Abstract: The uncertain, ever-changing and an ongoing nature of the COVID-19 pandemic means that it may take some time before we can fully appreciate the negative effect of the pandemic and lockdown on our sleep and mental health. It is increasingly recognised that in the aftermath of pandemic, several persistent sleep, neuropsychiatric and physical sequelae may continue long after the pandemic is over. A body of evidence to date also highlights a significant disparity in sleep and mental health difficulties in specific vulnerable groups in the community, with different temporal profiles and sleep issues that are reported. In this perspective, we argue for a possible mechanistic impact of the COVID-19 pandemic, with its imposed restrictions and social isolation on sleep quality. We similarly discuss some of the potential international differences, as well as similarities, behind reported idiosyncratic biological vulnerabilities that may have contributed to the genesis of sleep issues. Lastly, we propose some possible implementations and innovations that may be needed in restructuring of sleep disorders services in order to benefit recovering COVID-19 patients.

Keywords: sleep, insomnia, hypersomnia, lockdown, COVID-19 pandemic, social isolation

Introduction

During the ongoing COVID-19 pandemic across the globe, public health measures have been implemented to reduce community transmission of the virus, including stay-at-home orders, quarantine, and social distancing measures.¹ These measures have had a profound economic and social impact, including disruption to employment and education.^{1,2} Moreover, these restrictions have also had important neuropsychiatric consequences for the population as a whole, with forced social isolation leading to an increase in reported psychiatric symptoms, including stress, anxiety and depression for all individuals.¹⁻⁴ It has been suggested that this relationship seems to be moderated by the loneliness associated with prolonged periods of lockdown, and maladaptive changes in lifestyle, including disturbed sleep.¹⁻³ The notion that such a global event would lead to a further global pandemic of disturbed sleep in wide swathes of the population is perhaps unsurprising, given that sleep is pivotal for recovery and physiologic adaptation to the waking experiences.⁵ The bidirectional relationship between sleep and emotional brain function appears to be supported by the findings of studies that build on long-standing clinical observations of co-occurring mood and sleep disorders.^{6,7}

Over the last two years, impressive global scientific effort has been undertaken to examine the clinical sequelae and biology of the severe acute respiratory

syndrome coronavirus 2 (SARS-CoV-2) virus, with increasing awareness that SARS-CoV-2 can affect the central and peripheral nervous system.^{2,8} In a recent meta-analytical estimate of point prevalence of neurological or neuropsychiatric symptoms, sleep disorders were recognized as one of the most frequently reported symptoms, with a 23.5-point prevalence,² similar to depression and headache estimates.²

The heterogeneity of reported neuropsychiatric symptoms precludes us from drawing conclusions about the potential differential mechanistic platforms behind the detrimental biological effects of isolation and heightened stress versus those potentially solely exacerbated by the SARS-CoV-2 infection. The resulting effects and subsequent sleep issues in both cases are most likely due to a complex interplay of a myriad of biological and environmental factors, including: electrolyte abnormalities, liver inflammation, impaired renal function, impaired oxygenation, hyper-inflammation, and isolation due to public health concerns.^{4,9} Moreover, current evidence suggests that idiosyncratic factors, including, for example, pre-morbid psychiatric illness, may be both a risk factor for and a consequence of COVID-19.^{1,4} In a pre-COVID-19 study that analyzed sleep data from 41,094 participants,¹⁰ socio-economic disadvantage, ethnic minority background, shift work, unhealthy lifestyle, poor health, depressive symptoms and obesity were highlighted as the major risk factors associated with poor sleep.¹⁰ It has also been suggested that around a third of the total effect of socio-economic deprivation on poor sleep may be mediated through depressive symptoms.¹⁰

Thus, vulnerable individuals appear to be at greatest risk of developing sleep problems due to these multiple contributors, and may experience both acute and long-term sleep and other neuropsychiatric disorders.^{1,4} In this perspective review, we draw on evidence from various lines of ongoing research to assess how the impact of the COVID-19 pandemic, imposed restrictions and social isolation have impacted sleep quality. We evaluate how different countries and particular conditions, including idiosyncratic biological vulnerabilities, have contributed to the genesis of sleep issues, and we consider possible implementations and innovations needed in restructuring of sleep disorder services to benefit recovering COVID-19 patients.

