## Supplemental methods section

### Computational analysis of steroid metabolite excretion (supplementary material)

For computational steroid excretion data analysis, we employed a recently developed variant of Learning Vector Quantization (LVQ) [1], Generalized Matrix Relevance LVQ (GMLVQ) [2, 3]. For GMLVQ experiments, all numerical steroid excretion values were log-transformed and subsequently normalized by subtracting the respective mean values obtained in healthy controls with a similar age and sex distribution (n=88) and dividing by the corresponding standard deviations. This yielded 32 log-transformed steroid excretion values for each patient, expressed on a scale set by the control group. The vectors of log-transformed excretion values (rescaled with respect to the controls) labeled with the corresponding class membership, i.e. either ACC or ACA, served as input for the machine learning system.

For evaluation of the performance of the trained system, we split the ACC and ACA data into a training and test set, respectively, with 90% of the data from each class used in the training process to determine prototypes and relevance matrix. The remaining 10% served as a test set, which was used to quantify the true positive rate, i.e. the fraction of ACC test data classified correctly as ACC, and the false positive rate, i.e. the fraction of ACA test data misclassified by the system as ACC. In order to suppress the influence of possible *lucky* or *unlucky draws* of the test set on the performance of the system, we repeated the procedure for 1000 randomized training/test data set compositions. As an additional preprocessing step, we applied a z-score transformation in each training process, such that for all markers the mean of the transformed excretion over the training set was *zero* and the corresponding variance was *one*. We employed a single prototype per class. Initial values for the prototypes were determined from the class conditional means of a random selection of training data. The relevance matrix was initially set as the identity, i.e. all steroids equally important and pair-wise relevance being zero.

Subsequently, we obtained the full Receiver Operating Characteristics (ROC) of the classifier, generated by varying the threshold generalized distance margin separating the two classes, and computed the area under curve (AUC). The mean ROC and standard deviations were calculated using threshold averaging, as described in [4].

We have applied the GMLVQ machine learning analysis to the complete panel of 32 steroid markers. In addition, we studied the selection of discriminant features in GMLVQ: In each training run we determined the subsets of the most relevant three or nine steroids from the obtained relevance matrix. The GMLVQ training process was then repeated, restricting the system to the use of the individually selected subsets of steroids. The resulting mean ROC curves quantify the achievable classification performance when using reduced panels of three or nine steroids selected by GMLVQ.

For comparison, we also employed statistical modeling techniques, Fisher Linear Discriminant Analysis (LDA) and a standard implementation of logistic regression (27). Logistic

Regression was implemented using the NAG<sup>®</sup> library routine G02GB (Numerical Algorithms Group, Oxford, UK), for LDA we employed the implementation in van der Maaten's MATLAB<sup>®</sup> Toolbox for dimensionality reduction.

For a small number of data points, the excretion values were found to be zero within the sensitivity of the GC/MS analysis; for log-transformation and machine learning analysis, these values were set to  $10^{-10}$ . It was verified that the choice of this correction parameter did not affect the classification. While steroid data in ACA patients (n=102) displayed no missing values, the available steroid excretion data for ACC patients (n=45) contained a total of 3.9% (56 out of 1440) missing steroid excretion values. For the LVQ analysis, missing values were ignored when comparing distances of a particular feature vector from different prototypes. For LDA and logistic regression analyses we replaced missing values by class conditional means, which should theoretically give a performance advantage to these two methods in comparison to GMLVQ.
