NBER Working Paper No. 21722
November 2015, Revised March 2019
JEL No. E44,E58,F33,F42,G15

ABSTRACT

US monetary policy shocks induce comovements in the international financial variables that characterize the ‘‘Global Financial Cycle.’’ One global factor explaining an important share of the variation of risky asset prices around the world decreases significantly after a US monetary contraction. Monetary tightening in the US leads to significant deleveraging of global financial intermediaries, a decline in the provision of domestic credit globally, strong retrenchments of international credit flows, and tightening of foreign financial conditions. Countries with floating exchange rate regimes are subject to similar financial spillovers.

1 Introduction

Observers of balance of payment statistics and international investment positions all agree: the international financial landscape has undergone massive transformations since the 1990s. Financial globalization is upon us in a historically unprecedented way, and we have probably surpassed the pre-WWI era of financial integration celebrated by Keynes in “The Economic Consequences of the Peace.” The role of the United States as the hegemon of the international monetary system is however largely unchanged, and has long outlived the end of Bretton Woods, as emphasized in [Farhi and Maggiori \(2017\)](#) and [Gourinchas and Rey \(2017\)](#). The rising importance of cross-border financial flows and holdings has been documented in the literature;¹ what has not been explored as much, however, are the consequences of financial globalization for the workings of national financial markets, and for the transmission of US monetary policy beyond the national borders. How do international flows of money affect the international transmission of monetary policy? What are the effects of global banking on fluctuations in risky asset prices, and on credit growth and leverage in different economies? Using monthly data covering the past three decades, this paper’s main contributions are to describe the global financial cycle in risky asset prices, and to estimate the global financial spillovers of the monetary policy of the United States, the current hegemon of the international monetary system.

There are multiple channels of transmission of monetary policy. In a standard Keynesian or neo-Keynesian world, output is demand determined in the short-run, and monetary policy stimulates aggregate consumption and investment (see [Woodford, 2003](#) and [Gali, 2008](#) for classic discussions). In models with frictions in capital markets, expansionary monetary policy leads to an increase in the net worth of borrowers, be they financial intermediaries or firms, which in turn leads to an increase in lending. This is the *credit channel* of monetary policy ([Bernanke and Gertler, 1995](#)). Other papers have analyzed the *risk-taking channel* of monetary policy ([Borio and Zhu, 2012](#); [Bruno and Shin, 2015a](#); [Coimbra and Rey, 2017](#)), where the risk profile of financial intermediaries plays a key role, and loose monetary policy relaxes leverage constraints. These channels are complementary. In this paper, we explore empirically the *international* transmission of monetary

¹See e.g. [Lane and Milesi-Ferretti, 2007](#) and, for a recent survey, [Gourinchas and Rey \(2014\)](#).

policy that occurs through financial intermediation and global asset prices, an area that has been largely neglected by the literature.²

Using a dynamic factor model, we document the existence of a *unique* global factor in international risky asset prices which explains about 20% of the variance in the data. With a global Bayesian VAR, we then study the international transmission of US monetary policy mediated through the reaction of risky asset prices, global credit creation and capital inflows, and the leverage of financial intermediaries; these are the variables that characterize the ‘Global Financial Cycle’ (Rey, 2013). This is motivated by the dollar being an important funding currency for intermediaries, and by the fact that a large portion of portfolios worldwide are denominated in dollars.³ We identify US monetary policy shocks using an external instrument constructed with high-frequency price adjustments in the federal funds futures market around FOMC announcements, following the lead of Gürkaynak et al. (2005) and Gertler and Karadi (2015). At the same time, the use of a rich-information VAR ensures that we control for a wealth of other shocks, both domestic and international, to which the Fed endogenously reacts, above and beyond what is anticipated by market participants.⁴

We find evidence of powerful financial spillovers of US monetary policy to the rest of the world. When the US Federal Reserve tightens, domestic demand contracts, as do prices. The domestic financial transmission is visible through the rise of corporate spreads, the contraction of lending, and the sharp falls in the price of financial assets, such as housing and the stock market. But, importantly, we also document significant variations in the Global Financial Cycle, that is, the shock induces significant fluctuations in financial activity on a global scale. Risky asset prices, summarized by the single global factor contract very significantly. This is accompanied by strong deleveraging of global banks both in the US and Europe, and a surge in a measure of aggregate risk aversion in global asset markets. The supply of global credit contracts, and there is an important retrenchment of international credit flows that is particularly pronounced for the bank-

²See Rey (2016), Bernanke (2017) and Jorda et al. (2018) for longer discussions.

³For a recent study of the international reserve currency role of the dollar see Farhi and Maggiori (2017). Gopinath (2016) analyzes the disproportionate role of the dollar in trade invoicing, and Gopinath and Stein (2017) the synergies between some of those roles.

⁴For more detailed discussions see Miranda-Agrippino (2016) and Miranda-Agrippino and Ricco (2018).

ing sector. International corporate bond spreads also rise on impact, and significantly so. These results are consistent with a powerful transmission channel of US monetary policy across borders, via financial conditions. The contraction of domestic credit and international liquidity that follows the US monetary policy tightening is confirmed also for the subset of countries that have a floating exchange rate regime.

The importance of international monetary spillovers and of the world interest rate in driving capital flows has been pointed out in the classic work of [Calvo et al. \(1996\)](#).⁵ Some recent papers have fleshed out the roles of intermediaries in channeling those spillovers.⁶ Our empirical results on the transmission mechanism of monetary policy via its impact on risk premia, spreads, and volatility are related to those of [Gertler and Karadi \(2015\)](#) and [Bekaert, Hoerova and Duca \(2013\)](#) obtained in the domestic US context.⁷ A small number of papers have analyzed the effect of US monetary policy on leverage and on the VIX (see e.g. [Passari and Rey, 2015](#); [Bruno and Shin, 2015b](#)). But these studies rely on limited-information VARs (four to seven variables) and on Cholesky identification schemes to study the transmission of monetary policy shocks.⁸ Instead, using a rich-information Bayesian VAR allows, we believe for the first time, the joint analysis of financial, monetary and real variables, in the US and abroad. Moreover, the use of external instruments for identification allows us to dispense from often implausible timing restrictions in the reaction of the variables of interest.

The paper is organized as follows. In Section 2, we estimate a Dynamic Factor Model on world asset prices and show that one global factor explains a large part of the common variation of the data. In Section 3, we estimate a Bayesian VAR identified using

⁵A subsequent literature has echoed and extended some of these findings (see [Fratzscher, 2012](#); [Forbes and Warnock, 2012](#)).

⁶[Cetorelli and Goldberg \(2012\)](#) use balance sheet data to study the role of global banks in transmitting liquidity conditions across borders. Using firm-bank loan data, [Morais, Peydro and Ruiz \(2015\)](#) find that a softening of foreign monetary policy increases the supply of credit of foreign banks to Mexican firms. Using high-quality credit registry data combining firm-bank level loans and interest rates data for Turkey, [Baskaya, di Giovanni, Kalemli-Ozcan and Ulu \(2017\)](#) show that increased capital inflows, instrumented by movements in the VIX, lead to a large decline in real borrowing rates, and to a sizeable expansion in credit supply. Interestingly, they find that the increase in credit creation goes mainly through a subset of the biggest banks.

⁷For a discussion on the transmission of unconventional US monetary policy on global risk premia see [Rogers, Scotti and Wright \(2018\)](#).

⁸It is therefore unclear whether their results survive a more robust identification of monetary policy shocks. The problem of omitted variables is also an important issue in small scale VARs (see [Caldara and Herbst, 2019](#)).

high-frequency external instruments to analyze the interaction between US monetary policy and the Global Financial Cycle. Section 4 presents a simple theoretical framework featuring heterogeneous investors to interpret some of our results (Section 4.1), and microeconomic data on global banks to give evidence of their risk-taking behavior (Section 4.2). Section 5 concludes. Details on data and procedures, and additional results are in Appendices at the end of the paper.

2 One Global Factor in World Risky Asset Prices

In order to summarize fluctuations in global financial markets we specify a Dynamic Factor Model for a large and heterogenous panel of risky asset prices traded around the globe. The econometric specification, fully laid out in Appendix B, is very general, and allows for different global, regional and, in some specifications, sector specific factors.⁹ The panel includes asset prices traded on all the major global markets, a collection of corporate bond indices, and commodities price series (excluding precious metals). The geographical areas covered are North America, Latin America, Europe, Asia Pacific, and Australia, and we use monthly data from 1990 to 2012, yielding a total of 858 different prices series.¹⁰ Despite the heterogeneity of the asset markets considered, we find that the data support the existence of a *unique* common global factor; moreover, this factor alone accounts for over 20% of the common variation in the price of risky assets from all continents.¹¹ The factor is plotted in Figure 1, solid line.

While in this instance we prefer cross-sectional heterogeneity over time length, we are conscious of the limitations that a short time span may introduce in the VAR analysis we perform in the next section. To allow more flexibility in that respect, we repeat the factor extraction on a smaller set, where only the US, Europe, Japan and commodity

⁹A similar specification has been adopted by Kose et al. (2003) and Kose et al. (2012) for real variables; they test the hypothesis of the existence of a world business cycle and discuss the relative importance of world, region and country specific factors in determining domestic business cycle fluctuations.

¹⁰All the details on the construction and composition of the panels, shares of explained variance, and test and criteria used to inform the parametrization of the model (Table B.2) are reported in Appendix B. We fit to the data a Dynamic Factor Model (Stock and Watson, 2002a,b; Bai and Ng, 2002; Forni et al., 2000, among others) where each price series is modelled as the sum of a global, a regional, and an asset-specific component. All price series are taken at monthly frequency using end of month figures.

¹¹We formally test for the numbers of factors in our large panel of asset prices and find that the data support one common global factor. Results are reported in Table B.2 in the Appendix.