Sleep and Neuropsychiatric Complications of the COVID-19 Pandemic, Lockdown, Infection and Vaccination

COVID-19 Pandemic and Lockdown

One of the earliest studies of the effects of COVID-19 pandemic reported findings from a survey of 2254 participants, aged 16–75 years.¹¹ The findings echoed a general mood pervasive in the United Kingdom (UK) in May 2020, just a few months after the UK government announced lockdown measures.¹¹ This survey for the first time suggested a possible significant short (and long) term impact of the COVID-19 pandemic on the quality of sleep and anxiety levels in the UK.¹¹ In the survey, six out of ten people reported suffering from disturbed, unrefreshing sleep, of both shorter and longer duration, with unusually vivid dreams.¹¹ A slightly later UK cross-sectional online survey-based study on adults living through the COVID-19 pandemic similarly found that 69.4% of 843 participants had disturbed sleep patterns.¹² Of those, less than half (44.7%) had refreshing sleep, 45.6% were sleepier than before the lockdown and 65.2% reported an impact on their mental health, with 25.9% reporting drinking more alcohol during the lockdown.¹² Of note is that respondents with suspected COVID-19 were also found to have more vivid nightmares and abnormal sleep rhythms.¹² These findings were mirrored by an Italian online web-based study of 5988 adults, also undertaken during lockdown, which revealed that disturbed sleep patterns in part predicted higher dream recall, as well as nightmares.¹³ Other important psycho-social predictors of nightmares in this study included: anxiety, depression, those who had stopped working, and those who had friends/relatives who were infected by or who had died of COVID-19.¹³ As discussed further below, when taken together, these findings are in keeping with the continuity hypothesis of dreaming.^{14,15}

Very early on, we, and others, argued that some of those reported sleep symptoms (eg vivid dreams) possibly reflected the biological response to the extraordinary stress and uncertainty that the populace was facing.^{1,16–19} For example, it is known that rapid eye movement (REM) sleep structure, during which most of our dreaming occurs, changes first during chronic stress, and more so than any other measured sleep characteristic.⁵ Moreover, REM sleep has been suggested to play a role in recalibrating the sensitivity and specificity of the brain's response to

emotional events on both ends of positive and negative spectrum, suggesting a bidirectional impact of any such REM sleep disturbance on affected individuals.^{6,20} Similarly, Steenblock et al argued for a link between the ongoing SARS-CoV-2 outbreak and the neuroendocrine stress axis.¹⁹ They warned of uncertain long-term outcomes for those who have been actually infected, as well as for those who are not necessarily infected themselves, but who may suffer lasting consequences as a result of loss, grief, isolation, deprivation, and other psychological outcomes of ongoing quarantine or shelter in place measures.¹⁹ These groups include health care workers, and others whose lives were severely affected.¹⁹ From earlier coronavirus outbreaks, it has been evident that survivors and health care workers are at increased risk of developing mental illness years after the outbreak.¹⁹ It has been argued that such long-lasting impacts might be due to morphological changes in the brain and in the organs of the hypothalamic-pituitary-adrenal (HPA) axis,¹⁹ with the added complexity of widely differing gender responses to stress. Worryingly, it has also been suggested that permanent epigenetic changes in stem cells may occur due to actual infection, as well as that they may result from the different forms of severe stress,¹⁹ further suggesting likely profound and long-term effects of the current pandemic.

COVID-19 Infection

Studies to date have also suggested that microvascular infarcts and haemorrhages, which are part of the systemic coagulopathy and vasculopathy of COVID-19, may be critical in the development of encephalopathy, delirium and other neurological and psychiatric manifestations of SARS-CoV-2 infection.⁹ The consensus on whether disturbances of higher mental function occur predominantly without direct infection of the central nervous system neurons has not yet been reached; however, it does appear that the virus can enter the brain,⁹ when it may infect vascular and immune cells.⁹ The direct SARS-CoV-2 invasion of the CNS likely occurs at the blood-brain barrier via transcellular migration through host endothelial cells, paracellular migration through tight junctions, and an immune system “Trojan horse” cell passing through the blood-brain barrier.^{4,9}

