ABSTRACT: We discuss the possibility to explain the anomalies in short-baseline neutrino oscillation experiments in terms of sterile neutrinos. We work in a $3 + 1$ framework and pay special attention to recent new data from reactor experiments, IceCube and MINOS+. We find that results from the DANSS and NEOS reactor experiments support the sterile neutrino explanation of the reactor anomaly, based on an analysis that relies solely on the relative comparison of measured reactor spectra. Global data from the ν_e disappearance channel favour sterile neutrino oscillations at the 3σ level with $\Delta m_{41}^2 \approx 1.3 \text{ eV}^2$ and $|U_{e4}| \approx 0.1$, even without any assumptions on predicted reactor fluxes. In contrast, the anomalies in the ν_e appearance channel (dominated by LSND) are in strong tension with improved bounds on ν_μ disappearance, mostly driven by MINOS+ and IceCube. Under the sterile neutrino oscillation hypothesis, the p -value for those data sets being consistent is less than 2.6×10^{-6} . Therefore, an explanation of the LSND anomaly in terms of sterile neutrino oscillations in the $3 + 1$ scenario is excluded at the 4.7σ level. This result is robust with respect to variations in the analysis and used data, in particular it depends neither on the theoretically predicted reactor neutrino fluxes, nor on constraints from any single experiment. Irrespective of the anomalies, we provide updated constraints on the allowed mixing strengths $|U_{\alpha 4}|$ ($\alpha = e, \mu, \tau$) of active neutrinos with a fourth neutrino mass state in the eV range.

1 Introduction

For almost two decades, the possible existence of light sterile neutrinos — new species of neutral fermions participating in neutrino oscillation — has intrigued the neutrino physics community. The excitement is fuelled in particular by a number of unexpected experimental results: an unexplained excess of electron anti-neutrinos ($\bar{\nu}_e$) in a muon anti-neutrino ($\bar{\nu}_\mu$) beam observed at a baseline of ~ 30 m from the source in the LSND experiment [1]; a similar excess found by the MiniBooNE collaboration at higher energies and correspondingly larger baseline [2]; the disagreement between theoretically predicted $\bar{\nu}_e$ fluxes from nuclear reactors and observations [3, 4], known as the reactor anti-neutrino anomaly [5] (see also [6–8]); and a similar disagreement between expectations and observations in experiments using intense radioactive sources [9, 10].

These anomalies need to be contrasted with a large set of null results in the $\nu_\mu \rightarrow \nu_\mu$, $\nu_e \rightarrow \nu_e$, and $\nu_\mu \rightarrow \nu_e$ oscillation channels as well as the corresponding anti-neutrino channels. The observation of all of these channels overconstrains sterile neutrino models, therefore global fits of such models exhibit pronounced tension, even though different data sets on each individual oscillation channel are consistent, for recent analyses see e.g. [11–21].

In this work, we update our previous analyses from refs. [11, 14, 21] to incorporate new experimental results. These are in particular the following:

1. New constraints on $\bar{\nu}_e$ disappearance into sterile neutrinos from the reactor neutrino experiments Daya Bay [22], NEOS [23], and DANSS [24–26]. Unlike the results from previous short-baseline reactor experiments that have led to the reactor anti-neutrino anomaly, these new analyses are based on a comparison of measured spectra at different baselines rather than a comparison of data to theoretically predicted spectra. The new results are therefore insensitive to possible mismodelling of the $\bar{\nu}_e$ emission from nuclear reactors. In particular, they are insensitive to an observed, but so far unexplained, bump at neutrino energies ~ 5 MeV [27–29].¹ Spectral distortions in the recent data from DANSS and NEOS lead to a hint in favour of sterile neutrinos at the 3σ level, which supports the previous reactor anomaly independent of flux predictions.
2. Daya Bay measurements of the individual neutrino fluxes from different fissile isotopes [37]. By combining the time evolution of the observed reactor anti-neutrino spectra with the known evolution of the reactor fuel composition, the Daya Bay collaboration was able to determine independently the neutrino fluxes from the two most important fissile isotopes in a nuclear reactor, ^{235}U and ^{239}Pu . Their analysis suggests that the discrepancy between predicted and observed fluxes stems mainly from ^{235}U , while the neutrino flux from ^{239}Pu appears consistent with predictions. (The other potentially relevant isotopes ^{238}U and ^{241}Pu are subdominant in Daya Bay.) In contrast, oscillations into sterile neutrinos would lead to equal flux deficits in all isotopes. Implications of these results for sterile neutrino models have been discussed previously in refs. [20, 21]. In our previous paper [21] we have shown that both hypotheses (free flux normalizations versus sterile neutrino oscillations) give acceptable fits to Daya Bay data, and that the preference in favour of flux rescaling decreases once Daya Bay is combined with the global reactor data. We will update those results in section 3.1 below. Finally, it has been demonstrated recently that the theoretical predictions for the time-dependence of reactor anti-neutrino fluxes on which the Daya Bay analysis is based may need to be refined [38, 39]. In particular, the present analysis accounts neither for the time-dependent equilibration of decay chains nor for the possibility of neutron capture on fission products, which would lead to a non-linear dependence of anti-neutrino fluxes on the neutron flux in the reactor [38]. Taking these effects into account, Daya Bay’s preference for the flux misprediction hypothesis is estimated to drop to well below 2σ [39].
3. Final results from OPERA [40] and ICARUS [41, 42]. Both experiments constrain sterile neutrinos mixing with electron and muon neutrinos by searching for anomalous $\nu_\mu \rightarrow \nu_e$ appearance in the CNGS beam.

¹See refs. [30–35] for a discussion of possible nuclear physics or experimental origins of this bump, and ref. [36] for speculations about a possible new physics explanation.

4. Searches for sterile neutrinos in MINOS/MINOS+ [43] and in NO ν A [44]. The first analysis combines charged current ν_μ disappearance data and neutral current data from the MINOS experiment and from the MINOS+ setup operating the same detector in a higher energy beam. The second analysis is based on neutral current data from NO ν A. Especially the MINOS/MINOS+ analysis places stringent bounds on sterile neutrino mixing with ν_μ over a wide range of masses.
5. New solar neutrino data, including the 2055-day energy and day/night asymmetry spectrum from Super-Kamiokande phase 4 [45] and the measurement of neutrinos from the proton-proton (pp) fusion chain in the Sun recently presented by Borexino [46]. In addition, the results of all solar experiments have been updated to match the new solar neutrino fluxes predicted by the GS98 version of the Standard Solar Model presented in ref. [47].
6. Improved atmospheric neutrino data from Super-Kamiokande (including 1775 days of phase 4 data) from ref. [48], as well as the complete set of DeepCore 3-year data presented in ref. [49] and publicly released in ref. [50]. The calculations of atmospheric neutrino event rates for both detectors are based on the atmospheric neutrino flux calculations described in ref. [51].
7. First sterile neutrino limits from IceCube, based on one year of data [52–54]. This novel analysis exploits the fact that active-to-sterile oscillations of atmospheric neutrinos inside the Earth may be enhanced by a Mikheyev-Smirnov-Wolfenstein (MSW) resonance [55, 56]. The resonance affects the anti-neutrino sector, and for sterile neutrino masses around 1 eV occurs at energies of order 1 TeV, an energy well above IceCube’s detection threshold, but still low enough to benefit from a substantial flux [57, 58]. Consequently, IceCube is able to set strong limits on sterile neutrino mixing with ν_μ .

We will begin in section 2 by reviewing the formalism of neutrino oscillations in the presence of sterile neutrinos. Along the way, we will also fix our notation, such as our parameterization of the leptonic mixing matrix. In sections 3 to 5, we will then discuss the status of the global data sets in the $\nu_e \rightarrow \nu_e$, $\nu_\mu \rightarrow \nu_e$, and $\nu_\mu \rightarrow \nu_\mu$ channels (and the corresponding anti-neutrino channels) in turn. In particular, section 3 discusses the recent hints from reactor spectral data and section 4 reviews the anomalies in the appearance channel. In sections 5 and 6, we present updated constraints on the mixing of a sterile neutrino with the ν_μ and ν_τ flavour from global data, respectively. We will finally combine all oscillation channels in section 7 into a global fit. We will determine the goodness of fit at the global best fit point and quantify the tension between appearance and disappearance data. We will summarize our results and conclude in section 8. Supplementary material can be found in the appendices.

2 Neutrino oscillations in the presence of sterile neutrinos

The topic of this paper are scenarios in which the standard three-flavor framework for neutrino oscillations is augmented by adding one sterile neutrinos ν_s . We will refer to such

scenarios as “3 + 1 models”. We will comment on scenarios with more than one sterile neutrino in section 8.

The oscillation probability for $\nu_\alpha \rightarrow \nu_\beta$ transitions in vacuum ($\alpha, \beta = e, \mu, \tau, s$) is given by

$$P_{\alpha\beta} = \sum_{j,k=1}^4 U_{\alpha j}^* U_{\beta j} U_{\alpha k} U_{\beta k}^* \exp \left[-i \frac{\Delta m_{jk}^2 L}{2E} \right]. \quad (2.1)$$

Here, L is the baseline, E is the neutrino energy, $U_{\alpha j}$ are the elements of the leptonic mixing matrix (which is 4×4 in a 3 + 1 model), and $\Delta m_{jk}^2 \equiv m_j^2 - m_k^2$ are the mass squared differences, with m_j the neutrino mass eigenvalues. We will assume $m_{1,2,3} \ll 1$ eV, but allow m_4 to be larger, thus considering the case $\Delta m_{41}^2 > 0$. For experiments in which matter effects play a significant role, in general the evolution equation should be solved numerically. In cases where a constant matter density is a good approximation, $U_{\alpha j}$ and Δm_{jk}^2 in eq. (2.1) can be replaced by an effective mixing matrix and effective mass squared differences in matter. For anti-neutrino oscillations, U should be replaced by U^* .

The mixing matrix U in vacuum can be written as a product of two-dimensional rotation matrices. Where an explicit parameterization is required, we choose

$$U \equiv R_{34}(\theta_{34}) R_{24}(\theta_{24}, \delta_{24}) R_{14}(\theta_{14}) R_{23}(\theta_{23}) R_{13}(\theta_{13}, \delta_{13}) R_{12}(\theta_{12}, \delta_{12}), \quad (2.2)$$

where $R_{ij}(\theta_{ij})$ denotes a real rotation matrix in the (ij) -plane with rotation angle θ_{ij} , and $R_{ij}(\theta_{ij}, \delta_{ij})$ includes in addition a complex phase δ_{ij} . In most cases, however, we will present our results in terms of the parameterization-independent matrix elements $U_{\alpha\beta}$.