FIGURE 1: GLOBAL FACTOR IN RISKY ASSET PRICES

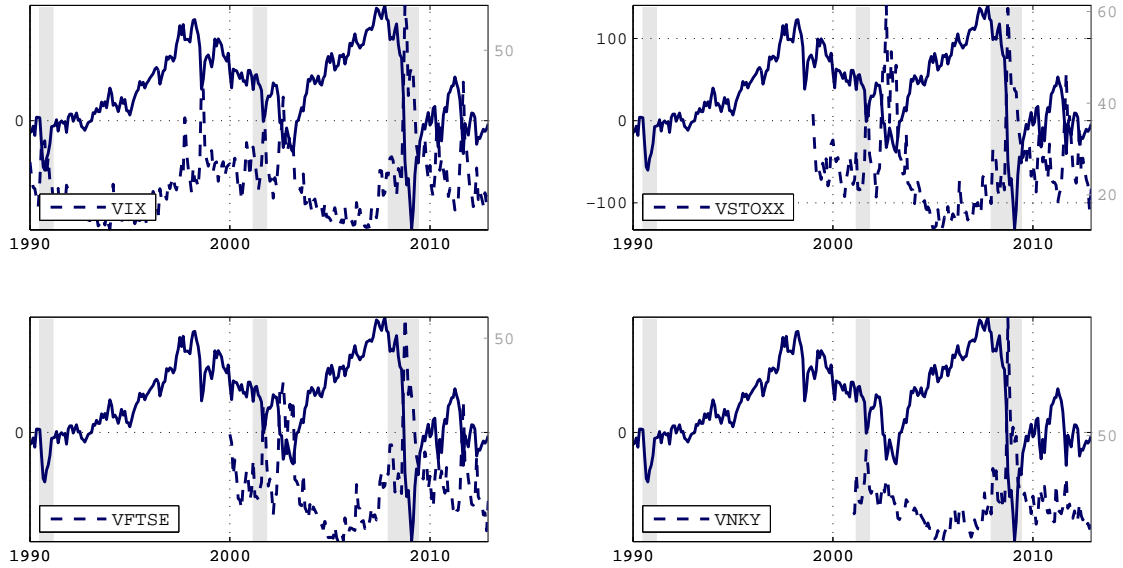

Note: The Figure plots the estimates of the global factor for the 1975:2010 sample (dotted line) together with the estimates on the wider, shorter sample 1990:2012 (solid line). Shaded areas denote NBER recession dates.

prices are included, but the time series go back to 1975. In this case the sample counts 303 series. The estimated global factor for the longer sample is the dashed line in Figure 1. Similar to the benchmark case, for this narrower panel too we find evidence of one global factor. In this case, however, the factor accounts for about 60% of the common variation in the data (see Table B.2). For both samples, factors are obtained via cumulation of those estimated on the stationary, first-differenced (log) price series, and are therefore consistently estimated only up to a scale and an initial value (see Bai and Ng, 2004, and Appendix B).¹² As a way of normalization, we rotate the factor such that it correlates positively with the major stock market indices in our sample, i.e. an increase in the index is interpreted as an increase in global asset prices.

Figure 1 shows that movements in the factor are consistent with both the US recession periods as identified by the NBER (shaded areas), and with major worldwide events. The index declines with all the recession episodes but remains relatively stable until the beginning of the nineties, when a sharp and sustained increase is recorded. The increase

¹²This implies that positive and negative values displayed in the chart do not convey any specific information per se. Rather, it is the overall shape and the turning points that are of interest and deserve attention.

FIGURE 2: GLOBAL FACTOR AND VOLATILITY INDICES

Note: Clockwise from top-left panel, the global factor (solid line) together with major volatility indices (dotted lines): VIX (US), VSTOXX (EU), VNKY (JP) and VFTSE (UK). Shaded grey areas highlight NBER recession times.

lasts until 1997-1998 when major global events like the Russian default, the LTCM bailout and the East Asian Crisis reverse the increasing path associated with the build up of the *dot-com* bubble. Starting from the beginning of 2003 the index increases again until the beginning of the third quarter of 2007. At that point, with the collapse of the subprime market, the first signals of increased vulnerability in financial markets become visible. This led to an unprecedented plunge.

In order to provide some interpretation for our estimated global factor, we note that in a large class of asset pricing models, including in the stylized framework that we present in Section 4, the common component of risky asset prices reflects aggregate volatility scaled by the aggregate degree of effective risk aversion in the market. In Figure 2 we highlight the comovement of our factor with a series of implied volatility indices for the markets included in our sample. Specifically, the VIX for the US, the VSTOXX and VFTSE for Europe and the UK respectively, and the VNKY for Japan. These indices capture both the price and quantity of risk, and hence reflect both expectations about future

FIGURE 3: GLOBAL FACTOR DECOMPOSITION

Note: [TOP PANEL] Monthly global realized variance measured using daily returns of the MSCI Index. The y axis is trimmed to enhance readability, during the credit crunch episode the index reached a maximum of 434.70. [BOTTOM PANEL] Index of aggregate risk aversion calculated as (the inverse of) the residual of the projection of the global factor onto the realized variance. Shaded grey areas highlight NBER recession times. *Source:* Global Financial Data and authors calculations.

realized volatility, and risk aversion.¹³ Because of our chosen normalization, we expect our factor to correlate negatively with the implied volatility indices. Indeed, this is clearly visible in the charts of Figure 2. The factor and the implied volatility indices display a remarkable common behaviour and peaks consistently coincide within the overlapping samples. While the comparison with the VIX is somehow facilitated by the length of the CBOE index, the same considerations extend to all other indices analyzed.¹⁴

Lastly, we separate the aggregate risk aversion and volatility components in our factor.¹⁵ The construction of our proxy for aggregate risk aversion is modelled along the lines of e.g. [Bekaert et al. \(2013\)](#), that estimate variance risk premia as the difference between

¹³These indices are typically regarded as instruments to assess the degree of strain and risk in financial markets.

¹⁴Comparison with other ‘risk indices’ such as the GZ-spread of [Gilchrist and Zakrajšek \(2012\)](#) and the Baa-Aaa corporate bond spread (not reported) show that these indices also display some commonalities, even if the synchronicity is slightly less obvious than the one we find with respect to the implied volatilities.

¹⁵Section 4 presents a simple model of international asset pricing that justifies this decomposition in our context.

FIGURE 4: AGGREGATE CAPITAL FLOWS

Note: Global flows as a percentage of world GDP. Annual moving averages. *Source:* IFS Statistics.

a measure of the implied variance (the squared VIX) and an estimated physical expected variance, which is primarily a function of realized volatilities. Specifically, we first obtain an estimate of realized monthly global volatility using daily returns of the global MSCI Index.¹⁶ Second, we calculate a proxy for aggregate risk aversion as the inverse of the centred residuals of the projection of the global factor on the realized variance. The results of this exercise are summarized in Figure 3. Our monthly measure of global realized variance is in the top panel, while the implied index of aggregate risk aversion is in the bottom panel. Interestingly, the degree of market risk aversion that we recover from this simple decomposition is in continuous decline between 2003 and the beginning of 2007, and it decreases to very low levels, at a time where volatility was uniformly low, global banks were prevalent, and may have been the ‘marginal buyers’ in international financial markets.¹⁷ Indeed, Shin (2012) documents the large and increasing share of banking flows in aggregate capital flows over that period and until 2008; subsequently, both as a consequence of the crisis and of the changes in regulation, their relative impor-

¹⁶We work under the assumption that monthly realized variances calculated summing over daily returns provide a sufficiently accurate proxy of realized variance at monthly frequency.

¹⁷Our empirical proxy for aggregate risk aversion could reflect also other factors such as expected cash flow growth or risk free rates. In the empirical analysis of Section 3 of the next section, these other factors are however controlled for by the information contained in our VARs, which include interest rates and industrial production.

tance has declined. For illustrative purposes, we report data relative to aggregate capital flows as a percentage of world GDP in Figure 4. Interestingly, the timing of the surge of banking flows coincides with the decline in global risk aversion in 2003. Estimated aggregate risk aversion starts increasing during 2007 then jumps up during the financial crisis with the bankruptcy of Lehman Brothers, and remains persistently at high levels, as the importance of global banks declines. We further explore the connection between the sharp increase in banking flows and the decline in global risk aversion in Section 4. In the next section we estimate the effects of US monetary policy on the global factor, on global risk aversion, and on other variables that characterize the Global Financial Cycle.

3 US Monetary Policy and the Global Financial Cycle

With the US dollar being the currency of global banking, monetary actions in the US may directly influence the Global Financial Cycle by altering the cost of funding for major global banks, and hence their leverage decisions. US monetary policy also affects the pricing of dollar assets, both in the US and abroad, through a direct discount channel and/or by changing the type of marginal investors in international asset markets.¹⁸ Furthermore, monetary conditions of the centre country can be transmitted through cross-border capital flows, or through the internal pricing of global banks, and influence the provision of credit outside US borders (see the corroborative evidence in [Morais et al., 2015](#) for Mexico, and in [Baskaya et al., 2017](#) for Turkey).

To study the effects of US monetary policy on the Global Financial Cycle (GFC), we use rich-information VARs with both domestic and international variables that provide us with a unique framework to analyze the transmission of monetary policy beyond national borders.¹⁹ There are a number of advantages that come with this choice. Most obviously, relying on a unique specification permits addressing the effects of US monetary policy on the GFC against the background of the response of the domestic business

¹⁸Security-level evidence provided by [Schreger et al. \(2017\)](#) shows that firms who finance themselves in dollars are by and large the only ones able to attract a worldwide investors base. For a model where low funding costs lower aggregate effective risk aversion and increase leverage see [Coimbra and Rey \(2017\)](#).

¹⁹Technical details on priors and estimation of the Bayesian VAR are reported in the Appendix.

cycle. This acts both as a complement to the analysis, and as a disciplining device to ensure that the identified shock is in fact inducing responses that do not deviate from the standard channels of domestic monetary transmission. Moreover, the dimensionality and composition of the set of variables included in the VAR greatly reduce the problem of omitted variables that generally plagues smaller systems and is likely to invalidate the identification of the structural shocks.²⁰

We start by looking at how US monetary policy affects domestic real and financial conditions in a ‘closed economy VAR’. Then, we augment a small set of core domestic variables with those that characterize the GFC; namely, global credit and capital inflows, global factor in asset prices and risk aversion, and the leverage of US and European banks. In this first version of our empirical framework, global variables are world aggregates, and bundle together countries with different exchange rate regimes. To evaluate to what extent a floating exchange rate can provide some insulation against foreign shocks, we then repeat the analysis by specifically focusing only on the subset of ‘floaters’, following the IMF’s de-facto classification.