Our group has recently proposed that a relatively unique fingerprint of sleep and ultradian rhythms disturbance, along with heightened levels of anxiety, during SARS-CoV-2 infection may in some patients result from viral binding to neuronal angiotensin-converting-enzyme-2 (ACE2)-receptors in a specific part of the brain's hypothalamic

paraventricular nucleus (PVN) (Figure 1).¹⁸ It is known that SARS-CoV-2 can directly decrease ACE2 activity and lead to cell toxicity in other tissues.^{9,18} This interaction is believed to subsequently lead to a myriad of symptoms, from increased blood pressure to kidney failure.^{18,21} Arguably, any such potential direct or indirect SARS-CoV-2 effect on the PVN circuitry, a major brain computational hub that ensures timely processing of multiple physiologic signals, would significantly affect pivotal short-term biological rhythms and sleep patterns, resulting in increased, debilitating and misdirected anxiety.¹⁸

Unsurprisingly, the data regarding the long-term cognitive consequences of COVID-19 is still lacking, but one study of 279 patients hospitalized with COVID-19 found that, three months after discharge, 34% reported significant memory loss and 28% described impaired concentration.^{4,22} Comparable findings have been observed following infection with other coronaviruses, in which 20% reported cognitive deficits months to years after initial infection.² In keeping with this, Taquet et al,²³ who have recently reported results from a large USA dataset, showed that in the six months after SARS-CoV-2 infection, about a third of these individuals had a neurological or psychiatric disorder, more than comparative figures for influenza.²³ Most of these heterogenic neurological or psychiatric disorders were more common in patients who had COVID-19 than in those who had influenza and those who had other respiratory tract infections.²³ Another study that examined the differential psychological impact of COVID-19 infection in 7917 participants, of whom 49.7 were healthcare professionals with a high representation of female participants,²⁴ reported suicidal thoughts in 32% of respondents.²⁴ Healthcare professionals reported mild depression and anxiety in higher proportions to other respondents.²⁴ Increasing age and female gender were linked to higher compliance with governmental advice on COVID-19, whereas higher education, homeowners, key worker status, high alcohol, drug use and participants with pre-existing suicidal thoughts were linked to lower compliance with governmental advice.²⁴ Moreover, a striking psychological impact on the wellbeing of frontline healthcare professionals was demonstrated, with many clinicians increasingly raising concerns about future retainment as well as recruitment to medical specialty and healthcare sector.²⁴

COVID-19 Vaccination

Finally, another potentially controversial side to the ongoing pandemic is the possible unknown long-term effect of different COVID-19 vaccines, for which the

Figure 1 The schematic illustration of the basic neuronal organization of the paraventricular nucleus (PVN) of the hypothalamus depicting its purported role in a four-step model of neurocircuitry of anxiety. On the left, a four-step model by Calhoun and Tye is shown: according to this model external events are detected, interpreted, evaluated, and responded to by succeeding levels of highly interconnected neural circuits. Reproduced by permission from Springer Nature, *Nat Neurosci*, Resolving the neural circuits of anxiety, Calhoun GG, Tye KM. 2015;18(10):1394–1404. Copyright © 2015, Nature Publishing Group, a division of Macmillan Publishers Limited.⁹² Events are further interpreted as threatening or nonthreatening depending on the balance between opposing circuits; when the balance is shifted toward projections interpreting events as threatening, this leads to anxiety. On the right, PVN's neurocircuitry is depicted. Afferent inputs to the nucleus arrive from many important integrative centers of the medulla, pons and hypothalamus. Subfornical organ is among major inputs with identified angiotensin release acting directly on magnocellular and parvocellular neurons, or indirectly via intranuclear circuitry that includes inhibitory Gamma-aminobutyric-acid (GABA) (red) and excitatory glutamate (green) interneurons. Changes within paraventricular angiotensin subcircuits are described under stress condition and are reflected on release of stress hormone and arousal. GABA interneurons have been shown to express angiotensin-converting-enzyme-2 (ACE2),⁹³ and as such might be targeted by severe-acute-respiratory-syndrome-coronavirus-2 (SARS-CoV-2). The majority of GABA interneurons have been localized to the halo zone surrounding the PVN, and their role as an additional gatekeeper and integrator in controlling the excitability of PVN outputs has been proposed.⁹⁴ Any changes in the PVN circuitries, due to their major control over most of neuro-endocrine axes and neuronal autonomic centers may cause robust alteration in homeostatic regulation, and through influence on regulatory brain centers impact on sleep and wakefulness, increased propensity to trigeminal autonomic cephalalgias and alteration of ultradian rhythms.