For the following discussion the so-called short-baseline limit of eq. (2.1) will be useful. This limit refers to the situation where $\Delta m_{21}^2 L/4E \ll 1$, $\Delta m_{31}^2 L/4E \ll 1$, so that standard three-flavor oscillations have not had time to develop yet. In this case, eq. (2.1) generically simplifies to

$$P_{\alpha\alpha}^{\text{SBL}} = 1 - 4|U_{\alpha 4}|^2(1 - |U_{\alpha 4}|^2) \sin^2 \left(\frac{\Delta m_{41}^2 L}{4E} \right), \quad (2.3)$$

$$P_{\alpha\beta}^{\text{SBL}} = 4|U_{\alpha 4}|^2|U_{\beta 4}|^2 \sin^2 \left(\frac{\Delta m_{41}^2 L}{4E} \right) \quad (\alpha \neq \beta). \quad (2.4)$$

As we will see later, the connection between the $\nu_e \rightarrow \nu_e$, $\nu_\mu \rightarrow \nu_\mu$, and $\nu_\mu \rightarrow \nu_e$ oscillation probabilities, inferred from these equations, will prove to be crucial to test the compatibility between different oscillation data sets.

An extended discussion of various other limiting cases and the corresponding parameter dependencies (including complex phases) can be found in ref. [14].

3 $\bar{\nu}_e$ disappearance data

In the ν_e and $\bar{\nu}_e$ disappearance channels, the most important constraints on sterile neutrinos come from reactor experiments at short baseline ($L \lesssim 1$ km). But we include also data from solar neutrinos, ν_e scattering on ^{12}C , and radioactive source experiments. The data

Table 1. Data sets included in our $\nu_e/\bar{\nu}_e$ disappearance analysis. The total number of data points is 594. More details can be found in ref. [21]; the only update with respect of [21] is new data from DANSS [26].

is summarized in table 1. The following analysis is based on our earlier publication [21] where more details can be found. In section 3.1 we give an update of the reactor neutrino analysis, high-lighting the impact of the recent results from the DANSS experiment [26], whereas in section 3.2 we present the global $\bar{\nu}_e$ disappearance analysis.

3.1 Updated reactor analysis

The reactor analysis includes the experiments listed in table 1. The fit by now is dominated largely by the recent NEOS [23] and DANSS [26] results, as well as the latest data from Daya Bay. For the latter we include the ratios of spectra measured in experimental halls (EH) 3 and 1, and in experimental halls 2 and 1 [71], as well as the measurement of

the individual neutrino fluxes from each fissible isotope [37]. The analysis presented here is based largely on ref. [21] where more details can be found. The important difference with respect to that analysis is the recent preliminary results from the DANSS experiment presented in December 2017 [26], which consists of a data sample of approximately four times increased exposure compared to the one shown in March 2017 [25] used in [21]. Another recent analysis including this latest DANSS data can be found in ref. [91].

Regarding reactor neutrino flux predictions we consider two scenarios: (i) fixed fluxes, where we set the uncertainties on the predicted anti-neutrino fluxes to the values estimated in the original publications [3, 4]; (ii) free fluxes, where the normalizations of the neutrino fluxes from the four main fissible isotopes ^{235}U , ^{238}U , ^{239}Pu and ^{241}Pu are allowed to float freely. (A weak constraint $\pm 20\%$ at 1σ is included for the numerically subdominant fluxes from ^{238}U and ^{241}Pu to avoid unphysical values.) Note that we never rely on the predicted anti-neutrino *spectra*, only on the predicted rates. Even in the case of fixed fluxes, those analyses which use spectral information are based entirely on ratios of spectra at different baselines.

The new spectral data from DANSS are shown in the left panel of figure 1. The DANSS experiment uses a movable detector. The plot shows the ratio of the spectra observed in two detector locations corresponding to baselines of 10.7 and 12.7 m. The data show a spectral distortion, leading to a preference in favour of sterile neutrino oscillations, as illustrated by the orange curve in figure 2. The remarkable observation is that the preferred region from DANSS overlaps with the one from NEOS, which also observes a spectral distortion consistent with sterile neutrino oscillations, see right panel of figure 1. Results of the combined analysis of DANSS and NEOS are given in table 2. The best fit of NEOS + DayaBay is located at $\Delta m_{41}^2 = 1.78 \text{ eV}^2$, however there is also a local minimum around $\Delta m_{41}^2 = 1.3 \text{ eV}^2$ consistent with DANSS. Note that the NEOS spectrum is statistically dominated by the low energy part, where the spectra for those two values of Δm_{41}^2 are similar, as shown in the right panel of figure 1. We find that the no-oscillation hypothesis is disfavoured with respect to sterile neutrino oscillations at a significance of 3.3σ . Let us stress that this result is completely independent of reactor neutrino flux predictions. It is only based on bin-by-bin spectral comparison between two detector locations in DANSS, and between the spectra observed in NEOS and Daya Bay.

Combing all available reactor data, we obtain the results shown in table 2 and figure 2. These results confirm the $\simeq 3\sigma$ hint in favour of sterile neutrinos from DANSS and NEOS in the analysis with free fluxes. If the fluxes are fixed and the predicted neutrino rate is used (“reactor anomaly”), the significance increases to 3.5σ , with a best fit point consistent with the DANSS/NEOS spectral indications. Note that in the analysis using fixed fluxes there is minor tension between “old” reactor data and the DANSS/NEOS best fit region, see figure 2. Despite this small tension, the significance for sterile neutrinos increases from 3.3σ for NEOS+DANSS to 3.5σ for the global data. We conclude that recent data support the indication in favour of sterile neutrinos from the reactor anomaly, a conclusion that is solely based on spectral distortions, but independent of reactor flux predictions.

Let us comment on the impact of the Daya Bay measurements of the individual neutrino fluxes from different fissible isotopes [37] by using the time evolution of the observed

Analysis	Δm_{41}^2 [eV ²]	$ U_{e4}^2 $	χ_{\min}^2/dof	$\Delta\chi^2(\text{no-osc})$	significance
DANSS+NEOS	1.3	0.00964	74.4/(84-2)	13.6	3.3 σ
all reactor (flux-free)	1.3	0.00887	185.8/(233-5)	11.5	2.9 σ
all reactor (flux-fixed)	1.3	0.00964	196.0/(233-3)	15.5	3.5 σ
$\bar{\nu}_e$ disap. (flux-free)	1.3	0.00901	542.9/(594-8)	13.4	3.2 σ
$\bar{\nu}_e$ disap. (flux-fixed)	1.3	0.0102	552.8/(594-6)	17.5	3.8 σ

Table 2. Results on $\bar{\nu}_e$ disappearance from DANSS+NEOS, from a fit to all reactor data (both for free fluxes and fixed fluxes), and from a fit to the combined $\bar{\nu}_e$ disappearance data listed in table 1. For each combination of data sets, we give the parameter values and the χ^2 value per degree of freedom at the best fit point. In all fits, we treat θ_{14} and Δm_{41}^2 as free parameters. For the “all reactor” sample, we also leave θ_{13} free. In the “ $\bar{\nu}_e$ disap.” analyses, all parameters listed in eq. (3.2) are allowed to float. For the analyses with free reactor fluxes, there are two additional free parameters corresponding to the normalization of the ^{235}U and ^{239}Pu fluxes. The last two columns of the table give the $\Delta\chi^2$ between the no-oscillation hypothesis and the best fit, as well as the significance at which the no-oscillation hypothesis is disfavoured. It is obtained by assuming that $\Delta\chi^2$ follows a χ^2 distribution with two degrees of freedom (Δm_{41}^2 and $|U_{e4}|$).

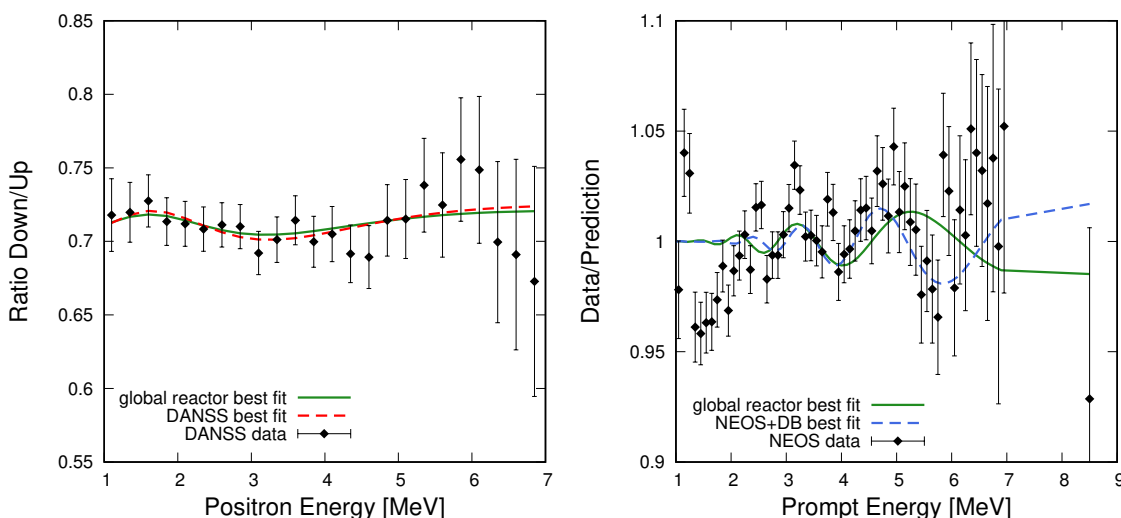

Figure 1. Observed spectra for the DANSS (left) and NEOS (right) experiments compared to the predicted spectra at the individual best fit points (dashed) and the best fit point from a global analysis of all reactor data (solid). The left panel shows the ratio of the observed event rates at the two detector locations in DANSS (24 bins). The right panel shows the NEOS spectral data relative to the prediction extrapolated from the measured Day Bay spectrum (60 bins). The best fit points are $\Delta m_{41}^2 = 1.32 \text{ eV}^2$, $\sin^2 \theta_{14} = 0.012$ for DANSS, $\Delta m_{41}^2 = 1.78 \text{ eV}^2$, $\sin^2 \theta_{14} = 0.013$ for NEOS + Daya Bay, and $\Delta m_{41}^2 = 1.29 \text{ eV}^2$, $\sin^2 \theta_{14} = 0.0089$ for the fit to all reactor data, assuming a free normalization for the neutrino fluxes from the four main fissible isotopes.