3.1 Identification of US Monetary Policy Shocks

We identify US monetary policy shocks using an external instrument ([Stock and Watson, 2012, 2018](#); [Mertens and Ravn, 2013](#)). The intuition behind this approach is that the mapping between the VAR innovations and the structural shock of interest can be estimated using only moments of observables, provided that a valid instrument for such shock exists. The contemporaneous transmission coefficients are a function of the regression coefficients of the VAR residuals onto the instrument, up to a normalization. Hence, given the instrument, this method ensures that we can isolate the causal effects of a US monetary policy shock on the dynamics of our large set of variables without imposing any timing restrictions on the responses. Intuitively, if the instrument correlates with the VAR innovations only via the contemporaneous monetary policy shocks, a projection

²⁰[Bańbura et al. \(2010\)](#) show that a medium-scale VAR of comparable size and composition to the one used in this paper is able to correctly recover the shocks and reproduce responses that match theoretical ones. Intuitively, the large degree of comovement among macroeconomic variables makes it possible for VARs of such size to effectively summarize the information contained in large VARs typically counting over hundred variables.

of the VAR innovations on the instrument isolates variations in the variables which are solely due to the shock (Miranda-Agrippino and Ricco, 2018).

The crucial step of this identification strategy is, naturally, the choice of the instrument. We rely on high-frequency movements in federal funds futures markets around FOMC announcements to identify the monetary policy shocks, following the lead of Gürkaynak et al. (2005) and Gertler and Karadi (2015). Specifically, we use 30-minutes price revisions (or surprises) around FOMC announcements in the fourth federal funds futures contracts (FF4), and we construct a monthly instrument by summing up the high-frequency surprises within each month. Because these futures have an average maturity of three months, the price revision that surrounds the FOMC monetary policy announcements captures revisions in market participants expectations about the future monetary policy stance up to a quarter ahead. As observed in Miranda-Agrippino (2016) and Miranda-Agrippino and Ricco (2017), market-based monetary surprises such as the ones we use map into the shocks only under the assumption that market participants can correctly and immediately disentangle the systematic component of policy from any observable policy action. In the presence of information asymmetries, the high-frequency surprises are also a function of the information about economic fundamentals that the central bank implicitly discloses at the time of the policy announcements.²¹ Failure to account for this effect hinders the correct identification of the shocks, resulting in severe price and real activity puzzles particularly in small VARs. Here we address this issue by relying on the rich information in our VARs. The information sets in our VARs controls for a wealth of other shocks, both domestic and international, to which the Fed endogenously reacts, and allows identification of monetary policy shocks above and beyond what is expected by market participants.

In Table 1, we report first stage IV statistics of the projection of the VAR innovation for the policy interest rate (1 year rate in our case) on our instrument (FF4). For comparison, we also include first-stage statistics obtained with the narrative instrument of Romer and Romer (2004), that we have extended up to the end of 2007 (MPN). A

²¹This implicit disclosure of information is referred to as the Fed information effect in Nakamura and Steinsson (2017), and the signalling channel of monetary policy in Melosi (2017). The concept is similar to the Delphic component of forward guidance announcements in Campbell, Evans, Fisher and Justiniano (2012).

TABLE 1: TESTS FOR INSTRUMENTS RELEVANCE

| DOMESTIC VAR (1) | F -stat | 90% posterior ci | reliability | 90% posterior ci |
|------------------|-----------|------------------|-------------|------------------|
| FF4 | 17.930 | [6.675 22.673] | 0.496 | [0.434 0.540] |
| MPN | 10.947 | [4.264 16.246] | 0.187 | [0.132 0.251] |
| GLOBAL VAR (2) | | | | |
| FF4 | 14.788 | [3.239 18.010] | 0.530 | [0.470 0.573] |
| MPN | 2.278 | [0.106 5.698] | 0.258 | [0.171 0.317] |
| GLOBAL VAR (3) | | | | |
| FF4 | 14.901 | [3.116 18.631] | 0.529 | [0.476 0.577] |
| MPN | 2.756 | [0.139 6.216] | 0.255 | [0.170 0.312] |

Note: First-stage F statistics, statistical reliability and 90% posterior coverage intervals. Candidate instruments are surprises in the three-months-ahead (FF4) federal fund futures and an extension to the narrative instrument of Romer and Romer (2004) up to 2007. VAR innovations are from monthly BVAR(12) estimated from 1980 to 2010. First-stage regressions are run on the overlapping sample between the VAR innovations and each instrument.

first-stage F statistic below 10 is an indication of potentially weak instruments (Stock et al., 2002). The three VARs in the table are (1) a closed economy 13-variable VAR that includes only US variables; (2) a global 15-variable VAR that includes GFC variables as world aggregates; (3) and a global 15-variable VAR that focuses on the subset of countries with floating exchange rates. All VARs are monthly and estimated with 12 lags over the sample 1980-2010 using standard macroeconomic priors. Details on the composition of each VAR are reported in Table 2 in the next subsection.

Results in Table 1 show that in a domestic context, and conditional on the rich-information VAR composition of Table 2, either instrument attains satisfactory levels of relevance, with first stage F -statistics safely above the weak instrument threshold. As we discuss in the next subsection, in this case the two instruments retrieve relatively similar dynamic responses to a monetary policy shock. The relevance of the narrative series, and the plausibility of the impulse response functions (IRFs) identified with this instrument however, deteriorate dramatically in both open economy global VARs. In contrast, the first stage IV statistics associated to the high-frequency based identification are only marginally altered in the three cases. This confirms the strong informative content of our preferred instrument.²²

²²Another paper using high frequency external instruments for the identification of US monetary policy

Note: The table lists the variables included in the baseline domestic and global BVARs. Models correspond to (1) domestic VAR; (2) & (3) global VARs with world aggregates for GFC; (4) & (5) global VAR on subset of countries with a floating exchange rate; (6) global VAR with focus on UK and EA monetary policy and financial conditions. Variables enter the VARs in (log) levels with the exception of interest rates and spreads.

3.2 The Transmission of US Monetary Policy through the Global Financial Cycle

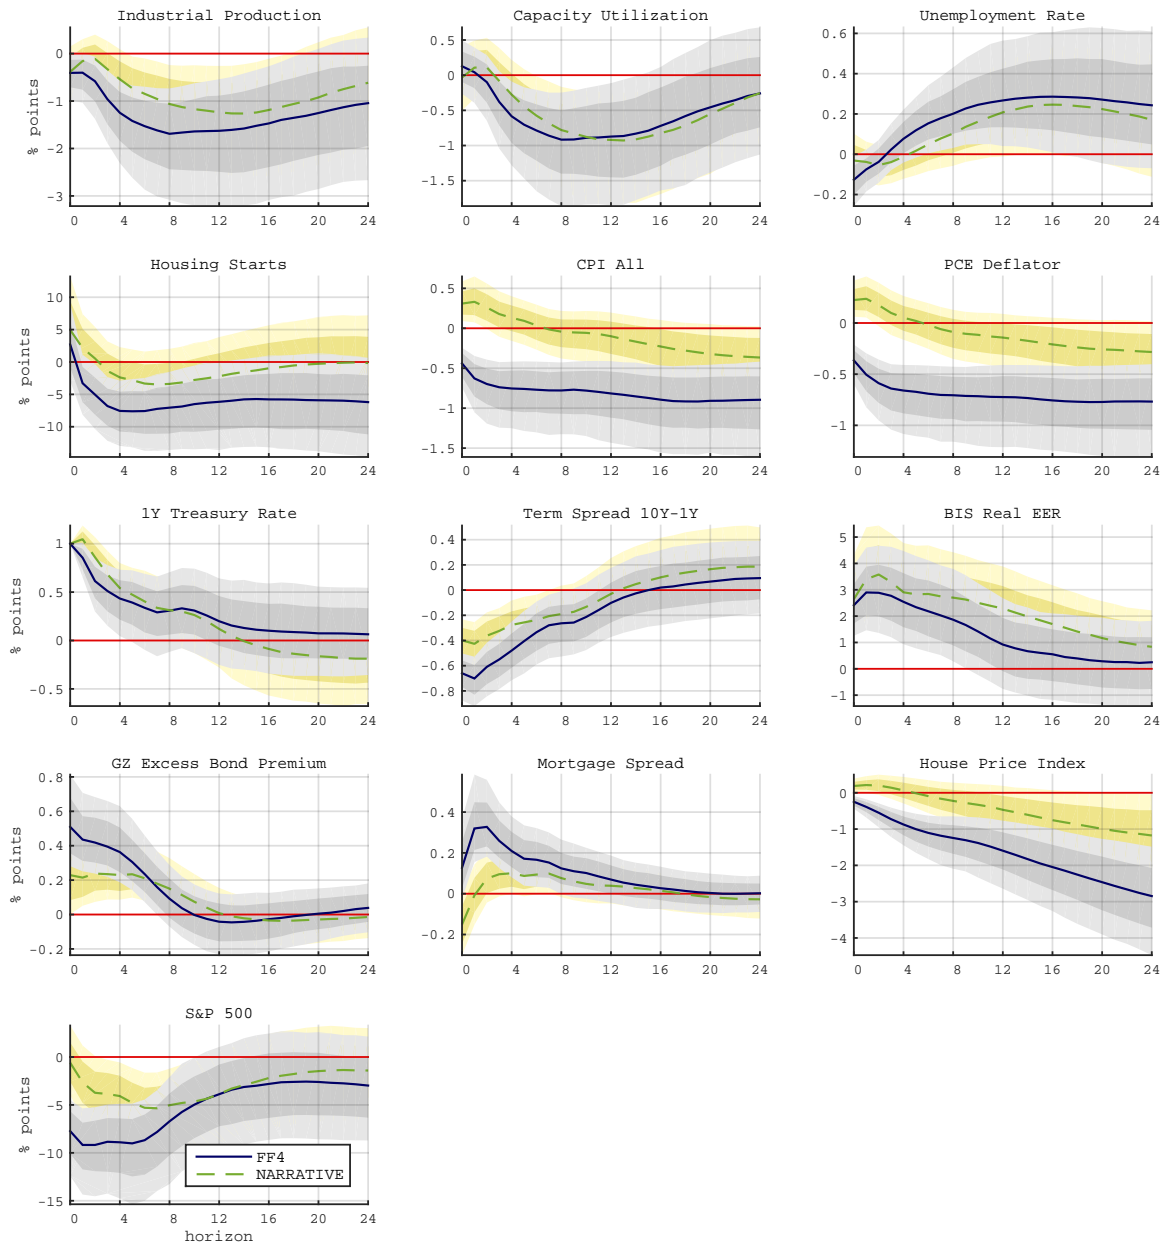

We present our results in the form of dynamic responses to a US monetary policy shock that is normalized to increase the policy rate by 1% on impact. We use the 1-year government bond rate as monetary policy variable; this, coupled with the 3-month horizon embedded in our external instrument implies that we capture standard monetary policy shocks that affect the fed funds rate, but also implicit and explicit Fed communication and actions that affect interest rates at longer maturities. All VARs are estimated using standard macroeconomic priors, with 12 lags at monthly frequency over the sample 1980:1 shocks and their effects on financial markets is [Ha \(2016\)](#).