SARS-CoV-2 spike protein was a major target.²¹ It is clear that the development of SARS-CoV-2 spike protein-based COVID-19 vaccine has been one of the major scientific and medical breakthroughs of the 21st century, which has provided much-needed hope on how to end the current pandemic. However, the limited findings of several in vitro and post-mortem studies suggest that the recombinant SARS-CoV-2 spike protein S1 subunit could be potentially

sufficient to promote cell signaling without the remaining viral components.^{21,25,26} Similarly, at present, the insertional mutagenesis safety of mRNA-based vaccines remains largely unresolved.²⁷ Going forward, it will be pivotal to keep evaluating the data from SARS-CoV-2 infected individuals, as well as from the healthy individuals who received the spike protein-based vaccines, with further stringent investigations of the effects of the SARS-

CoV-2 spike protein in appropriate animal models.²¹ Taken together, the data to date strongly suggest that monitoring of all affected populations for an extended time following the current pandemic might be needed.¹⁹

The Effects of Pandemic and Lockdown on Sleep, Circadian Timing and Mental Health Across the Globe

The COVID-19 pandemic and its associated lockdown(s) have evidently resulted in restrictive lifestyle changes,²⁸ with alterations in important zeitgebers, such as light exposure, meals, social interactions, and exercise resulting in further disruption of chronobiological rhythms.²⁹ Confinement to homes, which doubled as new workplaces, with simultaneous increase in responsibilities, such as home-schooling²⁹ additionally occurred in an anxious milieu, with fears regarding contracting COVID-19, employment security, finances, and concerns about the welfare of loved ones.³⁰ Many of these anxieties were further fueled by a constant deluge of ever-changing news and government information, leading some to nickname the crisis “an information pandemic”.^{31,32} The concomitant impact of these lifestyle changes has provided the perfect storm to adversely impact sleep quality, by individually affecting each of the three sleep regulatory processes: the homeostatic sleep drive, the circadian rhythm, and the arousal system.³³

During the very early days of the pandemic, in the early part of 2020, an interesting dichotomy with regard to reported changes in sleep was noted around the globe. Studies from Europe, US and UK have reported an increase in sleep opportunity, sleep duration and reduced “social jetlag” during the pandemic.^{11,12,34–37} Such positive changes are most likely due to alterations in pressurized social and environmental factors, including changes in employment practices, such as remote and flexible working.^{38,39} Smartphone data of 2.9 million nights of sleep recordings taken from participants across different continents indicated a sudden increase in sleep duration during the early stages of the pandemic, compared to the same time a year earlier.³⁶ In addition to increases in sleep duration, changes to sleep timing have also been observed. In one global survey, nearly three quarters of respondents indicated that their sleep patterns have changed as a result of lockdowns, with the majority indicating that their sleep and wake times were delayed compared to before the

pandemic, and 43% of respondents indicating that their current sleep timing was more in line with their body clock.⁴⁰ Increasing flexibility in sleep-wake routines resulting from stay-at-home orders has clearly been of benefit to many in society who would have otherwise suffered with reduced sleep opportunity due to occupational and lifestyle commitments. However, for others, being afforded greater flexibility in sleep timing appears to have resulted in more irregular sleep-wake timing, which is known to have adverse effect on academic performance and health outcomes.^{41,42} Indeed, despite some initial benefits that were reported in some sections of western society as the pandemic progressed, the majority of populace has overwhelmingly described disturbed sleep patterns, and diminished sleep quality in comparison to pre-pandemic sleep patterns across the globe.^{34,35,37,40,43}

In one global survey, 73% of respondents reported poor sleep quality, scoring more than five on the Pittsburgh Sleep Quality Index (PSQI),⁴⁰ with around 57% of respondents indicating that their sleep was worse currently compared to before the pandemic.⁴⁰ This is in line with other prevalence estimates of poor sleep of around 50–55% from Italy,^{40,43} however much lower levels were reported around the same time in China (36%).⁴⁴ These differing rates are likely due to the predominantly female respondents in some surveys, potentially amplifying the prevalence rates of poor sleep. This highlights the limitations of rapid data collection of convenience samples, which may not be representative of the population. Importantly, poor sleep quality has been linked to poorer mental health, both pre-pandemic and in the recent pandemic literature.^{40,45} In the same global study, it has been shown that individuals who scored more than eight points on the PSQI had a three-fold increased prevalence of significant anxiety, stress and depressive symptoms, even when controlling for pandemic-related factors and demographics.⁴⁰ While further longitudinal studies are needed to uncover the directionality of these associations, it would appear that addressing poor sleep during lockdowns may help to mitigate some of the adverse mental health effects.