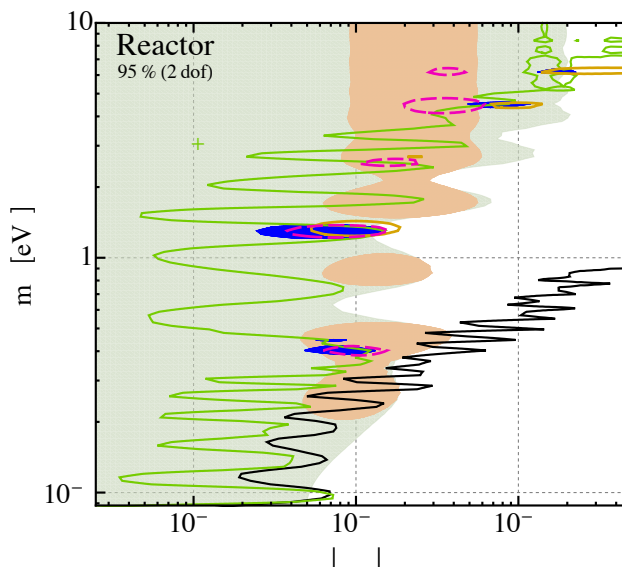

Figure 2. Allowed regions at 95% CL (2 dof) from reactor data. The solid curves correspond to Daya Bay spectral data (black), NEOS + Daya Bay (green), and DANSS (orange); they are independent of assumptions on fluxes because they are only based on spectral ratios. The light-shaded areas labelled “old” correspond to all data from table 1 except Daya Bay, DANSS, NEOS, and they are shown for the flux-free analysis making no assumptions about flux normalization and spectra (light green), as well as for the flux-fixed analysis (light orange), assuming reactor flux predictions and their published uncertainties. The blue shaded regions correspond to all reactor data from table 1 for the flux-free analysis, whereas the dashed magenta contours indicate the global data for the flux fixed analysis. The white (pink) star indicates the best fit point $\Delta m_{41}^2 = 1.29 \text{ eV}^2$, $\sin^2 \theta_{14} = 0.0089$ ($\Delta m_{41}^2 = 1.29 \text{ eV}^2$, $\sin^2 \theta_{14} = 0.0096$) for free (fixed) reactor fluxes.

reactor anti-neutrino spectra. These data have been used to compare the hypothesis H_1 of no-oscillations but free flux normalizations to the hypothesis H_0 that flux predictions [3, 4] (including their error estimates) are correct and a sterile neutrino exists. Considering the test statistic

$$T = \chi_{\min}^2(H_0) - \chi_{\min}^2(H_1), \quad (3.1)$$

Daya Bay data lead to $T_{\text{obs}} = 6.3$, which prefers H_1 (flux-free) over H_0 (oscillations) at 2.7σ [21, 37] (see, however, [39]). As shown previously [20, 21], this preference decreases, once the global reactor data is combined with DayaBay data. Using the numbers given in table 2, we find that with present combined reactor data, $T_{\text{obs}} = -1.3$, which actually shows a slight preference for oscillations over the no-oscillation but flux-free hypothesis. Again the main driver for this are spectral distortions, which can be fit better by oscillations than by re-scaling fluxes.

3.2 Global $\bar{\nu}_e$ disappearance analysis

We proceed now to combining reactor data with all other data on $\bar{\nu}_e$ disappearance listed in table 1. In fitting these data we scan the following set of parameters (see eq. (2.2) for

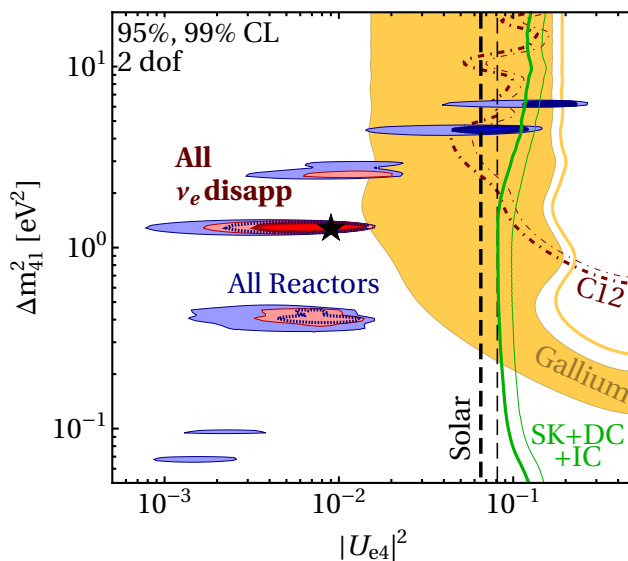

Figure 3. Constraints on $\nu_e/\bar{\nu}_e$ disappearance in the 3 + 1 scenario. We show the preferred parameter regions at 95% and 99% CL, projected onto the plane spanned by the mixing matrix element $|U_{e4}|^2$ and the mass squared difference Δm_{41}^2 . The parameter space inside the shaded areas and to the left of the exclusion curves is allowed. For the reactor analysis we adopt the conservative assumption of free flux normalizations. The red region includes all data listed in table 1. The green curves show the limit on $|U_{e4}|^2$ obtained from atmospheric neutrino data from SuperK, IceCube and DeepCore, discussed in section 5.

our mixing matrix convention):

$$\Delta m_{31}^2, \quad \Delta m_{41}^2, \quad \theta_{12}, \quad \theta_{14}, \quad \theta_{24}, \quad \theta_{34}. \quad (3.2)$$

We fix θ_{13} here since it is determined very accurately, and we have checked that its best fit value does not depend on the possible existence of sterile neutrinos [14]. The dependence on θ_{24} and θ_{34} appears due to solar neutrino data, which in addition to the ν_e survival probability includes also NC data sensitive to $\nu_e \rightarrow \nu_s$ transitions.² The results are shown in the last two rows of table 2 and in figure 3. We observe that the best fit point remains stable at $\Delta m_{41}^2 \approx 1.3 \text{ eV}^2$, in agreement with the reactor-only analysis.

From figure 3 we observe a slight tension between the global best fit point and the region favoured by the gallium anomaly. We have used the parameter goodness-of-fit (PG) test [92] to quantify the compatibility of the gallium anomaly with reactor data. We obtain for the PG test-statistic (see appendix A for a review) $\chi_{\text{PG}}^2 = 4.7$, irrespective of whether reactor fluxes are fixed or free. For 2 dof, this translates into a p -value of about 9% for the compatibility of reactors and gallium. From figure 3 we see, however, that the combined best fit point of reactor and gallium data lies in the island around $\Delta m_{41}^2 \approx 4.5 \text{ eV}^2$, which is disfavoured by solar neutrinos as well as neutrino scattering on ^{12}C . For the global best

²Formally solar neutrino data depend also on complex phases [14]. In our numerical scan we do take this effect into account. However, we have checked that the dependence is marginal and therefore we do not include phases in the counting of full degrees of freedom.

fit point around $\Delta m_{41}^2 \approx 1.3 \text{ eV}^2$, the PG test comparing reactor and gallium data gives $\chi_{\text{PG}}^2 = 6.9$ (7.2) for fixed fluxes (free fluxes). This corresponds to a p -value of 3.1% (2.8%), indicating some minor tension between these data sets. Despite this tension, table 2 shows that the significance of rejecting no-oscillations of the combined fit increases by about two units in $\Delta\chi^2$ compared to the reactor-only analysis, both for the flux-free and flux-fixed analyses.

In figure 3 we show also the bound on $|U_{e4}|^2$ obtained from the atmospheric neutrino experiments SuperKamiokande (SK), IceCube (IC), and DeepCore (DC), see section 5 for more details. We observe that this bound is comparable to the one from solar neutrino data. The effect of sterile neutrinos on low-energy atmospheric data as relevant for SK and DC has been discussed in the appendix of ref. [93]. It amounts mostly to a normalization effect of the electron and muon neutrino survival probability according to $P_{\alpha\alpha} \propto (1 - 2|U_{\alpha 4}|^2)$ with $\alpha = e, \mu$. In our SK/DC analyses we assume a 20% correlated normalization error on e and μ -like events, and a 5% error on the ratio of them. Therefore, we can expect a 1σ bound of order 0.1 on $|U_{\alpha 4}|^2$ from those data alone. If either $|U_{e4}|^2$ or $|U_{\mu 4}|^2$ is independently constrained from any other data, the bound on the other one from SK/DC becomes significantly stronger, due to the correlated uncertainty. Since the high-energy data relevant for IC provide such an independent constraint on $|U_{\mu 4}|^2$ due to the resonant matter effect (see section 5), the combined bound improves and we get $|U_{e4}|^2 \lesssim 0.1$ at 99% CL (2 dof). Note that we do not include atmospheric data in the global $\bar{\nu}_e$ disappearance analysis presented in this section, since in this work we classify atmospheric neutrino experiments as $\bar{\nu}_\mu$ disappearance to be discussed below.

We conclude that global $\bar{\nu}_e$ disappearance data show a robust hint in favour of sterile neutrinos at the 3σ level, independent of reactor flux predictions. If reactor flux predictions (including their uncertainties) are assumed to be correct, the significance reaches 3.8σ .

4 $\bar{\nu}_\mu \rightarrow \bar{\nu}_e$ oscillations at short baseline

The appearance channel $\bar{\nu}_\mu \rightarrow \bar{\nu}_e$ was the first oscillation channel to reveal possible hints for sterile neutrinos, namely in the LSND experiment [1]. This hint, which to date remains the oscillation anomaly with the largest statistical significance, was later reinforced at lower significance by MiniBooNE [2]. Other experiments, in particular KARMEN [94], NOMAD [95], E776 [96], ICARUS [41, 97], and OPERA [40], have not been able to confirm the findings by LSND and MiniBooNE, albeit not ruling them out either. We summarize the data sets included in our analysis of ν_e and $\bar{\nu}_e$ appearance data in table 3.