- 2010:12. In this section we report and discuss impulse response functions (IRFs) only for the variables of interest; full sets of IRFs are reported in the Appendix. The variables that we include in our baseline VARs are listed in Table 2, together with the composition of all the VARs we estimate for the results presented in the remainder of the section. Details on the construction of the data are reported in the Appendix that also collects robustness tests. We report median IRFs together with 68% and 90% posterior coverage bands.

Domestic Responses. We start our empirical exploration by looking at the domestic responses of financial markets and macroeconomic aggregates (Figure 5). To give further motivation for the choice of our instrument, Figure 5 compares for each variable the IRFs obtained with the high-frequency IV (FF4, solid lines) and the narrative IV (MPN, dashed lines). The VAR is the same in the two cases.

A contractionary monetary policy shock depresses prices and economic activity in line with the standard transmission channels. Production and capacity utilization contract, as do housing investments, while the unemployment rate rises significantly; these effects are not sudden, but build up over the horizons. Similarly, prices adjust downward. We note here that the MPN IV recovers responses that display a pronounced price puzzle. This is in contrast to our preferred identification via high-frequency instruments: following an initial downward revision, prices continue to slide into negative territory, in a manner consistent with the presence of price rigidities. The shock also has important consequences for domestic financial markets. The response of the one year rate dies out very quickly; comparing the responses of the policy rate and the slope of the yield curve we note that the fast rebound of the policy rate is not sufficient to generate the implied 40bps increase in the 10-year rate. Hence, a first effect of the shock is that it decreases the term spread. The heightened levels of perceived risk aversion are confirmed also by the sudden rise in the excess bond premium variable of [Gilchrist and Zakrajšek \(2012\)](#) that measures corporate bond spreads net of default considerations. This measure also implies increased costs of funding in the corporate market, and provides evidence of a powerful financial amplification mechanism of monetary policy shocks that operates at the domestic level. Expectations of lower economic activity are immediately priced-in in the stock market

FIGURE 5: RESPONSES OF DOMESTIC BUSINESS & FINANCIAL CYCLE

Note: Closed economy responses to a contractionary US monetary policy shock that induces a 1% increase in the policy rate. [BLUE SOLID LINES AND GREY AREAS] IV is the surprise in FF4 contracts, 68% & 90% posterior coverage bands. that registers a very strong and very sudden drop. Household finance also deteriorates substantially, with house prices falling and mortgage spreads increasing very significantly.

Finally, the monetary contraction results in a significant appreciation of the dollar against a basket of foreign currencies.

The system of domestic dynamic responses highlights a powerful transmission of monetary policy shocks through the domestic financial markets. In the remainder of this section we will explore how monetary policy shocks spill over across borders through their effect on global financial conditions.

Global Financial Cycle: World Aggregates. We start by analyzing the responses of global asset markets, as summarized by the global factor in risky asset prices, and the implied degree of aggregate risk aversion in global markets, as estimated in Section 2.

Second, we study the responses of global domestic credit and international capital flows. Our global credit variables are world aggregates, and bundle together countries with different exchange rate regimes.²³ We compute global variables as the cross-sectional sum of country-specific equivalents which are in turn constructed following the instructions detailed in Appendix A. Global inflows are direct cross-border credit flows provided by foreign banks to both banks and non-banks in the recipient country (see Avdjiev et al., 2012).

Finally, we look at banks' leverage. Here we separate brokers/dealers and G-SIBs²⁴ from the aggregate banking sector, due to their different risk-taking behavior. Data for credit, international inflows, and leverage are originally available at quarterly frequency. We convert them to monthly frequency by interpolation. Full sets of responses are collected in Figures D.1 to D.3 in the Appendix. Results are robust to starting the estimation sample in January 1990.

A contractionary US monetary policy shock impacts global asset markets (Figure 6). Upon realization of the monetary contraction, global risky asset prices, as summarized by the global factor, contract abruptly. While the factor has no meaningful measurement

²³The countries included in our study are Argentina, Australia, Austria, Belarus, Belgium, Bolivia, Brazil, Bulgaria, Canada, Chile, Colombia, Costa Rica, Croatia, Cyprus, Czech Republic, Denmark, Ecuador, Finland, France, Germany, Greece, Hong Kong, Hungary, Iceland, Indonesia, Ireland, Italy, Japan, Latvia, Lithuania, Luxembourg, Malaysia, Malta, Mexico, Netherlands, New Zealand, Norway, Poland, Portugal, Romania, Russia, Serbia, Singapore, Slovakia, Slovenia, South Africa, South Korea, Spain, Sweden, Switzerland, Thailand, Turkey, United Kingdom and the United States.

²⁴Globally Systemically Important Banks.

FIGURE 6: RESPONSES OF GLOBAL ASSET PRICES & RISK AVERSION

Note: Responses to a US contractionary monetary policy shock that induces a 1% increase in the policy interest rate. Median IRFs with posterior coverage bands at 68% and 90% levels. The shock is identified using a high-frequency external instrument.

unit, we can quantify the effects on global stock markets by looking at its contribution to the overall fluctuations in the major indices. The factor explains about 20% of the common variation in our panel of international asset prices. If we assume that all asset prices load equally on the factor, the 40% impact fall would roughly translate into a 8% impact decrease in the local stock market. This number is consistent with both the response of the local US stock market (Figure 5), and European markets discussed at the end of the section (Figure 10).

The aggregate degree of risk aversion – i.e. the component of our factor that is orthogonal to realized volatilities in global markets as constructed in Section 2 – rises sharply. The rise is consistent with the heightened levels of domestic measures of risk premia. Importantly, it offers a potentially very powerful channel of international transmission of domestic monetary policy by altering the degree of risk aversion of international investors. We explore this point further when we discuss the response of global banks’ leverage below. Quantifying the rise in risk aversion is less straightforward; but the shock substantially raises it by over 50% above its average trend.

Figure 7 collects the responses of global economic activity, global domestic credit, and global credit inflows. The Figure combines together responses extracted from the VARs (2) and (3) in Table 2. The US monetary policy contraction leaves global growth

FIGURE 7: RESPONSES OF GLOBAL CREDIT & CAPITAL FLOWS

Note: Responses to a US contractionary monetary policy shock that induces a 1% increase in the policy interest rate. Median IRFs with posterior coverage bands at 68% and 90% levels. The shock is identified using a high-frequency external instrument.

unchanged on impact. The inclusion of global growth here serves two purposes. First, it allows us to consider changes in global financial conditions once we have controlled for economic activity on a global scale. Second, it helps ensure that we are not confounding the effects of a US monetary policy shock with other global shocks that affect credit through their effects on growth.

Following a US monetary policy contraction we register a sharp decrease in credit provision and a strong retrenchment of global capital inflows. The contraction in global domestic credit is not driven by US domestic credit, as shown in the lower left panel of the figure. Global capital inflows respond in a similar fashion: following an initial contraction, international funding flows continue to decrease to rebound at larger horizons. In the lower section of the figure we report the responses of capital inflows split by recipient

FIGURE 8: RESPONSES OF LEVERAGE OF GLOBAL BANKS

Note: Responses to a US contractionary monetary policy shock that induces a 1% increase in the policy interest rate. Median IRFs with posterior coverage bands at 68% and 90% levels. The shock is identified using a high-frequency external instrument.

type. The overall picture is consistent with a reduction of flows directed to both banking and private sectors. The decline in credit, both domestic and cross-border, whether we look at flows to banks or to non-banks, is in the order of several percentage points and thus economically significant.

Lastly, we present the responses of banks' leverage in Figure 8. We use data on the leverage of US Security Brokers and Dealers (USBD) and Globally Systemically Important Banks (GSIBs) operating in the Euro Area and the UK. Data on total financial assets and liabilities for USBD are from the Flow of Funds of the Federal Reserve Board, while the aggregate leverage ratios for global banks in the EA and the UK are constructed using bank-level balance sheet data following the instructions detailed in Appendix A.²⁵ Consistent with increased funding costs, heightened levels of risk aversion and declining asset prices that alter the valuation of banks' balance sheets, the financial leverage of global investors strongly and quickly contracts after a monetary tightening, both among US Brokers & Dealers, and European global banks. Again, the responses are in the order of several percentage points, and hence economically relevant. But the responses appear to be more delayed and more muted for the total balance sheet of the banking

²⁵Adrian and Shin (2010) present evidence on the procyclicality of leverage in the US context. In Section 4.2 we extend these results to an international sample of banks.

sector. While no appreciable change is visible for the US, the leverage of European banks contracts significantly to bottom about a year after the shock hits. The reduction in leverage is more modest and more delayed when compared to that of the G-SIB and the Broker-Dealers. Domestically oriented retail banks take longer to adjust, so that broader banking aggregates only react with a delay to monetary policy shocks, which instead affects more immediately the large banks with important capital market operations.