Moreover, for those who were home confined during lockdown, circadian rhythm disruption,²⁹ compounded by increased digital screen time^{46,47} has adversely affected sleep timing and quality.^{30,48} Increased daytime napping, also seen during home confinement, has been shown to reduce sleep pressure (ie the homeostatic sleep drive), resulting in delayed bedtimes, and prolonged sleep onset latency.^{30,49} Arguably, later bedtimes can also adversely

impact slow wave sleep, and its purported function of enabling the glymphatics clearance of brain toxins,⁵⁰ as well as impact on the overall sleep quality.⁵¹ Thus, circadian and homeostatic factors that interact to regulate sleep have all been adversely affected by lockdown.

When exploring differences between countries in terms of the rates of sleep difficulties or mental health symptoms, little difference emerged despite dramatic differences in infection rates and COVID-19 related deaths across countries^{1,11,12,17,35,37,52} (also see Figure 2).¹ Respondents from countries with high case numbers did report higher stress levels, although the effect size was small.⁴⁰ An interesting case study by Czeisler et al explored the impact on sleep and mental health in respondents from Victoria, Australia – a city with one of the longest and most stringent lockdowns globally (112 days) with relatively low SARS-CoV-2 case numbers (0.32%).⁵³ Compared to the status before the pandemic, during Stage 4 restrictions in September 2020 participants reported spending more time in bed and having more trouble sleeping, with one third of respondents reporting anxiety or depressive symptoms and one in ten reporting suicide ideation occurring over the last 30 days.⁵³ Around 21% of respondents reported insomnia symptoms, slightly higher than that reported in April 2020

near the start of lockdown.⁵³ Critically, suicide ideation was 1.86-fold more prevalent in those with insomnia symptoms.³⁶ Victorians, who endorsed higher mental health symptoms, had a shorter sleep duration (<six hours), spent more time in bed, had more trouble falling asleep and reported maintaining a less regular sleep-wake schedule.⁵³ On a positive note, those who adapted their behavior and were able to keep more regular sleep times and avoid COVID-19 media coverage had a lower prevalence of depression and anxiety symptoms.⁵³ This study provided a unique perspective on the impact of lockdown on sleep and mental health symptoms, suggesting that these effects may not be transient, as well as that individual idiosyncratic factors might play a significant role in the valence of the reported outcomes.⁵³

Mediating Factors and Vulnerable Groups

A body of evidence to date similarly highlights a significant disparity in sleep and mental health difficulties in specific groups in the community. For instance, it has been reported that in South Africa, the lockdown has caused substantial economic hardship, especially among poor and vulnerable people, with possible important long-term consequences.⁵⁴ Moreover, restrictions on movement and the risk of

Figure 2 Stress, depression, anxiety, and insomnia symptoms across countries with the top five number of respondents by insomnia group (n = 2525). Error bars indicate 95% confidence intervals.
Abbreviations: PSS, perceived stress scale; STAI-6, 6-item state anxiety inventory; PHQ-9, patient health questionnaire-9 item; SCI, sleep condition indicator.

contracting COVID-19 in health care facilities in South Africa have brought major reductions in the use of health services, thereby compromising continuity of care for people with HIV, tuberculosis, and chronic noncommunicable diseases.⁵⁴ The COVID-19 pandemic has also had a particularly significant impact on people with Alzheimer's disease (AD) and other dementias internationally.³ This vulnerable population has been shown to be particularly susceptible not just to SARS-CoV-2 infection, but also to the negative effects of the measures taken worldwide to control the spread of the virus, with loneliness and isolation aggravating and accelerating the clinical picture.³