Compared to our previous publication, ref. [14], in which more technical details on our fits are given, we have added the following data sets:

1. New results from the ICARUS [41, 97] and OPERA [40] experiments in the high energy ($\sim 20 \text{ GeV}$) CNGS beam. Both experiments have searched for anomalous $\nu_\mu \rightarrow \nu_e$ appearance, but have not found any evidence. They are thus able to impose constraints over a wide range of Δm_{41}^2 values.

Experiment	References	Comments	Data points
LSND	[1]	$\bar{\nu}_\mu$ from stopped pion source (DaR)	11
LSND	[1]	combined DaR and DiF data ($\bar{\nu}_\mu \rightarrow \bar{\nu}_e$)	N/A
MiniBooNE	[2, 98]	ν_μ and $\bar{\nu}_\mu$ from high-energy Fermilab beam	22
KARMEN	[94]	$\bar{\nu}_\mu$ from stopped pion source	9
NOMAD	[95]	ν_μ from high-energy CERN beam	1
E776	[96]	ν_μ from high-energy Brookhaven beam	24
ICARUS	[41, 97]	ν_μ from high-energy CERN beam	1
OPERA	[40]	ν_μ from high-energy CERN beam	1

Table 3. Experimental data sets included in our $\bar{\nu}_\mu \rightarrow \bar{\nu}_e$ analysis. For LSND, we have carried out analyses using only decay-at-rest (DaR) data, or the combination with decay-in-flight (DiF) data. In the latter case we use a χ^2 table provided by the collaboration, which cannot be associated with a number of data points. The total number of data points in the appearance channel (when using LSND DaR data only) is 69.

2. Decay-in-flight data from LSND. The neutrino oscillation analysis of LSND is based on a search for anomalous $\bar{\nu}_e$ appearance in the neutrino flux from a stopped pion source. Since the LSND detector was placed downstream from the pion production target, it received not only ν_μ , $\bar{\nu}_\mu$, and ν_e from π^+ decays at rest (DaR), but also neutrinos and anti-neutrinos from pions decaying in flight (DiF). A discussion of the impact of DiF data in the context of the global sterile neutrino fit can be found in ref. [99]. The LSND collaboration has kindly provided tabulated χ^2 values from their combined DaR+DiF fit. The LSND fit is based on the two-flavour approximation, so to include the tabulated χ^2 values in our 4-flavour analysis, we compute at each parameter point the effective two-flavour mixing angle

$$\sin^2 2\theta_{\mu e} \equiv 4|U_{e4}|^2|U_{\mu 4}|^2 \quad (4.1)$$

from the full four-flavour mixing matrix U . In the following, we will show results using both our previous fitting code that includes only DaR data as well as results based on the tabulated two-flavour χ^2 values from LSND for DaR+DiF data.

Our results are plotted in figure 4, which shows the favoured parameter regions projected onto the $\sin^2 2\theta_{\mu e} - \Delta m_{41}^2$ plane. We see that all $\bar{\nu}_\mu \rightarrow \bar{\nu}_e$ data sets are consistent among each other: a large chunk of the parameter region favoured by LSND and MiniBooNE is not probed by any of the other searches. The strongest constraints come from OPERA at $\Delta m_{41}^2 \lesssim 0.5 \text{ eV}^2$, and from KARMEN at larger Δm_{41}^2 . Note that data from E776 is combined with solar neutrino data because a fit to E776 data alone would not be meaningful as it would leave possible oscillations of the ν_e and $\bar{\nu}_e$ backgrounds into sterile states unconstrained. Fitting E776 data jointly with solar neutrino data provides a reasonable constraint on $|U_{e4}|$, cf. figure 3.

The conclusions drawn from figure 4 agree qualitatively with the ones from our earlier paper ref. [14]. Some constraints, in particular those from OPERA and ICARUS, have

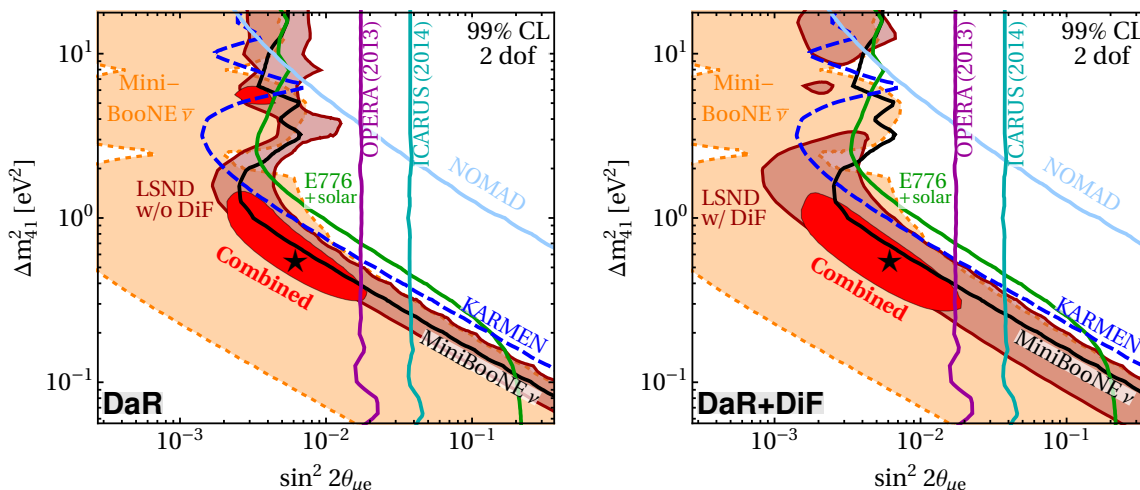

Figure 4. Constraints on short-baseline $\nu_\mu \rightarrow \nu_e$ and $\bar{\nu}_\mu \rightarrow \bar{\nu}_e$ oscillations in the presence of sterile neutrinos in $3 + 1$ scenarios. We show the allowed parameter regions, projected onto the plane spanned by the effective mixing angle $\sin^2 2\theta_{\mu e} \equiv 4|U_{e4}|^2|U_{\mu 4}|^2$ and the mass squared difference Δm_{41}^2 . In the left panel only decay-at-rest (DaR) data from LSND is included, while in the right panel also decay-in-flight data (DiF) is used.

become significantly stronger and now disfavour values of $\sin^2 2\theta_{\mu e} \gtrsim 0.02$ that were still allowed previously. Note that our OPERA and ICARUS limits deviate slightly from those published by the respective collaborations [40, 41, 97] because we include oscillations of the backgrounds. Moreover, for consistency with the other exclusion curves in figure 4, we interpret the χ^2 values from our OPERA and ICARUS fits assuming two degrees of freedom. We have checked that our code reproduces the official limits from refs. [40, 41, 97] very well when the same assumptions as in the official publications are used.

Let us mention that the global $\bar{\nu}_\mu \rightarrow \bar{\nu}_e$ analysis has a relatively poor goodness of fit. For the combined best fit point using the LSND DaR analysis we find $\chi_{\min}^2/\text{dof} = 89.9/(69-2)$, which corresponds to a p -value of 3.3%. This is mostly driven by the Mini-BooNE low-energy excess, which cannot be fitted well in the $3 + 1$ scenario, and by the contribution from E776 whose spectrum gives a relatively poor fit. This feature has been present also in our previous analysis [14], where a more detailed discussion can be found.

In all cases LSND dominates the appearance fit. LSND alone disfavors the no-oscillation hypothesis with $\Delta\chi^2 = 44$ (29) when using DaR (DaR+DiF) data. For the combined appearance analysis these numbers increase slightly, due to the hint for appearance in MiniBooNE data. We find that the no-oscillation hypothesis for all appearance data is disfavoured compared to the best fit by $\Delta\chi^2 = 46$ (35) when using LSND DaR (DaR+DiF) data.

Comparing the allowed regions with and without the inclusion of decay-in-flight data in LSND, we see that the impact on the global fit is relatively minor. This is because although the LSND region with DiF data extends to slightly smaller values of $\sin^2 2\theta_{\mu e}$, MiniBooNE appearance data prefers smaller Δm_{41}^2 and mixing angles (especially for the neutrino mode data), somewhat limiting the impact of LSND DiF data when LSND and

MiniBooNE data are combined. We observe only a slight broadening of the parameter regions preferred by LSND and by the combination of all $\nu_\mu \rightarrow \nu_e$ and $\bar{\nu}_\mu \rightarrow \bar{\nu}_e$ appearance data. We will see in section 7 that this slightly reduces the tension between appearance and disappearance data, but does not remove it.

5 $\bar{\nu}_\mu$ disappearance data

Searches for muon neutrino disappearance due to oscillations involving a fourth neutrino mass state have recently received a significant boost thanks to novel results on sterile neutrinos from atmospheric neutrino data (both in the TeV energy window from IceCube [52] and at lower energy from DeepCore [49]) as well as from a combined analysis of MINOS and MINOS+ charged current (CC) and neutral current (NC) data [43]. Also NO ν A has presented a first search for sterile neutrinos based on NC data [44]. Searches for a deficit of NC events are of particular interest because they are sensitive to mixing of sterile neutrinos with *any* active neutrino flavor. As such, any deficit found would be a unique signature of sterile neutrinos. The new analyses by IceCube, DeepCore, MINOS/MINOS+, and NO ν A complement, and significantly extend, the exclusion regions from the short-baseline experiments CDHS [100] and MiniBooNE [101, 102], from Super-Kamiokande data on atmospheric neutrinos [48, 103], and from MINOS [104].