Taken together, the responses collected in Figures 6 to 8 provide evidence of a powerful channel of international transmission of US monetary policy that operates through global financial markets, besides the more standard channels related to international trade. By being able to generate comovements in asset prices, credit, risk appetite and financial leverage of global investors, US monetary policy can influence fluctuations in the Global Financial Cycle. A monetary policy contraction rises funding costs, not only domestically, but also on a global scale. This is likely the joint outcome of the dollar being the dominant currency for international financial transactions, and the interconnectedness of global financial intermediaries. In this respect, a key role is played by global investors, namely, global banks in both the US and Europe, who influence the way in which funds are channeled. The strong retrenchments in domestic credit and international capital flows directed towards both the banking and private sectors provides compelling evidence of how the deterioration of global financial conditions concretely affects countries.

Global Financial Cycle: Floaters. An important question regarding Figure 7 is whether the global contraction in credit is driven by countries that have a fixed or pegged exchange rate regime vis-a-vis the Dollar. In order to address this question, we use the IMF's de-facto classification of exchange rate regimes to isolate the subset of countries in our panel classified as 'independently floating'.²⁶ We then construct aggregates for these countries as the cross-sectional sum of their respective levels of domestic credit and capital inflows, using the same definitions as before (further details on the data are in Appendix A). Full sets of responses are collected in Figures D.4 and D.5 in the

²⁶Independently floating countries in our sample are Australia, Austria, Belgium, Brazil, Canada, Chile, Cyprus, Czech Republic, Finland, France, Germany, Greece, Hungary, Iceland, Ireland, Italy, Japan, Luxembourg, Malta, Mexico, Netherlands, New Zealand, Norway, Poland, Portugal, Slovenia, South Africa, Spain, Sweden, Turkey, and the United Kingdom. Source <https://www.imf.org/external/np/mfd/er/2008/eng/0408.htm>.

FIGURE 9: RESPONSES OF GLOBAL CREDIT & CAPITAL FLOWS: FLOATERS

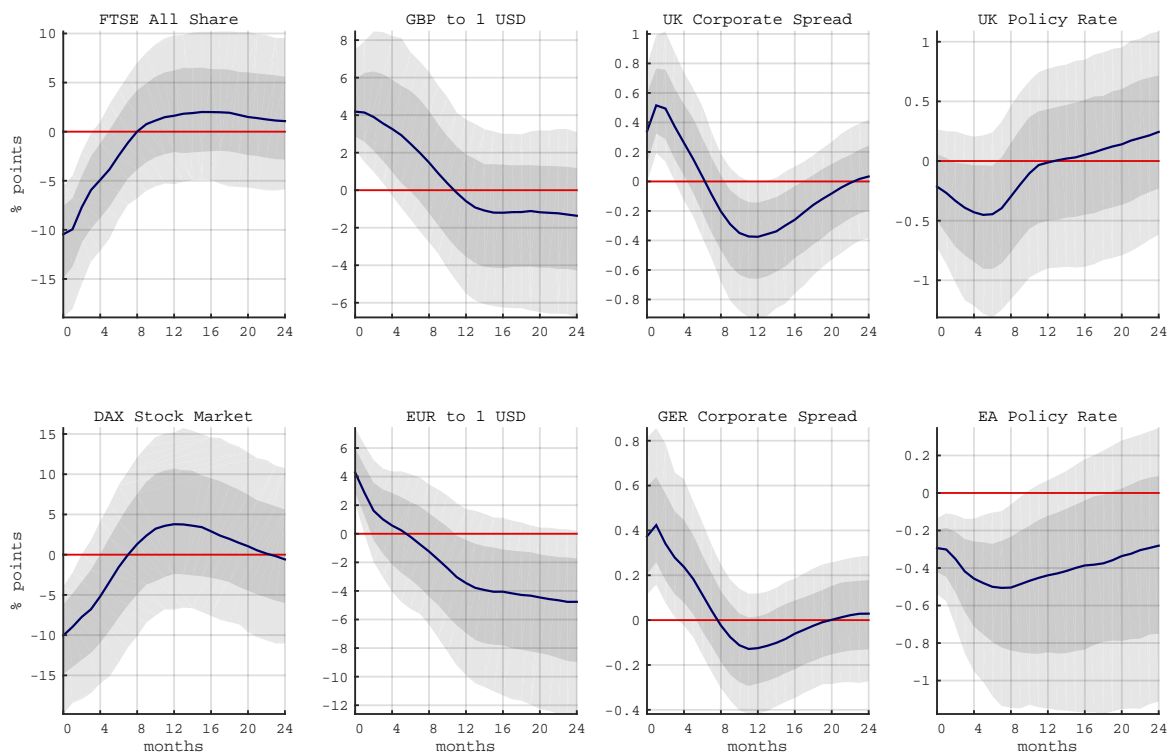

Note: Responses to a US contractionary monetary policy shock that induces a 1% increase in the policy interest rate. Median IRFs with posterior coverage bands at 68% and 90% levels. The shock is identified using a high-frequency external instrument.

Appendix. Figure 9 collects the responses of credit and capital inflows for the subset of floaters. These are obtained by substituting world aggregates with floaters country aggregates in the same VAR used to estimate the previous sets of responses (see Table 2). Again in this case we control for global economic activity. The IRFs in Figure 9 show that countries with a floating exchange rate regime seem to be equally exposed to US monetary policy shocks. In fact, the magnitude of the contraction in the credit variables is very similar to that obtained over the full sample. It should be clear that these results do not imply that exchange rate regimes are equivalent. However, they do indicate that the exchange rate regime may not be successful in providing a fully protective shield against US monetary policy shocks, and that fluctuations in the Global Financial Cycle can affect in a significant way all countries, even those with a floating exchange rate. We explore this point further below.

Global Financial Cycle: Currencies, Credit, and Monetary Independence.

We finally turn to evaluate in more details how financial conditions transmit across borders by restricting our attention to the case of the UK and Euro Area, two important currency areas with flexible exchange rates against the dollar. Full set of responses are shown in Figures D.6 and D.7 in the Appendix.

FIGURE 10: CROSS-BORDER FINANCIAL CONDITIONS & MONETARY POLICY

Note: Responses to a US contractionary monetary policy shock that induces a 1% increase in the policy interest rate. Median IRFs with posterior coverage bands at 68% and 90% levels. The shock is identified using a high-frequency external instrument.

Figure 10 collects the responses of the local stock market indices, of bilateral exchange rates vis-à-vis the dollar, corporate bond spreads, and policy interest rates for the UK (top row of the figure) and the Euro Area (bottom row of the figure).²⁷ We note that for all these variables the responses across the two countries are remarkably similar. Consistent with the fall in the global factor in risky asset prices, the local stock market indices plummet on impact to a very similar degree. The dollar appreciates significantly against both currencies. The exchange rate is in both cases measured as units of the foreign currency per one US dollar, such that a positive reading corresponds to an appreciation of the dollar. The appreciation is relatively short-lived in both cases, and reverts in the

²⁷For periods preceding the introduction of the Euro, we use the German Mark as the relevant European benchmark currency and convert it using the fixed exchange rate with the Euro chosen at the time of introduction of the common currency.

span of one to four quarters after the shock hits. The US monetary policy shock sizeably alters funding costs in both the UK and Euro Area, with corporate bond spreads rising very significantly and on impact in both cases. Finally, the responses of the policy rates suggest that a US contractionary monetary policy shock is likely to be followed by an endogenous easing in both the UK and the Euro Area, as a response to the deterioration in the local financial conditions. While estimated with a higher degree of uncertainty in the case of the UK, the magnitude of the responses is very similar in the two cases, and implies an endogenous monetary easing of about 30bps. This also implies that the tightening of financial conditions in the UK and the Euro Area cannot be ascribed to a domestic monetary policy tightening, and are instead a consequence of the US monetary policy spillovers.

4 Interpretation of the Results

4.1 A Simple Model with Heterogeneous Investors

The empirical results show that US monetary policy affects global banks' leverage, risky asset prices and global risk aversion. In this section, we present a stylized framework to help with the interpretation of these empirical findings; the model builds directly on the work of [Zigrand et al. \(2010\)](#).²⁸ Our illustrative model of international asset pricing features investors with heterogeneous risk-taking propensities, in order to make sense of a time-varying degree of aggregate effective risk aversion.²⁹ The risk premium depends on the wealth distribution between leveraged global banks on the one hand, and asset managers, such as insurance companies or sovereign wealth funds, on the other hand. As the relative wealth of the two types of investors fluctuates, asset pricing will be determined mostly by one type of investor or the other.

We consider a world with two types of investors: global banks and asset managers. Global banks and asset managers account for a large part of cross-border flows, as noted

²⁸See also [Etula \(2013\)](#) and [Adrian and Shin \(2014\)](#).

²⁹For a more realistic dynamic stochastic general equilibrium model of asset pricing with heterogeneous investors and monetary policy see [Coimbra and Rey \(2017\)](#). Other types of models which generate time-varying risk aversion are for example models with habits in consumption (see [Campbell and Cochrane \(1999\)](#)).

in Figure 4. Global banks are leveraged entities that fund themselves in dollars for their operations in capital markets. They can borrow at the US risk-free rate and lever to buy a portfolio of world risky securities, whose returns are in dollars. They are risk-neutral investors and subject to a Value-at-Risk (VaR) constraint, which is imposed by regulation.³⁰ We present microeconomic evidence pertaining to the leverage and risk taking behaviour of banks in Section 4.2. The second type of investors are asset managers who, like global banks, acquire risky securities in world markets and can borrow at the US risk-free rate. Asset managers also hold a portfolio of regional assets (for example regional real estate) which is not traded in financial markets, perhaps because of information asymmetries. Asset managers are standard mean-variance investors and exhibit a positive degree of risk aversion that limits their desire to leverage.³¹

Global Banks

Global banks maximize the expected return of their portfolio of world risky assets subject to a Value-at-Risk (VaR) constraint.³² The VaR imposes an upper limit on the amount a bank is predicted to lose on a portfolio with a certain probability. We denote by \mathbf{R}_t the vector of excess returns of all traded risky assets in the world (in dollars). We denote by \mathbf{x}_t^B the portfolio shares of a global bank, and by w_t^B the equity of the bank. The maximization problem of a global bank is

$$\begin{aligned} \max_{\mathbf{x}_t^B} \mathbb{E}_t (\mathbf{x}_t^{B'} \mathbf{R}_{t+1}) \\ \text{subject to } \text{VaR}_t \leq w_t^B, \end{aligned}$$

where VaR_t is defined as a multiple α of the standard deviation of the bank portfolio

³⁰Their risk neutrality is an assumption which may be justified by the fact that they benefit from an implicit bailout guarantee, either because they are universal banks, and are therefore part of a deposit guarantee scheme, or because they are too systemic to fail. Whatever the microfoundations, the crisis has provided ample evidence that global banks have taken on large amounts of risk and that this risk was not priced by creditors.