Internationally, an overwhelming trend towards later bedtimes, delayed sleep onset, a reduction in total sleep time and quality, has been reported together with increased daytime napping during lockdowns.^{30,49} Loneliness, uncertainty, depression and COVID-19 related-worries were only some of the important psycho-social drivers in underlying these changes.⁴⁹ These changes were more pronounced in younger people, women, those with a pre-existing neurologic and psychiatric conditions, unpaid caregivers and front-line workers, those who were unemployed, and in those who lived in less supportive welfare states,⁵⁵ suggesting that these groups may be more vulnerable to the acute and longer term effects of the pandemic.^{40,56} Younger adults (under 45 years) appeared to be more affected during the pandemic, and higher levels of stress, anxiety and depressive symptoms were reported in that age group by comparison to older age groups.^{40,56,57} In addition, loneliness and financial difficulties have been linked to the higher rates of mental health symptoms in this age group.⁴⁰

Reflecting the pre-pandemic sex disparity in insomnia prevalence, women increasingly appear to be more affected by lockdown in terms of their sleep. In a longitudinal study in Italy, insomnia severity and mental health symptoms were reported to be greater in women than men during the early stages of lockdown,⁵⁸ and this finding closely echoes other reports across the globe.^{40,49,52} Interestingly, however, in follow-up surveys and as the lockdown continued, the gender-gap narrowed across all measures.⁵⁸ Thus, the impact of prolonged lockdown may have differential temporal effects on men and women, which may necessitate differential therapeutic approaches.

Historically and during the pandemic, poor sleep has been linked to greater financial difficulties, greater disability, and an increase in alcohol consumption.⁴⁰ Behavioral factors are also likely to directly impact sleep during lockdowns. For

instance, a decrease in sunlight exposure, daily exercise and increased phone usage before bedtime have been linked to poorer sleep quality during lockdown.⁴⁰ The interactions between sleep, diet, substance use and exercise are complex, with changes in one domain likely to impact the others.⁵⁹ For example, we know that inadequate sleep is likely to promote poorer health behaviors, such as reducing the motivation to exercise and to eat healthily.⁶⁰ Moreover, those with poorer sleep during lockdown may be tempted to self-medicate with alcohol⁶¹ and/or other illicit substances,⁶² in hopes of improving their sleep. Unfortunately, such strategies merely worsen sleep, and further accelerate or initiate insomnia.⁶³ An association between alcohol abuse and the risk of violent offending has previously also been shown, with particular relevance for vulnerable sections of the society, including those with premorbid psychiatric disorders.⁶⁴

Many of these health behaviors have been shown to be affected by the psychological status and social connectedness of the individual, both of which have been adversely affected by lockdown.^{65,66} For many, lonely days mean lonely nights, resulting in poor sleep quality, with subsequent adverse effects on other health behaviors.⁶⁷ Social isolation can potentially also lead to a precarious state of chronic heightened anxiety that can increase individual's vulnerability to coercion and abuse during the pandemic.⁶⁸ Indeed, poorer sleep quality and higher levels of loneliness have been found to mediate the relationship between stress and mental health symptoms (depression, anxiety), highlighting the critical, but modifiable, impact of sleep on mental health during lockdown.⁴⁰

Pragmatic Focus on Sequelae of Insomnia and Hypersomnia

Insomnia symptoms frequently manifest in the face of acute life changes or stressors, such as pandemics,⁶⁹ and unsurprisingly, studies conducted during the COVID-19 pandemic have overwhelmingly and consistently shown a significant increase in insomnia symptoms, ranging from 18% to 63%.^{16,37,70,71} Whilst some of these insomnia symptoms may be categorized as mild, it has been well accepted that transient sleep disturbances can later lead to chronic insomnia disorders.³³ A recent study by Meaklim et al reported on difference in mental health symptoms in individuals with pre-existing insomnia, individuals who had developed insomnia symptoms during the pandemic and healthy sleepers.¹ For individuals with post-pandemic insomnia symptoms, 77% believed that factors

surrounding the pandemic triggered their insomnia symptoms.¹ Those who developed insomnia symptoms during the pandemic also had higher levels of stress, anxiety and depressive symptoms compared to individuals with pre-existing insomnia symptoms, or compared to those who were sleeping well (Figure 2).¹