The high-energy IceCube analysis from ref. [52] exploits the fact that active-to-sterile neutrino oscillations in matter are resonantly enhanced by the MSW effect [55, 56] at an energy of

$$E_{\text{res}} = 5.3 \text{ TeV} \times \left(\frac{5 \text{ g/cm}^3}{\rho_\oplus} \right) \left(\frac{\Delta m_{41}^2}{1 \text{ eV}^2} \right). \quad (5.1)$$

Here ρ_\oplus is the mass density of the material through which neutrinos are propagating. It is on average $\sim 3 \text{ g/cm}^3$ in the Earth's crust and outer mantle, $\sim 5 \text{ g/cm}^3$ in the inner mantle, and between 10 and 13 g/cm^3 in the core [105]. Equation (5.1) implies that, for sterile neutrinos at the eV-scale, neutrino telescopes like IceCube can in principle observe maximal oscillations at TeV energies — a sweet spot well above the detection threshold, but still low enough for the atmospheric neutrino flux to be appreciable [57, 58]. For larger or smaller Δm_{41}^2 , the sensitivity is expected to dwindle as the resonance moves to energies with a lower neutrino flux, or moves below the energy threshold of the detector. A limiting factor to this analysis is the fact that, for $\Delta m_{41}^2 > 0$ as considered here, the resonance is in the anti-neutrino sector. Since neutrino telescopes cannot distinguish neutrinos from anti-neutrinos on an event-by-event basis, and since anti-neutrino cross-sections are smaller by about a factor of three than neutrino cross-sections, the magnitude of the observable effect is reduced.³ Moreover, for small mixing angles, the resonance width,

$$\Delta E_{\text{res}} \sim \frac{\Delta m_{41}^2 \sin^2 2\theta_{24}}{2V_{\text{MSW}}}, \quad (5.2)$$

³For $\Delta m_{41}^2 < 0$ the resonance would occur for neutrinos and the signal would therefore be stronger. However, such scenarios are in strong tension with cosmology.

is small, so that only a very small fraction of the energy spectrum is affected. The narrow width, combined with the limited experimental energy resolution, further reduces the sensitivity of IceCube. In eq. (5.2), $V_{\text{MSW}} \simeq 1.9 \times 10^{-14} \text{ eV} \times [\rho_{\oplus}/(\text{g}/\text{cm}^3)]$ is the neutral current-induced MSW potential for muon and tau neutrinos. Finally, systematic uncertainties play a crucial role in the analysis from ref. [52]. Technical details on our implementation of the IceCube analysis are given in appendix B.

In addition to the TeV neutrino events discussed above, the IceCube collaboration has also observed atmospheric neutrinos in the tens-of-GeV range through its sub-detector DeepCore. The information on sterile neutrinos which can be extracted from this low-energy sample is very similar to that provided by Super-Kamiokande atmospheric data, which has been discussed in detail in refs. [14, 93]. As explained there, low-energy atmospheric neutrino data can put a strong bound on $|U_{\mu 4}|^2$ through the suppression of the $P_{\mu\mu}$ oscillation probability which a mixing of ν_{μ} with a heavy state would imply. Moreover, such data also constrains $|U_{\tau 4}|^2$ because the zenith-angle dependence of $P_{\mu\mu}$ is modified if oscillations driven by Δm_{31}^2 deviate from vacuum-like $\nu_{\mu} \rightarrow \nu_{\tau}$ oscillations. The formalism for neutrino oscillations discussed in appendix D of ref. [14] for Super-Kamiokande phase 1–3 data is also applied here to phase 4 results as well as to DeepCore data.

The MINOS detector is particularly interesting for sterile neutrino searches as it has observed neutrino oscillations over a fairly wide range of energies: during the original MINOS run, the NuMI beam was tuned to a peak energy of $\sim 2 \text{ GeV}$, while in the MINOS+ phase, the peak energy was at about 6 GeV , with the spectrum extending to tens of GeV. Moreover, the MINOS collaboration has analysed not only CC ν_{μ} disappearance sensitive mainly to $U_{\mu 4}$, but has also searched for disappearance in NC events. Since MINOS/MINOS+ has near and far detectors, the experiment is sensitive over a wide range of Δm_{41}^2 values. For $\Delta m_{41}^2 \sim 10^{-3} - 10^{-1} \text{ eV}^2$, an oscillation pattern can be observed in the far detector, while no oscillations are expected in the near detector. At larger mass squared difference, oscillations in the far detector enter the averaging regime. At $\Delta m_{41}^2 \sim 1 - 100 \text{ eV}^2$, oscillation patterns begin to emerge in the near detector. In our analysis of MINOS/MINOS+ data, we follow very closely the recommendations accompanying the MINOS/MINOS+ data release [43].⁴

We have also implemented the NO ν A neutral current analysis from ref. [44]. Due to the low number of events and the difficult reconstruction of the neutrino energy in NC events, only total rates are used in the analysis. The dominant background in this analysis are misidentified charged current events. Following ref. [44], we implement a 12.2% (15.3%) systematic uncertainty on the signal (background) rates. Compared to the MINOS/MINOS+ NC search, the narrow-band beam employed in NO ν A means that

⁴The validity of the MINOS/MINOS+ analysis from ref. [43] has been called into question in ref. [106] based on the fact that the limit on $U_{\mu 4}$ is surprisingly strong at large Δm_{41}^2 , while on the other hand a per cent level deviation from unity in the far/near ratio of NC events indicates non-negligible systematic bias. We have checked that a more conservative MINOS/MINOS+ fit with a completely free flux normalization would indeed significantly deteriorate the limit at large Δm_{41}^2 . However, we have also checked that the impact of a free normalization would be very small at Δm_{41}^2 in the region relevant to the global fit. We will also show in section 7 that even removing MINOS/MINOS+ completely from our fit would not change our conclusions. Therefore, all results presented below will be based on the official MINOS/MINOS+ fit from the data release accompanying ref. [43].

the experiment is sensitive to a much smaller range of Δm_{41}^2 values, namely between 0.05 eV^2 and 0.5 eV^2 . Even in this mass range, the NO ν A search for sterile neutrinos is not competitive with other searches yet as it suffers from large systematic uncertainties related to detector modelling and energy reconstruction, but it is expected to improve considerably in the future.

We summarize the $\nu_\mu/\bar{\nu}_\mu$ disappearance data sets included in our analysis in table 4. Details on the CDHS and MiniBooNE analyses are given in ref. [14] and in the references therein. Our results are shown in figure 5 as a function of the mixing matrix element $|U_{\mu 4}|^2$ and the mass squared difference Δm_{41}^2 . The plot reveals strong limits of order $|U_{\mu 4}|^2 \lesssim 10^{-2}$ across a wide range of Δm_{41}^2 values from $\sim 2 \times 10^{-1} \text{ eV}^2$ to $\sim 10 \text{ eV}^2$. MINOS/MINOS+ gives an important contribution in most of the parameter space. The strong constraint from atmospheric neutrino data at $\Delta m_{41}^2 \lesssim 1 \text{ eV}^2$ is dominated by IceCube. At large masses, MiniBooNE and to some extent CDHS are competitive with the MINOS/MINOS+ bound. Comparing to the parameter region preferred by appearance and $\nu_e/\bar{\nu}_e$ disappearance data (which includes the oscillation anomalies), we see dramatic tension. Given the constraints on U_{e4} from reactor experiments, the values of $\sin^2 2\theta_{\mu e} \equiv 4|U_{e4}|^2|U_{\mu 4}|^2$ required by LSND and MiniBooNE can only be reached if $|U_{\mu 4}|$ is large. This, however, is clearly disfavoured by multiple $\nu_\mu/\bar{\nu}_\mu$ disappearance null results. This is the origin of the severe tension in the global fit we are going to report below. As we are going to discuss, this tension has become very robust and does not rely on any single $\bar{\nu}_\mu$ disappearance data set.

6 Constraints on $|U_{\tau 4}|$

Mixing between tau neutrinos and possible sterile states is particularly difficult to constrain since no ν_τ sources are available. Nevertheless, constraints can be obtained in the following two ways: (i) studying matter effects. All active neutrino flavors experience an MSW potential caused by coherent forward scattering through Z boson exchange, while sterile neutrinos do not. This influences ν_e disappearance observed in solar neutrino experiments, as well as ν_μ disappearance observed in beam experiments and in atmospheric neutrinos. The latter yield particularly strong limits as they possess the longest baselines in matter. (ii) exploiting neutral current events, which are sensitive to *any* disappearance of active

Figure 5. Constraints on the 3 + 1 scenario from $\nu_\mu/\bar{\nu}_\mu$ disappearance. We show the allowed parameter regions, projected onto the plane spanned by the mixing matrix element $|U_{\mu 4}|^2$ and the mass squared difference Δm_{41}^2 . Note that the exclusion limit from $\text{NO}\nu\text{A}$ is still too weak to appear in the plot. It is, however, included in the curve labelled “combined”, which includes all data listed in table 4. The curve labelled DC+SK+IC combines all our atmospheric neutrino data; for this bound we have fixed the parameters $\theta_{12}, \theta_{13}, \theta_{14}$ but minimize with respect to all other mixing parameters, including complex phases. For comparison, we also show the parameter region favoured by ν_e disappearance and $\nu_\mu \rightarrow \nu_e$ appearance data (using LSND DaR+DiF), projected onto the $|U_{\mu 4}|^2 - \Delta m_{41}^2$ plane; we show the allowed regions for the analyses with fixed and free reactor neutrino fluxes.

neutrinos. This approach allows us to derive constraints from the sterile neutrino searches in MINOS/MINOS+ [43] and $\text{NO}\nu\text{A}$ [44], and from SNO solar neutrino data [79–81]. The corresponding analysis codes used in our fit are the same as discussed in sections 3 and 5. Compared to ref. [14], we have in particular added IceCube, DeepCore, MINOS/MINOS+, and $\text{NO}\nu\text{A}$ data to the fit.