³¹The fact that only asset managers, and not the global banks, have a regional portfolio is non essential; global banks could be allowed to hold a portfolio of regional loans or assets as well. The asymmetry in risk aversion (risk neutral banks with VaR constraint and risk averse asset managers), however, is important for the results.

³²VaR constraints have been used internally for the risk management of large banks for a long time and have entered the regulatory sphere with Basel II and III. For a microfoundation of VaR constraints, see [Adrian and Shin \(2014\)](#).

$$\text{VaR}_t = \alpha w_t^B [\text{Var}_t(\mathbf{x}_t^B \mathbf{R}_{t+1})]^{\frac{1}{2}}.$$

Taking the first order condition, and using the fact that the constraint is binding (since banks are risk neutral) gives the following solution for the vector of asset demands:

$$\mathbf{x}_t^B = \frac{1}{\alpha \lambda_t} [\text{Var}_t(\mathbf{R}_{t+1})]^{-1} \mathbb{E}_t(\mathbf{R}_{t+1}), \quad (1)$$

where we use Var to denote the variance. This is formally similar to the portfolio allocation of a mean-variance investor. In Eq. (1), λ_t is the Lagrange multiplier: the VaR constraint plays the same role as risk aversion.³³

Asset Managers

Asset managers are standard mean-variance investors with a constant degree of risk aversion equal to σ . They have access to the same set of traded assets as global banks. We call \mathbf{x}_t^I the vector of portfolio weights of the asset managers in tradable risky assets. Asset managers also invest in local (regional) non-traded assets. We denote by \mathbf{y}_t^I the fraction of their wealth invested in those regional assets (their net supply is \mathbf{y}_t). The vector of excess returns on these non tradable investments is \mathbf{R}_t^N . Finally, we call w_t^I the equity of asset managers. An asset manager chooses his portfolio of risky assets by maximizing

$$\max_{\mathbf{x}_t^I} \mathbb{E}_t(\mathbf{x}_t^{I'} \mathbf{R}_{t+1} + \mathbf{y}_t^{I'} \mathbf{R}_{t+1}^N) - \frac{\sigma}{2} \text{Var}_t(\mathbf{x}_t^{I'} \mathbf{R}_{t+1} + \mathbf{y}_t^{I'} \mathbf{R}_{t+1}^N).$$

The optimal portfolio choice in risky tradable securities for an asset manager will be

$$\mathbf{x}_t^I = \frac{1}{\sigma} [\text{Var}_t(\mathbf{R}_{t+1})]^{-1} [\mathbb{E}_t(\mathbf{R}_{t+1}) - \sigma \text{Cov}_t(\mathbf{R}_{t+1}, \mathbf{R}_{t+1}^N) \mathbf{y}_t^I]. \quad (2)$$

Market clearing conditions

The market clearing condition for risky traded securities is $\mathbf{x}_t^B \frac{w_t^B}{w_t^B + w_t^I} + \mathbf{x}_t^I \frac{w_t^I}{w_t^B + w_t^I} = \mathbf{s}_t$ where \mathbf{s}_t is a world vector of net asset supplies for traded assets.

Proposition 1 (Risky Asset Returns) *Using Eq. (1) and (2) and the market clear-*

³³It is possible to solve out for the Lagrange multiplier using the binding VaR constraint (see Zigrand et al., 2010). We find $\lambda_t = [\mathbb{E}_t(\mathbf{R}_{t+1})' [\text{Var}_t(\mathbf{R}_{t+1})]^{-1} \mathbb{E}_t(\mathbf{R}_{t+1})]^{-1/2}$.

ing conditions, the expected excess returns on tradable risky assets can be rewritten as the sum of a global component and a regional component:

$$\mathbb{E}_t(\mathbf{R}_{t+1}) = \Gamma_t \mathbb{V}ar_t(\mathbf{R}_{t+1}) \mathbf{s}_t + \Gamma_t \mathbb{C}ov_t(\mathbf{R}_{t+1}, \mathbf{R}_{t+1}^N) \mathbf{y}_t, \quad (3)$$

where $\Gamma_t \equiv \left[\frac{w_t^B}{\alpha \lambda_t} + \frac{w_t^I}{\sigma} \right]^{-1} (w_t^B + w_t^I)$. The global component of risky asset prices is equal to the aggregate variance scaled by the aggregate degree of effective risk aversion Γ_t .

Γ_t is the wealth-weighted average of the ‘risk aversions’ of the asset managers and the global banks. It can be interpreted as the aggregate degree of effective risk aversion of the market. If all the wealth were in the hands of asset managers, for example, aggregate risk aversion would be equal to σ . Using Eq. (3) as a guiding framework, in Section 2 we extracted the global factor in world risky asset prices by writing each price series as the sum of a global, a regional and an asset specific component. We then used Eq. (3) to extract our empirical proxy for aggregate risk aversion Γ_t .³⁴ One possible interpretation of the decline in the measure of aggregate risk aversion observed between 2003 and 2007 in Figure 3 is therefore that it was driven by risk-neutral global banks becoming large and important for the pricing of risky assets, sustaining an increase in risky asset prices on a global scale. This trend reversed after the crisis, when instead more risk-averse asset managers became relatively bigger (see Figure 4).

Proposition 2 (Global Banks Returns) *The expected excess return of a global bank portfolio in our economy is given by*

$$\begin{aligned} \mathbb{E}_t(\mathbf{x}_t^{B'} \mathbf{R}_{t+1}) &= \Gamma_t \mathbb{C}ov_t(\mathbf{x}_t^{B'} \mathbf{R}_{t+1}, \mathbf{s}_t' \mathbf{R}_{t+1}) + \Gamma_t \mathbb{C}ov_t(\mathbf{x}_t^{B'} \mathbf{R}_{t+1}, \mathbf{y}_t' \mathbf{R}_{t+1}^N) \\ &= \beta_t^{BW} \Gamma_t \mathbb{V}ar_t(\mathbf{R}_{t+1}) \mathbf{s}_t + \Gamma_t \mathbb{C}ov_t(\mathbf{x}_t^{B'} \mathbf{R}_{t+1}, \mathbf{y}_t' \mathbf{R}_{t+1}^N), \end{aligned} \quad (4)$$

where β_t^{BW} is the beta of a global bank with the world market portfolio.

The higher the correlation of a global bank portfolio with the world portfolio (i.e. high- β_t^{BW}), the more the bank loads on world risk, the higher the expected asset return, *ceteris paribus*.

³⁴As mentioned earlier, in general our empirical proxy for aggregate risk aversion could also reflect other factors such as expected dividend growth or risk free rates. We however control for these other factors in the Bayesian VARs.

4.2 Evidence on Global Banks

In this section we use balance sheet data to provide some evidence on the risk taking behavior of banks, in line with our simple model. [Adrian and Shin \(2010\)](#) show that the leverage of US brokers-dealers is procyclical. Using balance sheet data for a large sample of international financial institutions (see [Table A.4](#)), some of which were used to construct the leverage aggregates in [Section 3](#), we find that the positive association between leverage growth and balance sheet growth goes well beyond US borders. We report these results in [Figure A.3](#) in the Appendix.³⁵ The procyclicality of leverage tends to be a stronger feature of the behavior of financial institutions that engage in global capital markets operations, a subset which included in particular the former stand-alone investment banks. The same holds true for the large European (UK, Euro Area and Switzerland) universal banks, whose investment departments have played a central role in channelling US dollar liquidity worldwide in the years immediately preceding the financial crisis (see [Shin, 2012](#)). Many of those large European Banks are GSIBs.

[Figure 11](#) is the empirical counterpart of [Eq. \(4\)](#), and reports the correlation between the returns of each bank and their loading (β_t^{BW}) on the world portfolio, summarized by our global factor of [Section 2](#). Results in panels (a) and (b) are calculated over the entire population of banks, while panels (c) and (d) refer to the GSIBs subsample, and we use August 2007 to distinguish between pre and post crisis periods. Results confirm a positive association between high β_t^{BW} and high returns in the pre crisis sample. Panels (a) and (c) show that, relative to the larger population, GSIBs tend to have both higher average betas, and larger returns. This suggests that global banks were systematically loading more on world risk in the run-up to the financial crisis, and that their behaviour was delivering larger average returns, compared to the average bank in our sample. The higher loadings on risk are consistent with the build-up of leverage in the years prior to the crisis documented in [Figure A.2](#). Furthermore, panels (b) and (d) sort the banks on the x-axis according to their pre-crisis betas, but report their post crisis returns on the y axis. The charts show how the institutions that were loading more on global risk pre

³⁵We calculate leverage along the lines of [Kalemli-Ozcan et al. \(2012\)](#). We use a panel 166 financial institutions in 20 countries from 2000 to 2010. We identify a subset of 21 large banks who have been classified as Globally Systemically Important Banks (GSIBs). A complete list of institutions included in our set is in [Table A.4](#).

FIGURE 11: CORRELATION BETWEEN BANKS' RETURNS AND LOADING ON THE GLOBAL FACTOR

Note: In each subplot, the x axis reports the average β^{BW} in the three years preceding the onset of the financial crisis (August 2007), while the y axis records average returns in percentage points. Filled blue circles highlight GSIBs within the broader population of banks (hollow circles); the sign of the correlation is visualized by a red regression line in each plot. Panels (a) and (b): banks average returns pre (2003-2007) and post (2007-2010) crisis as a function of their pre-crisis betas. Panels (c) and (d) GSIBs subsample. *Source:* Datastream, authors calculations.

crisis suffered the largest losses after the systemic meltdown began.

