, or hypoxia. In contrast to necrosis, apoptotic cells do not trigger a generalized immune response, nor do apoptotic cells release harmful cytoplasmic contents (e.g., lytic enzymes, potassium) that would have adverse effects on neighboring cells. Because of this "good neighbor policy," cardiac apoptosis may be an effective suicide mechanism that limits the site of injury by preventing damaged cells from injuring neighboring healthy cells. By comparison with necrotic cell death, apoptosis may thus be beneficial to the heart if it could act to limit the area of involvement; for example, during myocardial infarction, cardiac tumor growth, or viral infection of cardiac tissue. The recent finding that apoptosis and not necrosis determines the size of myocardial infarcts (10) is consistent with the notion that apoptosis may define and possibly limit the damaged area. The ability of heart cells to readily undergo apoptosis may also help explain the rare incidence of primary cardiac tumors (57). On the other hand, unregulated or inappropriate apoptosis of the heart could produce adverse consequences, such as the potential loss of cardiac cells resulting from TNF α -induced apoptosis that we predict to occur during severe sepsis. The ability of TNF α to drive adult cardiac cells into apoptosis may contribute to the cardiotoxic effects of TNF α that have limited its usefulness as a therapeutic agent in human cancer therapy and as an antiviral agent (58). The elucidation of cardiac apoptosis mechanisms will provide useful information that could potentially aid in the understanding and treatment of a wide variety of cardiac disorders.