Our results are shown in the four panels of figure 6. Each panel corresponds to a different fixed value of Δm_{41}^2 , and the corresponding contours have been drawn based on the χ^2 differences relative to the best fit point for this fixed Δm_{41}^2 . The difference in χ^2 between the individual best fit points and the global one are, however, very small, as indicated in each panel. The reason is that in all cases the best fit point is very close to zero mixing, and therefore has very similar χ^2 values. In defining the exclusion contours we have assumed a χ^2 distribution with two degrees of freedom. We see that depending on Δm_{41}^2 , the limit on $|U_{\mu 4}|$ is driven by MINOS/MINOS+, IceCube, or the short-baseline experiments MiniBooNE and CDHS, in agreement with figure 5. The strongest constraints on $|U_{\tau 4}|$ typically come from atmospheric neutrinos. We find that the combined bound is independent of Δm_{41}^2 and is given by

$$|U_{\tau 4}|^2 < 0.13 \text{ (0.17)} \quad \text{at} \quad 90\% \text{ (99\%) CL.} \quad (6.1)$$

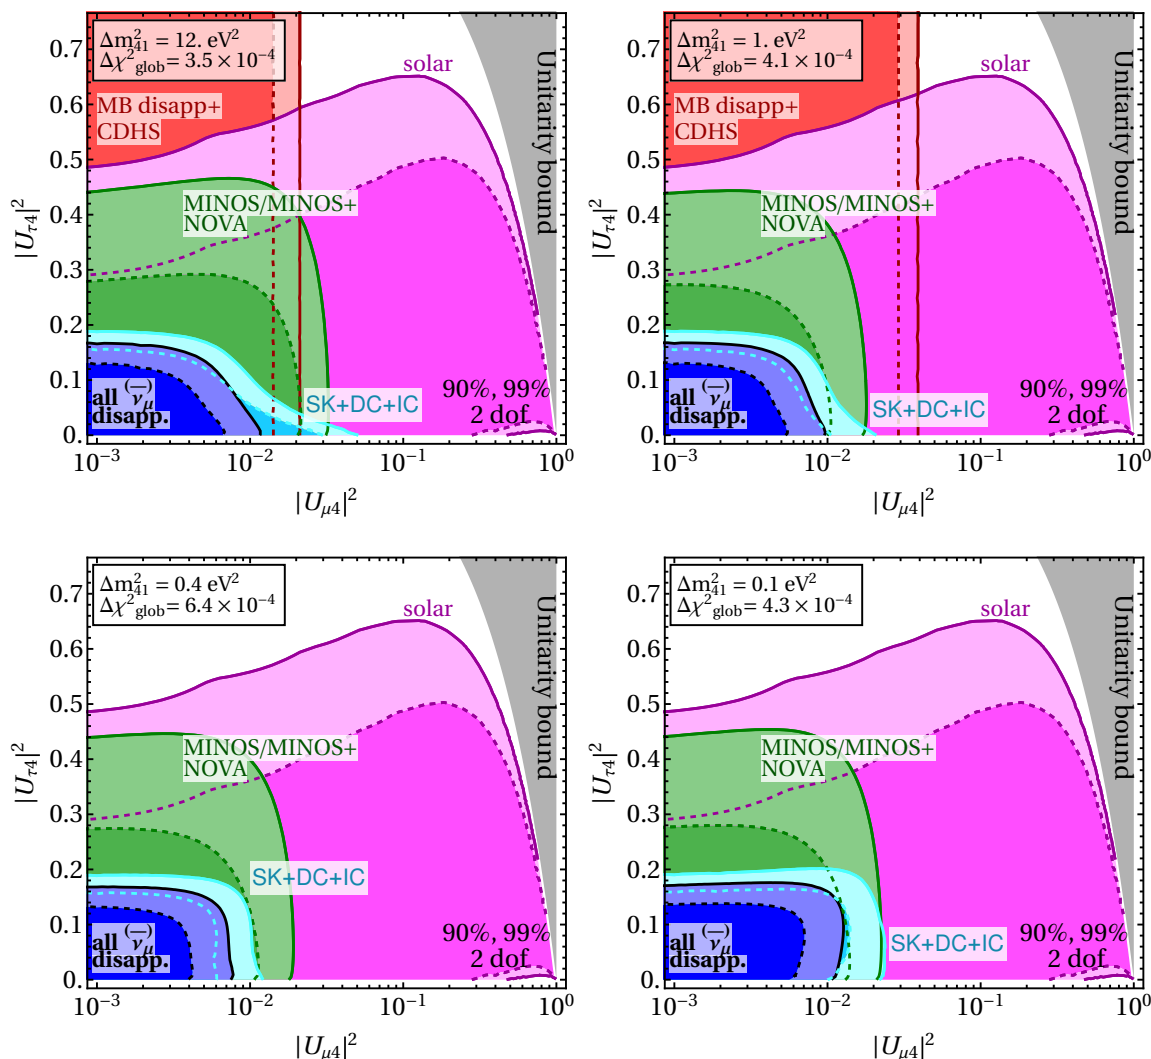

Figure 6. Constraints on the mixing of sterile neutrinos with muon and tau neutrinos, parameterized by the corresponding elements $|U_{\mu 4}|$ and $|U_{\tau 4}|$ of the leptonic mixing matrix. In each panel, Δm_{41}^2 has been fixed to a different value, while Δm_{31}^2 , θ_{23} , θ_{12} and θ_{14} , as well as complex phases have been profiled out in those experiments where they have a significant impact. Exclusion contours are drawn relative to the minimum χ^2 in each panel; the difference to the global minimum χ^2 is indicated in each plot. Grayed out areas show the parameter region incompatible with the unitarity of the leptonic mixing matrix.

Let us mention that recently ref. [108] has found a 2σ hint from Ice Cube data in favour of sterile neutrinos with non-zero ν_4 - ν_τ mixing in the high-mass region, with $\Delta m_{41}^2 \simeq 100 \text{ eV}^2$. With our code we cannot reproduce their results and we do not find any hint for sterile neutrino mixing in that mass range. The origin of these different results is currently under investigation.

Data set	Reference	Data points	Relevant parameters
$\bar{\nu}_e$ disappearance	Table 1	594	$\Delta m_{31}^2, \Delta m_{41}^2, \theta_{12}, \theta_{14}, \theta_{24}, \theta_{34}$
$\bar{\nu}_\mu$ disappearance	Table 4	504	$\Delta m_{31}^2, \Delta m_{41}^2, \theta_{23}, \theta_{14}, \theta_{24}, \theta_{34}$
$\bar{\nu}_\mu \rightarrow \bar{\nu}_e$ appearance (w/o LSND DiF)	Table 3	69	$\Delta m_{41}^2, U_{e4}U_{\mu4} $
Total number of data points:		1167	

Table 5. Number of degrees of freedom and parameters relevant to the counting of degrees of freedom for each data set. More details on the individual experiments are given in the corresponding tables. The number of degrees of freedom for the LSND decay-in-flight analysis is not available. Thus, in the sum of degrees of freedoms for appearance and all data sets, we used the LSND decay-at-rest number. See text for details and comments on additional nuisance parameters.

7 The disappearance-appearance tension

As discussed above, results on the $\nu_e \rightarrow \nu_e, \nu_\mu \rightarrow \nu_e,$ and $\nu_\mu \rightarrow \nu_\mu$ oscillation channels (and the corresponding anti-neutrino modes) over-constrain eV-scale sterile neutrino models. The reason can be easily understood by going to the short-baseline limit in which baselines are so short that oscillations induced by Δm_{31}^2 and Δm_{21}^2 did not yet develop. In this limit, eqs. (2.3) and (2.4) show that the bounds on $|U_{e4}|$ and $|U_{\mu4}|$ from electron and muon disappearance data lead to a quadratic suppression of the effective amplitude $\sin^2 2\theta_{e\mu}$, eq. (4.1), relevant for $\nu_\mu \rightarrow \nu_e$ appearance [109–111]. Thus constraints from disappearance data challenge an explanation of the anomalies in the appearance channel in terms of sterile neutrino oscillations. While this tension has persisted for a very long time, see for instance ref. [99], it has become exceedingly severe with recent data, rendering the sterile neutrino hypothesis as an explanation for the appearance anomalies very unlikely, see below.

The results of the combined fit are summarized in table 6, which shows the results for $\bar{\nu}_e$ disappearance, $\bar{\nu}_\mu$ disappearance, and $\bar{\nu}_e$ appearance data separately as well as combined. The total numbers of data points in these analyses are summarized in table 5. The last column of that table also indicates which parameters need to be considered when counting degrees of freedom. For the $\bar{\nu}_\mu$ disappearance data we do take into account complex phases in the fit [14], but since numerically their effect is very small we do not count them as full dof. We do, however, treat the normalization of the atmospheric neutrino flux as a free parameter in the IceCube analysis. Concerning the appearance sample, for most of the data summarized in table 3 the short-baseline approximation holds, motivating the use of only the effective mixing angle quoted in table 5. Exceptions are the long-baseline experiments ICARUS and OPERA, which depend on more parameters, but play a role neither for the appearance best fit point nor for the global best fit point. Therefore, we consider only two effective parameters for the appearance sample. For the global analysis we count seven parameters plus the IceCube global normalization. The reactor analysis with free fluxes has two additional free parameters.

We would now like to quantify the tension between different subsets of the global data that is evident from figure 5. We first note that combining all data sets we find a goodness-of-fit for the global best fit point around 65%, see table 6. This good p -value does not

Analysis	Δm_{41}^2 [eV ²]	$ U_{e4} $	$ U_{\mu 4} $	χ_{\min}^2/dof	GOF	χ_{PG}^2	PG
appearance (DaR)	0.573	$4 U_{e4} ^2 U_{\mu 4} ^2 = 6.97 \times 10^{-3}$		89.8/67	3.3%		
appearance (DiF)	0.559	$4 U_{e4} ^2 U_{\mu 4} ^2 = 6.31 \times 10^{-3}$		79.1/—			
$\bar{\nu}_\mu$ disapp	2×10^{-3}	0.12	0.039	468.9/497	81%		
Reactor fluxes fixed at predicted value \pm quoted uncertainties							
$\bar{\nu}_e$ disapp	1.3	0.1	—	552.8/588	85%		
Global (DiF)	6.03	0.2	0.1	1127/—		25.7	2.6×10^{-6}
Global (DaR)	5.99	0.21	0.12	1141/1159	64%	28.9	5.3×10^{-7}
Reactor fluxes floating freely							
$\bar{\nu}_e$ disapp	1.3	0.095	—	542.9/586	90%		
Global (DiF)	6.1	0.20	0.10	1121/—		29.6	3.7×10^{-7}
Global (DaR)	6.0	0.22	0.11	1134/1157	68%	32.1	1.1×10^{-7}

Table 6. Parameter values at the global best fit point and at the best fit points obtained for subsets of the data. We also indicate the χ^2 per degree of freedom at the best fit points, as well as the corresponding goodness-of-fit values. The numbers of data points, and the parameters relevant to the counting of degrees of freedom are summarized in table 5. For the global fit, we also indicate the results of the parameter goodness-of-fit test [92] comparing appearance to disappearance data. The labels “DaR” and “DiF” refer to the LSND analysis employed, where “DiF” implies the joint use of DaR+DiF data, see section 4. Note that, as the number of degrees of freedom for the LSND DiF data is not available, we do not list the corresponding goodness of fit values.

reflect the tension we found because many data points entering the global fit have only little sensitivity to sterile neutrino oscillations, thus diluting the power of a goodness-of-fit test based on χ^2/dof .