5 Conclusions

This paper establishes the importance of US monetary policy as one of the drivers of the Global Financial Cycle. First, we show that a single global factor explains an important share of the common variation of a large cross section of risky asset prices around the world. Using a simple model of international asset pricing featuring heterogeneous investors, we interpret this global factor as reflective of global market volatility, and the aggregate degree of risk aversion in global markets. Second, using data covering world aggregates, we show that US monetary policy shocks induce strong comovements in the international financial variables that characterize the Global Financial Cycle. In partic-

ular, monetary contractions are followed by a significant deleveraging of global financial intermediaries, a rise in aggregate risk aversion, and a significant contraction in the global factor in asset prices, global credit, a widening of corporate bond spreads and strong retrenchments of international capital flows. These results also hold for the countries of our sample with floating exchange rates. This is an important result, as it challenges the degree of monetary policy sovereignty of open economies, and echoes the claim of [Rey \(2013\)](#) that the Mundellian trilemma may have really morphed into a dilemma: as long as capital flows across borders are free, and macroprudential tools are not used, monetary conditions in any country, even one with a flexible exchange rate, are partly dictated by the monetary policy of the hegemon (the US). This of course does not mean that exchange rate regimes do not matter, as [Klein and Shambaugh \(2013\)](#) and [Obstfeld \(2015\)](#) rightly point out.³⁶ This international transmission mechanism of monetary policy is a priori consistent with models where financial market imperfections play an important role, for example via Value-at-Risk constraints. It still remains to be seen, however, whether open economy extensions of these models would be able to generate a Global Financial Cycle whose features would match the empirical regularities uncovered in this paper.³⁷

³⁶For interesting theoretical modelling of the challenges of the trilemma in a standard neo-Keynesian model, see [Farhi and Werning, 2012, 2013](#)).

³⁷For a more detailed discussion of the theoretical challenges when modelling international monetary policy transmission channels, see [Bernanke \(2017\)](#) and [Rey \(2016\)](#).

A Credit and Banking Data – For Online Publication

A.1 Domestic and Cross-Border Credit

Credit data, both domestic and cross-border, are constructed using data collected and distributed by the IMF’s International Financial Statistics (IFS) and the Bank for International Settlements (BIS) databases respectively, for the countries listed in table A.1.

FIGURE A.1: GLOBAL CREDIT

Note: Global Domestic Credit and Global Cross-Border Inflows constructed as the cross sectional sum of country-specific credit variables. The unit in both plots is Billion USD.

Following [Gourinchas and Obstfeld \(2012\)](#) we construct National Domestic Credit for each country as the difference between Domestic Claims to All Sectors and Net Claims to Central Government reported by each country’s financial institutions; however, we only consider claims of depository corporations excluding central banks. Specifically, we refer to the Other Depository Corporation Survey available within the IFS database and construct Claims to All Sectors as the sum of Claims On Private Sector, Claims on Public Non Financial Corporations, Claims on Other Financial Corporations and Claims on State And Local Government; while Net Claims to Central Government are calculated as the difference between Claims on and Liabilities to Central Government. This classification was adopted starting from 2001, prior to that date we refer to the Deposit Money Banks Survey. Raw data are quarterly and expressed in national currency, we convert them in Billion USD equivalents using end of period exchange rates again available within the IFS. Whenever there exists a discontinuity between data available under the old and new classifications we interpolate the missing observations. Global

TABLE A.1: LIST OF COUNTRIES INCLUDED

| North America | Latin America | Central and Eastern Europe | Western Europe | Emerging Asia | Asia Pacific | Africa and Middle East | |
|---------------|---------------|----------------------------|----------------|---------------|--------------|------------------------|--|
| Canada | Argentina | Belarus | Austria | China | Australia | Israel | |
| US | Bolivia | Bulgaria | Belgium | Indonesia | Japan | South Africa | |
| | Brazil | Croatia | Cyprus | Malaysia | Korea | | |
| | Chile | Czech Republic | Denmark | Singapore | New Zealand | | |
| | Colombia | Hungary | Finland | Thailand | | | |
| | Costa Rica | Latvia | France | | | | |
| | Ecuador | Lithuania | Germany | | | | |
| | Mexico | Poland | Greece* | | | | |
| | | Romania | Iceland | | | | |
| | | Russian Federation | Ireland | | | | |
| | | Slovak Republic | Italy | | | | |
| | | Slovenia | Luxembourg | | | | |
| | | Turkey | Malta | | | | |
| | | | Netherlands | | | | |
| | | | Norway | | | | |
| | | | Portugal | | | | |
| | | Spain | | | | | |
| | Sweden | | | | | | |
| | Switzerland | | | | | | |
| | UK | | | | | | |

Note: Countries included in the construction of the Domestic Credit and Cross-Border Credit variables used throughout the paper. Greece is not included in the computation of Global Domestic Credit due to poor quality of original national data.

Domestic Credit is finally constructed as the cross-sectional sum of the National Domestic Credit variables.

To construct the Cross-Border Capital Inflows measures used within the paper we adopt the definition of Direct Cross-Border Credit in [Avdjiev et al. \(2012\)](#). We use original data available at the BIS Locational Banking Statistics Database and collected under External Positions of Reporting Banks vis-à-vis Individual Countries (Table 6). Data refer to the outstanding amount of Claims to All Sectors and Claims to Non-Bank Sector in all currencies, all instruments, declared by all BIS reporting countries with counterparty location being the individual countries in Table A.1. We then construct Claims to the Banking Sector as the difference between the two categories available. Original data are available at quarterly frequency in Million USD. Global Inflows are

finally calculated as the cross-sectional sum of the national variables. Global domestic credit and global cross-border capital inflows are plotted in Figure A.1.

A.2 Banking Sector and Individual Banks Leverage data

To construct an aggregate country-level measure of banking sector leverage we follow [Forbes \(2012\)](#) and build it as the ratio between Claims on Private Sector and Transferable plus Other Deposits included in Broad Money of depository corporations excluding central banks. Original data are in national currencies and are taken from the Other Depository Corporations Survey; Monetary Statistics, International Financial Statistics database. The classification of deposits within the former Deposit Money Banks Survey corresponds to Demand, Time, Savings and Foreign Currency Deposits. Using these national data as a reference, we construct the European Banking Sector Leverage variable as the median leverage ratio among Austria, Belgium, Denmark, Finland, France, Germany, Greece, Ireland, Italy, Luxembourg, Netherlands, Portugal, Spain and United Kingdom.

FIGURE A.2: EUROPEAN BANKS LEVERAGE

Note: [LEFT PANEL] Leverage ratio calculated for the European GSIBs with a detail on EUR and GBP banks using the institutions and classification in Table A.2. [RIGHT PANEL] Aggregated European banking sector leverage ratio measured as the median of European countries banking sector leverage variables following [Forbes \(2012\)](#).

The aggregate Leverage Ratios (defined as Total Assets over Equity) for the Global Systemic Important Banks in the Euro-Area and United-Kingdom used in the BVAR are constructed as weighted averages of individual banks data. Balance sheet Total Assets (DWTA) and Shareholders' Equity (DWSE) are from the Thomson Reuter Worldscope

TABLE A.2: EUROPEAN G-SIBS.

| NAME | ISIN | GICS INDUSTRY | COUNTRY | EA LEV | UK LEV |

| Lloyds Banking Group | GB0008706128 | Commercial Banks | UK | | • |
| Standard Chartered | GB0004082847 | Diversified Fin'l | UK | | • |

Note: European Global Systemically Important Banks included in the construction of GSIBs Leverage Ratios; the last two columns highlight the components of EUR and GDP Leverage respectively.

Datastream database and available at quarterly frequency. Weights are proportional to Market Capitalisation (WC08001) downloaded from the same source. Details on the banks included and their characteristics are summarised in Table A.2 below. The aggregated banking sector leverage and the leverage ratio of the European GSIBs are plotted in Figure A.2.

Figures 11 and A.3 are built using data on individual banks total return indices excluding dividends taken from Thomson Reuters Worldscope database at quarterly frequency. Data are collected directly from banks balance sheets and Leverage Ratios are computed as the ratio between Total Assets (DWTA) and Common/Shareholders' Equity (DWSE). Total Assets include cash and due from banks, total investments, net loans, customer liability on acceptances (if included in total assets), investment in unconsolidated subsidiaries, real estate assets, net property, plant and equipment, and other assets. Descriptive statistics for bank level data and a complete list of the institutions included in the sample are provided in Tables A.3 and A.4 respectively. Although the data source is different, the calculation follows Kalemli-Ozcan et al. (2012).

TABLE A.3: BANK DATA SUMMARY STATISTICS.

Notes: In the first column are the ISIN identification codes followed by the institution's name, geographical location and country of reference. The last column highlights the subset of institutions which have been classified as Global Systemically Important Banks (G-SIBs) previously known as G-SIFs (Systemically Important Financial Institutions); the classification has been adopted by the Financial Stability Board starting from November 2011 and lastly updated in November 2013.

FIGURE A.3: QUARTERLY ASSET GROWTH OVER QUARTERLY LEVERAGE GROWTH ACROSS DIFFERENT GLOBAL FINANCIAL INSTITUTIONS

Note: The red line in each subplot is the 45 degree line. Clockwise, from top left panel, the relationship between balance sheet size and leverage for GIBs, commercial banks, institutions operating in capital markets and other financial institutions. The classification matches GICS industry codes for each entry in the sample. Source: Datastream, authors calculations.

B Dynamic Factor Model for World Risky Asset Prices – For Online Publication

Let p_t be an n -dimensional vector collecting monthly (log) asset price series $p_{i,t}$, where $p_{i,t}$ denotes the price for asset i at date t . We assume

$$p_t = \Lambda F_t + \xi_t . \quad (\text{B.1})$$

F_t is an $(r \times 1)$ vector of common factors ($F_t = [f_{1,t}, \dots, f_{r,t}]'$) that capture systematic sources of variation among prices and are loaded via the coefficients in Λ that determine how each price series reacts to the common shocks. ξ_t is a $(n \times 1)$ vector of idiosyncratic shocks $\xi_{i,t}$ that capture series-specific variability or measurement errors. We allow elements in ξ_t to display some degree of autocorrelation while we rule out pairwise correlation between assets assuming that all the co-variation is accounted for by the common component. Both the common factors and the idiosyncratic terms are assumed to be zero mean processes.