Paradoxically, 25–28% of individuals with pre-existing insomnia disorder reported clinically meaningful improvements in sleep quality during the pandemic,^{1,72} suggesting that changes in sleep in response to the stressor of the pandemic are not uniform across individuals. While the reasons for this are likely to be multi-faceted, reduction of social and occupational pressure and attenuation of negative mood states have been proposed as potential mechanisms.¹ Moreover, individual experiences of lockdown can vary considerably, and for some people with insomnia, lockdown restrictions may have created a beneficial environment, reducing the stress of work and social commitments. Indeed, a qualitative synthesis of personal experiences during lockdown revealed that those with better sleep quality used more positive language, indicative of social support and positive well-being (eg “friend”).⁴⁰ Some clinicians have argued that enhancement of social support, and an increased social cohesion in some societies during lockdown might have helped to buffer predominantly negative impacts of the pandemic on sleep and well-being.¹

A meta-analysis of 177 published studies revealed that insomnia symptoms were most prevalent in healthcare professionals (43%), which further indicated that age, gender, country and marital status did not impact prevalence rates.⁷¹ As already mentioned, health professionals, especially frontline workers who regularly care for COVID-19 infected patients, may be at higher risk of insomnia, because of increased fear of risk of infection and death, as well as irregular and more frequent work schedules.^{73–75} For other “essential” workers besides healthcare, earlier wake times, and reduced total sleep times were also seen, when compared to “non-essential” workers.^{17,76}

There is a paucity of published research regarding lockdown and hypersomnolence, although the data from surveys around the globe clearly suggest that decreased sleep quality has been accompanied by both the decreases, and increases in sleep duration during the pandemic.^{11,12} Historically, hypersomnolence has been seen as a direct consequence of viral infection and/or treatment in pandemics;^{77–79} and such neuropsychiatric consequences

may be delayed ie it may be too early to judge the fallout of COVID-19 in this regard.^{18,21,79,80} Indirectly, the increased stress experienced by people during lockdown, may lead to hypersomnolence; either as a coping mechanism, or as part of a mental health disorder such as depression or Post-Traumatic Stress Disorder.^{81,82} For those who are home confined in lockdown, excessive daytime somnolence may also be a way of escaping social isolation, loneliness and/or boredom.^{30,83} Moreover, some people with insomnia present with excessive daytime sleepiness as their principal symptom, and may under-appreciate the effect of poor nocturnal sleep quality and/or maladaptive sleep-related behaviors in driving this.⁸⁴ Finally, many patients do not differentiate between hypersomnolence, tiredness and fatigue, and may use these terms interchangeably; and/or confuse hypersomnolence with clinophilia.^{81,85} An appreciation of the bio-psycho-social determinants of reported hypersomnolence will be essential for clinicians in the post-lockdown era, as we are likely to face an increase in atypical sleep and neuropsychiatric presentations.⁷⁹

Conclusions and Suggestions for Post-COVID Sleep Disorder's Clinical Infrastructure

Our scientific understanding of the impact of COVID-19 continues to evolve rapidly, with a concomitant influence on the provision of clinical sleep services and new therapeutic recommendations.⁸⁶ It is increasingly recognized that in the aftermath of SARS-CoV-2 infection/pandemic-related traumatic experiences, several persistent sleep, neuropsychiatric and physical sequelae may continue long once the pandemic is over.^{1,4,8,19,30,36,79} In addition, due to the complexity of COVID-19 and its treatment, some affected patients may require longitudinal follow-up, most appropriately delivered by the interdisciplinary post-COVID-19 clinics that should ideally include sleep physicians.^{2,4,8,86} Such post-COVID-19 clinics should aim to provide care in a systematic and carefully coordinated fashion across multiple specialties with complementary expertise (i.e., internal medicine, psychiatry, sleep medicine, neuropsychology and physical therapy), with further accelerated access to cardiology, nephrology, infectious disease, pain specialists, pulmonary, geriatrics, neurology, nutrition, occupational health and other specialists.⁴ This unique design should also help facilitate exceptional teaching and international research opportunities.⁴ Going

forward, shared clinical databases and open access to clinical research data, with an emphasis on educational outreach to other healthcare professionals and the wider community should be encouraged and nurtured.