A more reliable method for quantifying the compatibility of different data sets is the parameter goodness-of-fit (PG) test [92], which measures the penalty in χ^2 that one has to pay for combining data sets, see appendix A for a brief review of this test. If the global neutrino oscillation data were consistent when interpreted in the framework of a 3 + 1 model, *any* slicing into two statistically independent data sets A and B should result in an acceptable p -value from the PG test. To illustrate an inconsistency in the data, it is however sufficient to demonstrate that at least one way of dividing it leads to a poor value. Here, we choose to split the data into disappearance data encompassing the oscillation channels $\bar{\nu}_e \rightarrow \bar{\nu}_e$ and $\bar{\nu}_\mu \rightarrow \bar{\nu}_\mu$, and appearance data covering the $\bar{\nu}_\mu \rightarrow \bar{\nu}_e$ channel. Note that it is important to chose data sets independent of their “result”. For instance, dividing data into “evidence” and “no-evidence” samples would bias the PG test.

The tension between appearance and disappearance data is shown graphically in figure 7. The figure illustrates the lack of overlap between the parameter region favoured by appearance data (driven by LSND and MiniBooNE) and the strong exclusion limits from disappearance data. The tension persists independently of whether reactor fluxes are fixed or kept free, and whether the LSND DaR or DaR+DiF samples are used. The corresponding results from the PG test are shown in the last two columns of table 6. To evaluate the p -value of the PG test statistic we use two degrees of freedom, corresponding to the two parameters in common to appearance and disappearance data, see table 5 and the related

Figure 7. Appearance versus disappearance data in the plane spanned by the effective mixing angle $\sin^2 2\theta_{\mu e} \equiv 4|U_{e4}U_{\mu 4}|^2$ and the mass squared difference Δm_{41}^2 . The blue curves show limits from the disappearance data sets using free reactor fluxes (solid) or fixed reactor fluxes (dashed), while the shaded contours are based on the appearance data sets using LSND DaR+DiF (red) and LSND DaR (pink hatched). All contours are at 99.73% CL for 2 dof.

discussion. We observe that for none of the analyses given in the table, the p -value for appearance and disappearance data being consistent exceeds 10^{-5} , with the “best” compatibility of $p = 2.6 \times 10^{-6}$ emerging for fixed reactor fluxes and using LSND DaR+DiF data. We conclude that the appearance/disappearance tension excludes a sterile neutrino oscillation explanation of the $\bar{\nu}_\mu \rightarrow \bar{\nu}_e$ anomalies at the 4.7σ level.

Note that the parameter goodness-of-fit for the analysis using free reactor fluxes is worse than the one for fixed reactor fluxes. The reason can be understood from the χ^2 numbers given in table 6. We see that the χ^2_{\min} of $\bar{\nu}_e$ disappearance decreases by more (9.9 units) than the global best fit point (7 or 6 units for DaR or DaR+DiF, respectively), when leaving reactor fluxes free. Therefore, reactor data alone benefits more from free fluxes than the appearance/disappearance tension, which increases the χ^2 penalty to pay for the combination in the case of free fluxes.

In table 7 we investigate the robustness of the appearance/disappearance tension. We show how the PG would improve if individual experiments or classes of experiments were removed from the fit. We stress that we are not aware of any strong reason to discard data from particular experiments. The sole purpose of this exercise is to demonstrate the impact of individual data sets and establish the robustness of our conclusion.

The first row in table 7 corresponds to the global analysis using free reactor fluxes and LSND DaR+DiF data, which is the combination of data we use throughout this table. The remaining part of the table shows that very strong tension remains even after removing any individual experiment. In particular, the PG remains below $\approx 5 \times 10^{-6}$ when any of the $\bar{\nu}_\mu$ disappearance data sets are removed, so it does not rely on the particular treatment of any of those experiments. Even when *all* reactor data are removed, the PG remains very small (3.8×10^{-5}).

Table 7. Results of the parameter goodness-of-fit (PG) test [92] comparing appearance to disappearance data. In this table we use the reactor flux-free analysis and LSND DaR+DiF data; therefore we do not quote dof for the χ^2 values. The first row corresponds to the global fit, while the other rows show the impact of removing individual experiments or sets of experiments from the fit. In columns 2–8, we list the χ^2 at the global best fit point ($\chi_{\min,\text{global}}^2$), the χ^2 at the appearance best fit ($\chi_{\min,\text{app}}^2$), the difference in χ_{app}^2 between the appearance best fit point and the global best fit point ($\Delta\chi_{\text{app}}^2$), the χ^2 at the disappearance best fit ($\chi_{\min,\text{disapp}}^2$), the difference in χ_{disapp}^2 between the disappearance best fit point and the global best fit point ($\Delta\chi_{\text{disapp}}^2$), the χ^2 per dof for the PG test ($\chi_{\text{PG}}^2/\text{dof}$, computed according to eq. (A.1)), and the resulting p -value given by eq. (A.3).

The only significant improvement is obtained when removing LSND. The still somewhat low PG of 0.16% is a manifestation of the tension between the MiniBooNE excess and the disappearance data. But it is clear that the very strong appearance/disappearance tension is driven by LSND. Note also that this remains true when MiniBooNE is removed, and therefore the result does not depend on the low-energy excess in MiniBooNE.

The only way to reconcile LSND would be to discard $\bar{\nu}_\mu$ disappearance data altogether. Note that even if we remove all $\bar{\nu}_e$ disappearance data, the PG remains low, at 2.4×10^{-4} . The reason is the non-trivial constraint on $|U_{e4}|$ from the data sample we call $\bar{\nu}_\mu$ disappearance (defined in table 4), see figure 3. Remarkably, just using $\bar{\nu}_\mu$ disappearance plus solar neutrinos pushes the PG already to 7.4×10^{-6} . This demonstrates once again that our conclusion is independent of reactor neutrino data.

We observe from table 7 that the PG gets nearly an order of magnitude worse when removing the gallium data. The reason is the slight tension between gallium and reactor data discussed in section 3.2. If gallium is removed, the $\bar{\nu}_e$ disappearance fit alone improves, and therefore the tension with appearance data increases.

Finally, we have also performed a slightly different PG test, by dividing the data into ν_μ disappearance versus the combined ν_e appearance and ν_e disappearance data. This

corresponds to the samples compared in figure 5. Using LSND DaR+DiF data and free reactor fluxes we obtain a $\chi_{\text{PG}}^2 = 23.4$. According to table 5, the common parameters in those two data sets are $\Delta m_{31}^2, \Delta m_{41}^2, \theta_{14}, \theta_{24}, \theta_{34}$. Therefore, χ_{PG}^2 has to be evaluated for 5 dof, leading to a p -value of 2.8×10^{-4} .

8 Discussion and conclusions

We have presented an updated global analysis of neutrino oscillation data within a $3 + 1$ sterile neutrino mass scheme. We have obtained two main results, which can be summarized as follows:

1. Reactor neutrino data show a $\gtrsim 3\sigma$ preference for sterile neutrino oscillations with $\Delta m_{41}^2 \approx 1.3 \text{ eV}^2$ and $|U_{e4}| \approx 0.1$. This is driven by recent data from DANSS and NEOS and is based only on the relative comparisons of measured energy spectra and is therefore independent of predictions for the reactor neutrino fluxes and spectra. If flux predictions are taken into account, the preference for sterile neutrino oscillations in global $\bar{\nu}_e$ disappearance data increases to 3.8σ .
2. Constraints on $\bar{\nu}_\mu$ disappearance have become exceedingly strong, due to recent data from MINOS/MINOS+ and IceCube. This leads to very strong tension between the anomalies in the appearance sector (LSND and MiniBooNE) and disappearance data. We find that appearance and disappearance data are incompatible, with a parameter goodness-of-fit test yielding a p -value of less than 2.6×10^{-6} . This result does not rely on any single experiment in the $\bar{\nu}_\mu$ sector and is robust with respect to theoretical predictions of reactor fluxes; the p -value remains at 3.8×10^{-5} even if all reactor data are removed. The tension is dominated by LSND; the MiniBooNE anomaly plays a subleading role.

Our results rule out the sterile neutrino oscillation hypothesis as an explanation of the LSND and MiniBooNE anomalies, but it remains a viable option for the reactor and gallium anomalies.

Some comments are in order. Our conclusion in item 1 above is largely based on preliminary data from DANSS presented at conferences [25, 26]. Our results are in agreement with another recent analysis done outside the DANSS collaboration [91]. However, those results will need to be supported by an official publication by the collaboration.

Throughout this work we have restricted ourselves to the $3 + 1$ scenario, adding just one mass state at the eV scale. However, we expect that the tension between appearance and disappearance data cannot be resolved by adding more sterile neutrinos. This has been quantitatively investigated previously, e.g. [14, 93]. There, it had been shown that adding more neutrinos does not relax the tension. The reason is that the quadratic suppression of the $\nu_\mu \rightarrow \nu_e$ oscillation amplitudes by constraints on the elements $|U_{ei}|$ and $|U_{\mu i}|$ ($i \geq 4$) from disappearance data remains equally true in scenarios with more than one eV-scale mass states. Therefore we expect that our conclusion concerning the sterile neutrino explanation of appearance anomalies remains qualitatively true also for more sterile neutrinos.

Finally, we remind the reader that a completely orthogonal set of constraints on eV-scale sterile neutrinos comes from cosmology. The standard picture is that active neutrinos evolve into a superposition of active and sterile states at temperatures \gtrsim MeV. Hard, flavour-sensitive collisions mediated by W and Z bosons collapse these superpositions into purely active or purely sterile states, with the relative probability given by the active-sterile mixing angles. After a large number of collisions, active and sterile neutrinos come into thermal equilibrium. Because of this, the vanilla $3 + 1$ model appears to be strongly disfavoured by constraints on the number of relativistic species N_{eff} at the time of Big Bang Nucleosynthesis (BBN) [112] and during the recombination epoch [113]. Moreover, constraints on the sum of neutrino masses, $\sum m_\nu$ from Cosmic Microwave Background and structure formation data disfavour extra neutrino species with masses $\gtrsim 0.3$ eV [113]. However, these constraints are model-dependent, and in non-minimal scenarios they can be weakened or absent. A full review of such scenarios is well beyond the scope of this work, therefore we only mention a few exemplary ones: in particular, mechanisms discussed in the literature include new interactions in the sterile sector [114–117], an extremely low reheating temperature [118], large neutrino-anti-neutrino asymmetries [119], late entropy production [120], and the presence of matter and antimatter domains during BBN [121]. It is also worth noting that the prevailing tension between local and cosmological determinations of the Hubble constant would be relaxed if N_{eff} is somewhat larger than in the SM [122].

Note added. After the completion of this work new short-baseline data appeared. The STEREO and PROSPECT collaborations announced first results from their search for reactor neutrino disappearance [123, 124]. While no hint for oscillations has been found, their limits are still too weak to constrain our preferred regions shown in figures 2 and 3 and therefore we expect that the results of our global reactor analysis remain qualitatively unchanged.

MiniBooNE has confirmed their hint for $\nu_\mu \rightarrow \nu_e$ appearance with a significant of 4.5σ [125]. This implies that the joint MiniBooNE/LSND significance for appearance becomes 6.1σ [125]. We have performed a preliminary analysis of the new MiniBooNE data and found that (a) the joint allowed region for appearance data shown in figure 4 is hardly affected by the new data, and (b) the PG values for the consistency of appearance and disappearance data given in table 6 remain very similar. The reason is that while the MiniBooNE results increase the significance of oscillations, the $\Delta\chi^2$ from appearance data of the global best fit point remains similar to the previous data set.

A The parameter goodness-of-fit test

In this appendix we briefly review the parameter goodness-of-fit (PG) test [92], which measures the compatibility of sub-sets of a data set. Let us subdivide the global data into two statistically independent sets A and B . Let $\chi_{\min,A}^2$ and $\chi_{\min,B}^2$ be the minimum χ^2 values obtained from individual fits to the two data sets, and let $\chi_{\min,\text{global}}^2$ be the χ^2 at the global best fit point obtained from a combined fit to all the data. The quantity

$$\chi_{\text{PG}}^2 \equiv \chi_{\min,\text{global}}^2 - \chi_{\min,A}^2 - \chi_{\min,B}^2 = \Delta\chi_A^2 + \Delta\chi_B^2 \quad (\text{A.1})$$

measures by how much the fit worsens when the two data sets are combined. This can be seen from the second equality in eq. (A.1), in which we have defined, for each subset of the data, the χ^2 difference $\Delta\chi_{A,B}^2$ between the individual best fit point and the global best fit point. If χ_A^2 and χ_B^2 depend on P_A and P_B parameters, respectively, and P is the total number of parameters of the model ($P_A, P_B \leq P$), then one can show [92] that χ_{PG}^2 follows a χ^2 distribution with

$$N_{\text{PG}} \equiv P_A + P_B - P \quad (\text{A.2})$$

degrees of freedom.⁵ We can thus compute a p -value measuring the compatibility of the data sets A and B according to

$$p = \int_{\chi_{\text{PG}}^2}^{\infty} dx f_{\chi^2}(x; N_{\text{PG}}), \quad (\text{A.3})$$

where $f_{\chi^2}(x; N_{\text{PG}})$ is the probability density function of the χ^2 distribution with N_{PG} degrees of freedom.

B Details of the IceCube fit

The event numbers measured by the IceCube detector have been provided in a grid with 210 bins [52, 53], which depends on the reconstructed muon energy E_μ (logarithmically spaced in 10 bins ranging from 400 GeV to 20 TeV) and the reconstructed muon direction (linearly spaced in 21 bins from $\cos\theta = -1.02$ to $\cos\theta = 0.24$). We make the assumption

⁵ N_{PG} counts the number of “joint” parameters of the data sets A and B . As an example, if A and B depend on exactly the same P parameters, then $P_A = P_B = N_{\text{PG}} = P$.

that the reconstructed muon direction is the same as the direction of the initial neutrino. The predicted number of events in bin number (ij) (where i indexes $\cos\theta$ and j indexes E_μ) is computed according to

$$N_{ij}^{d,f} = \int dE_\nu \left[\phi_+^{\text{atm},f}(E_\nu, \theta^i, N_0, \gamma, R_{\pi/K}) \bar{P}_{\mu\mu}^+(E_\nu, \theta^i) A_{\text{eff},+}^d(E_\nu, E_\mu^j, \theta^i) + R_\pm \phi_-^{\text{atm},f}(E_\nu, \theta^i, N_0, \gamma, R_{\pi/K}) \bar{P}_{\mu\mu}^-(E_\nu, \theta^i) A_{\text{eff},-}^d(E_\nu, E_\mu^j, \theta^i) \right]. \quad (\text{B.1})$$

Here, $\phi_\pm^{\text{atm},f}(E_\nu, \theta^i, N_0, \gamma, R_{\pi/K})$ is the atmospheric muon neutrino (+) or anti-neutrino (−) flux, which depends on the true neutrino energy E_ν , the neutrino direction θ^i , and on the nuisance parameters N_0 , γ , and $R_{\pi/K}$ discussed below. It also depends on the theoretical flux model, indicated by the subscript f . The effective area $A_{\text{eff},\pm}^d(E_\nu, E_\mu^j, \theta^i)$ in eq. (B.1) encodes the detector response to a ν_μ (+) or $\bar{\nu}_\mu$ (−) with energy E_ν and direction θ^i . The IceCube collaboration provides $A_{\text{eff},\pm}^d(E_\nu, E_\mu^j, \theta^i)$ in the form of a three-dimensional array in E_μ , $\cos\theta$ (same binning as for the data), and E_ν (200 bins logarithmically spaced between 200 GeV and 1 PeV) [52]. Separate arrays are provided for different assumptions on the Digital Optical Module (DOM) efficiency, indicated by the superscript d .

The muon neutrino and anti-neutrino survival probability $\bar{P}_{\mu\mu}^\pm$ is computed using GLoBES [126, 127], including a low-pass filter to suppress fast oscillation and to account for the limited energy resolution of the detector. For the production height of the neutrinos we interpolate linearly between 28 km for horizontal neutrinos and 18 km for vertical neutrinos [51]. To model the attenuation of the neutrino flux due to absorption in the Earth, we multiply the oscillation probability by an exponential damping factor given by

$$e^{-X(\theta) \sigma^\pm(E)(1-P_{\mu\mu}^\pm)}, \quad (\text{B.2})$$

where $X(\theta)$ is the column density along the neutrino trajectory and $\sigma^\pm(E)$ the inclusive absorption cross-section for neutrinos and antineutrinos, respectively. The factor $(1 - P_{\mu\mu}^\pm(E, L))$ accounts for the fact that only the active flavors interact with matter. This formula holds exactly only for an oscillation probability independent of the length of the trajectory. We make the assumption that in much of the parameter space the oscillations are either averaged out, or the oscillation length is so long that the probability is approximately constant along the trajectory. We have checked that our results do not depend significantly on this assumption.

In the published IceCube fit [52], systematic uncertainties are included either as discrete or as continuous nuisance parameters. The only discrete nuisance parameter in our analysis is the theoretical flux model. We found that out of the seven flux models considered by the IceCube collaboration, only two contribute significantly, namely the ones tagged “PolyGonato QGSJET-II-04” and “Honda-Gaisser”. We therefore restrict our analysis to these two discrete models. Hence the index f in eq. (B.1) runs from 1 to 2.

The continuous nuisance parameters can be divided into two classes: those related to the neutrino flux, and those related to the detector response and the optical properties of the ice. In our analysis we use the following atmospheric neutrino flux uncertainties:

- the normalization N_0 . Formally we assume a large uncertainty of 40% on the normalization, but results are very similar for completely free normalization. Therefore we consider N_0 to be effectively unconstrained.
- the tilt of the energy spectrum, which is parameterized by including a factor $(E/E_0)^\gamma$, with a 5% error on the power law index γ and a central value of $\gamma = 0$;
- the ratio between the pion and the kaon decay contributions to the flux, $R_{\pi/K}$, with an error of 10%;
- the ratio between the neutrino and the anti-neutrino fluxes, R_{\pm} , with an error of 2.5%.

Out of the uncertainties associated with the detector response and the ice properties, we only include the uncertainty on the DOM efficiency. As stated above, the tabulated effective area is provided for four different models for the DOM efficiency. We interpolate linearly between the per-bin-prediction for each DOM model and allow the minimizer to choose the optimal superposition of DOM models. Concerning the ice properties, we restricted ourselves to the nominal model because effective areas for each DOM efficiencies are only provided for the nominal ice model.

For each point in the parameter space a χ^2 value is calculated from the theoretical predictions and the experimental values by means of a log-likelihood function.

We have cross-check our IceCube fit with a second version of the analysis, which was developed completely independently. This analysis is not using the GLoBES software but is based on a dedicated probability code and it uses a partially different approach to systematics. The most noteworthy difference is the treatment of the discrete systematics. In our second implementation we restrict ourselves to only one flux model, the “Honda-Gaisser-model”. Several other discrete systematics associated with the detector response are treated as continuous quantities, and their effects on the number of events are assumed to be linear. In detail, in our second implementation we use:

- the DOM efficiency, where as nominal value we have used the table corresponding to 99% efficiency, and as 1σ deviation we have used the table corresponding to 95% efficiency;
- photon scattering in the ice, where the 1σ deviation is defined from the table corresponding to a 10% increase with respect to the nominal response;
- photon absorption in the ice, where the 1σ deviation is defined as a 10% increase in the absorption rate with respect to the nominal response;
- the azimuthal anisotropy in the scattering length due to the dust grain shear; here the 1σ deviation is obtained from the data set denoted ‘SPICELEA ice model’;
- the optical properties of the ice column surrounding each string, where the 1σ deviation is obtained from the data set labelled ‘SPICEMIE ice model’. This data set does not include hole ice effects.

Furthermore, in our second implementation, we average the oscillation probability over the altitude of the neutrino production point. The averaged probability is given by

$$\langle P_{\mu\mu}^{\pm}(E_{\nu}, \theta) \rangle = \int dh P_{\mu\mu}^{\pm}(E_{\nu}, \cos \theta, h) \kappa^{\pm}(E_{\nu}, \cos \theta, h), \quad (\text{B.3})$$

where $P_{\mu\mu}^{\pm}(E_{\nu}, \cos \theta, h)$ is the unaveraged oscillation probability for a neutrino produced at altitude h and $\kappa^{\pm}(E_{\nu}, \cos \theta, h)$ is the distribution of production altitudes, normalized to one [51].

We find good agreement between our two implementations, and between each of our implementations and the official IceCube results [52]. We therefore conclude that our IceCube analysis is robust.