These educational projects and outreaches should be preferably coordinated by international and national sleep societies, which should all work together to address the sleep difficulties incurred during lockdown, by advocating good sleep practices (e.g., minimizing pre-bed screen exposure, setting a fixed rising time, morning light exposure and exercise),⁸⁷ as well as looking after mental, emotional and social health.⁸⁸ Many of these recommendations have already received media attention, but await research and validation.⁸⁵

Managing the sheer number of people reporting sleep difficulties, and associated health and functioning sequelae will be challenging. As we have seen with other pandemics, insomnia and associated daytime dysfunction persist long after the threat of infection has passed.⁸⁹ Non-pharmacological techniques, like digital Cognitive Behavioral Therapy for Insomnia (dCBT-I) have been successful during lockdown, improving insomnia measures and daytime function.⁹⁰ Further validation of the provision of these therapeutic modalities, including digital therapeutics, and an expansion to other sleep disorders,⁹¹ is now urgently required in order to stem the tsunami of lockdown-associated sleep difficulties and its consequences. Future clinical trials are similarly needed to clarify the optimal treatment strategies for sleep and other potentially long-term neuropsychiatric impacts of COVID-19.⁴

Finally, on the individual level, one of the rare silver linings of the pandemic is that it allowed a significant minority to take a step back and to reflect on how they live and sleep, and particularly how they work, and some of those insights have been reported as potentially life-changing.⁶⁸ These are the types of insights that can enable people to stay resilient in the face of adversity, and it will be important to try to implement these strategies into our new normal. Workplaces may need to think about adopting more flexibility in terms of working from home, or flexible work hours in industries that permit this, so that employees can better align their work and sleep with their own natural body clocks – which will make them happier and more productive in the long run.

Acknowledgments

The authors wish to thank Dr Perna Varma and Ms Hailey Meaklim (Australia) for their leadership of the Sleep in the Time of COVID surveys, and Ms Meaklim for creating the

figure for this manuscript. The authors further wish to thank all the members of the Sleep Disorders Centre at Guy's Hospital (London, UK) for all their unwavering dedication to their patients during the COVID-19 pandemic time.

Disclosure

Professor Young's independent research is funded by the National Institute for Health Research (NIHR) Biomedical Research Centre at South London and Maudsley NHS Foundation Trust and King's College London. Professor Allan H Young reports personal fees from Lundbeck, grants, personal fees, from Janssen, grants, personal fees, from Livanova, personal fees from Sunovion, grants from Compass, grants, personal fees from Novartis, personal fees from Sumitomo Dainippon Pharma, personal fees from Bionomics, personal fees from Allegan, outside the submitted work; and Employed by King's College London; Honorary Consultant SLAM (NHS UK) Deputy Editor, BJPsych Open Paid lectures and advisory boards for the following companies with drugs used in affective and related disorders: AstraZeneca, Eli Lilly, Lundbeck, Sunovion, Servier, Livanova, Janssen, Allegan, Bionomics, Sumitomo Dainippon Pharma, COMPASS Consultant to Johnson & Johnson Consultant to Livanova Received honoraria for attending advisory boards and presenting talks at meetings organised by LivaNova. Principal Investigator in the Restore-Life VNS registry study funded by LivaNova. Principal Investigator on ESKETINTRD3004: "An Open-label, Long-term, Safety and Efficacy Study of Intranasal Esketamine in Treatment-resistant Depression." Principal Investigator on "The Effects of Psilocybin on Cognitive Function in Healthy Participants" Principal Investigator on "The Safety and Efficacy of Psilocybin in Participants with Treatment-Resistant Depression (P-TRD)" UK Chief Investigator for Novartis MDD study MIJ821A12201 Grant funding (past and present): NIMH (USA); CIHR (Canada); NARSAD (USA); Stanley Medical Research Institute (USA); MRC (UK); Wellcome Trust (UK); Royal College of Physicians (Edin); BMA (UK); UBC-VGH Foundation (Canada); WEDC (Canada); CCS Depression Research Fund (Canada); MSFHR (Canada); NIHR (UK). Janssen (UK) No shareholdings in pharmaceutical companies.

The authors declare that the research was conducted in the absence of any commercial or financial relationships that could be construed as a potential conflict of interest. The views expressed are those of the authors and not necessarily those of the NHS, the NIHR, or the Department of Health.