The factors are assumed to follow a VAR process of order p

$$F_t = \Phi_1 F_{t-1} + \dots + \Phi_p F_{t-p} + \varepsilon_t, \quad (\text{B.2})$$

where the autoregressive coefficients are collected in the p matrices Φ_1, \dots, Φ_p , each of which is $(r \times r)$; the error term ε_t is a normally distributed zero mean process with covariance matrix Q . Any residual autocorrelation is captured by the idiosyncratic component which we assume being a collection of independent univariate autoregressive processes.

In order to distinguish between comovements at different levels of aggregation we model asset prices such that each series is a function of a global factor, a regional factor and an idiosyncratic term. We do so by allowing the vector of common shocks to include both aggregate shocks that affect all series in y_t , and shocks that affect many but not all of them:

$$p_{i,t} = \lambda_{i,g} f_t^g + \lambda_{i,m} f_t^m + \xi_{i,t} . \quad (\text{B.3})$$

In Eq. (B.3) the common component ΛF_t is separated into a global factor (f_t^g) and a regional or market-specific factor (f_t^m) which is meant to capture commonalities among many but not all price series. Each $p_{i,t}$ is thus a function of a global factor loaded by all the variables in p_t , a regional or market-specific factor only loaded by those series in p_t that belong to the (geographical or sector-specific) market m , and of a series-specific factor.

Such hierarchical structure is imposed via zero restrictions on some of the elements in

Λ . In particular, we assume the common component to be partitioned into a global and several regional factors. To this aim, let the variables in y_t be such that it is possible to univocally allocate them in B different blocks or regions and, without loss of generality, assume that they are ordered according to the specific block they refer to such that $y_t = [y_t^1, y_t^2, \dots, y_t^B]'$. Eq. (B.1) can be rewritten as

$$p_t = \begin{pmatrix} \Lambda_{1,g} & \Lambda_{1,1} & 0 & \cdots & 0 \\ \Lambda_{2,g} & 0 & \Lambda_{2,2} & & \vdots \\ \vdots & \vdots & & \ddots & 0 \\ \Lambda_{B,g} & 0 & \cdots & 0 & \Lambda_{B,B} \end{pmatrix} \begin{pmatrix} f_t^g \\ f_t^1 \\ f_t^2 \\ \vdots \\ f_t^B \end{pmatrix} + \xi_t. \quad (\text{B.4})$$

Moreover, further restrictions are imposed on the coefficient matrices in Eq. (B.2) such that Φ_i (i, \dots, p) and Q are block diagonal.

The model in Eq. (B.1-B.2) can be cast in state space form and the unknowns consistently estimated via Maximum Likelihood (Doz et al., 2011; Engle and Watson, 1981; Reis and Watson, 2010; Bańbura et al., 2011). The algorithm is initialized using principal component estimates of the factors that are proven to provide a good approximation of the common factors when the cross sectional dimension is large.³⁸ We estimate the model on the price series in (log) difference and obtain the factors via cumulation.³⁹ We set the number of lags in the factors VAR (p) to be equal to 1. We fit to the data a model with one global and one factor per block/market; the parametrization is motivated by the results in Table B.2.

We fit the model to a vast collection of prices of different risky assets. The geographical areas covered are North America (US and Canada), Latin America (Brazil, Chile, Colombia, and Mexico), Europe (Euro Area, UK, Switzerland and the Scandinavian Countries), Asia Pacific (Japan, Hong Kong, Singapore, Korea, Taiwan), and Australia. The set of commodities considered does not include precious metals. The time span covered is from January 1990 to December 2012. In order to select the series that are included in the global set we proceed as follows: first, for each market, we pick a representative market index (i.e. S&P) and all of its components as of the end of 2012, we then select those that allow us to cover at least 80% of the cross sectional observations by the beginning of 1990, and such that by 1995 we reach a 95% coverage.⁴⁰ The procedure allows us to build

³⁸Forni et al. (2000); Bai and Ng (2002); Stock and Watson (2002b,a) among others.

³⁹Let $\tilde{x}_t \equiv \Delta x_t$ denote the first difference for any variable x_t , then consistent estimates of the common factors in F_t can be obtained by cumulating the factors estimated from the stationary, first-differenced model: $\tilde{p}_t = \Lambda \tilde{F}_t + \tilde{\xi}_t$. In particular, $\hat{F}_t = \sum_{s=2}^t \hat{\tilde{F}}_s$ and $\hat{\xi}_t = \sum_{s=2}^t \hat{\tilde{\xi}}_s$. Bai and Ng (2004) show that \hat{F}_t is a consistent estimate of F_t up to a scale and an initial condition F_0 .

⁴⁰While estimating the Dynamic Factor Model using Maximum Likelihood does not constrain us to

TABLE B.1: COMPOSITION OF ASSET PRICE PANELS

| | North America | Latin America | Europe | Asia Pacific | Australia | Cmdy | Corporate | Total |
|-----------|---------------|---------------|--------|--------------|-----------|------|-----------|-------|
| 1975:2010 | 114 | – | 82 | 68 | – | 39 | – | 303 |
| 1990:2012 | 364 | 16 | 200 | 143 | 21 | 57 | 57 | 858 |

Note: Composition of the panels of asset prices used for the estimation of the global factor. Columns denote blocks/markets in each set, while the number in each cell corresponds to the number of elements in each block.

a final dataset with an overall cross-sectional dimension of $n = 858$. The composition is reported in Table B.1, where each category (in columns) corresponds to one of the blocks (m) within the structure imposed.

Although all series included in the set are priced in US dollars, we verify that the shape of the global factor is not influenced by this choice by estimating the same model on price series in their local currencies (i.e. the currency in which the assets are originally traded). The resulting global factor (not shown) is very similar to the one constructed from the dollar-denominated set both in terms of overall shape and of peaks and troughs that perfectly coincide throughout the time span considered. Intuitively, the robustness of the estimate of the global factor with respect to currency transformations comes directly from the structure imposed in Eq. (B.3). The blocks/markets structure imposed roughly coincides with currency areas, therefore this aspect is likely to be largely captured by the regional factors (see Table B.1).

B.1 The Number of Factors

To choose the number of global factors we use a number of criteria and tests, collected in Table B.2. The table reports the percentage of variance that is explained by the i -th eigenvalue (in decreasing order) of both the covariance matrix and the spectral density matrix, the information criteria in Bai and Ng (2002), where the residual variance of the idiosyncratic component is minimized subject to a penalty function increasing in r , and the test developed in Onatski (2009), where the null of $r - 1$ factors is tested against the alternative of r common factors. The largest eigenvalue alone, in both the time and frequency domain, accounts for about 60% of the variability in the data in the longer set and about a fourth of the variation in the shorter, but more heterogeneous set; similarly, the IC criteria reach their minimum when one factor is used, and the overall picture is confirmed by the the p-values for the Onatski test.

work with a fully balanced panel, we want to ensure that none of the categories included in the set is overrepresented at any point in time.

TABLE B.2: NUMBER OF GLOBAL FACTORS.

| r | % Covariance Matrix | % Spectral Density | IC_p1 | IC_p2 | IC_p3 | Onatski (2009) Test |
|---------------|---------------------|--------------------|---------|---------|---------|---------------------|
| (a) 1975:2010 | | | | | | |
| 1 | 0.662 | 0.579 | -0.207 | -0.204 | -0.217 | 0.015 |
| 2 | 0.117 | 0.112 | -0.179 | -0.173 | -0.198 | 0.349 |
| 3 | 0.085 | 0.075 | -0.150 | -0.142 | -0.179 | 0.360 |
| 4 | 0.028 | 0.033 | -0.121 | -0.110 | -0.160 | 0.658 |
| 5 | 0.020 | 0.024 | -0.093 | -0.079 | -0.142 | 0.195 |
| (b) 1990:2012 | | | | | | |
| 1 | 0.215 | 0.241 | -0.184 | -0.183 | -0.189 | 0.049 |
| 2 | 0.044 | 0.084 | -0.158 | -0.156 | -0.169 | 0.064 |
| 3 | 0.036 | 0.071 | -0.133 | -0.129 | -0.148 | 0.790 |
| 4 | 0.033 | 0.056 | -0.107 | -0.102 | -0.128 | 0.394 |
| 5 | 0.025 | 0.049 | -0.082 | -0.075 | -0.108 | 0.531 |

Note: For both sets and each value of r the table shows the % of variance explained by the r -th eigenvalue (in decreasing order) of the covariance matrix of the data, the % of variance explained by the r -th eigenvalue (in decreasing order) of the spectral density matrix of the data, the value of the IC_p criteria in Bai and Ng (2002) and the p-value for the Onatski (2009) test where the null of $r - 1$ common factors is tested against the alternative of r common factors.

C Bayesian VAR – For Online Publication

Let Y_t denote a set of n endogenous variables, $Y_t = [y_{1t}, \dots, y_{Nt}]'$, with n potentially large, and consider for it the following VAR(p):

$$Y_t = c + A_1 Y_{t-1} + \dots + A_p Y_{t-p} + u_t. \quad (\text{C.1})$$

In Eq. (C.1) c is an $(n \times 1)$ vector of intercepts, the n -dimensional A_i ($i = 1, \dots, p$) matrices collect the autoregressive coefficients, and u_t is a normally distributed error term with zero mean and variance $\mathbb{E}(u_t u_t') = \Sigma$. We estimate the VAR using standard macroeconomic priors (Litterman, 1986; Kadiyala and Karlsson, 1997; Sims and Zha, 1998; Doan et al., 1983; Sims, 1993); in particular, we use a Normal-Inverse Wishart prior for the VAR coefficients. The Normal-Inverse Wishart prior takes the following

form:

$$\Sigma \sim \mathcal{W}^{-1}(\Psi, \nu) \quad (\text{C.2})$$

$$\beta|\Sigma \sim \mathcal{N}(b, \Sigma \otimes \Omega) \quad (\text{C.3})$$

where β is a vector collecting all the VAR parameters, i.e. $\beta \equiv \text{vec}([c, A_1, \dots, A_p]')$. The degrees of freedom of the Inverse-Wishart are set such that the mean of the distribution exists and are equal to $\nu = n + 2$, Ψ is diagonal with elements ψ_i which are chosen to be a function of the residual variance of the regression of each variable onto its own first p lags. More specifically, the parameters in Eq. (C.2) and Eq. (C.3) are chosen to match the moments for the distribution of the coefficients in Eq. (C.1) defined by the Minnesota priors:

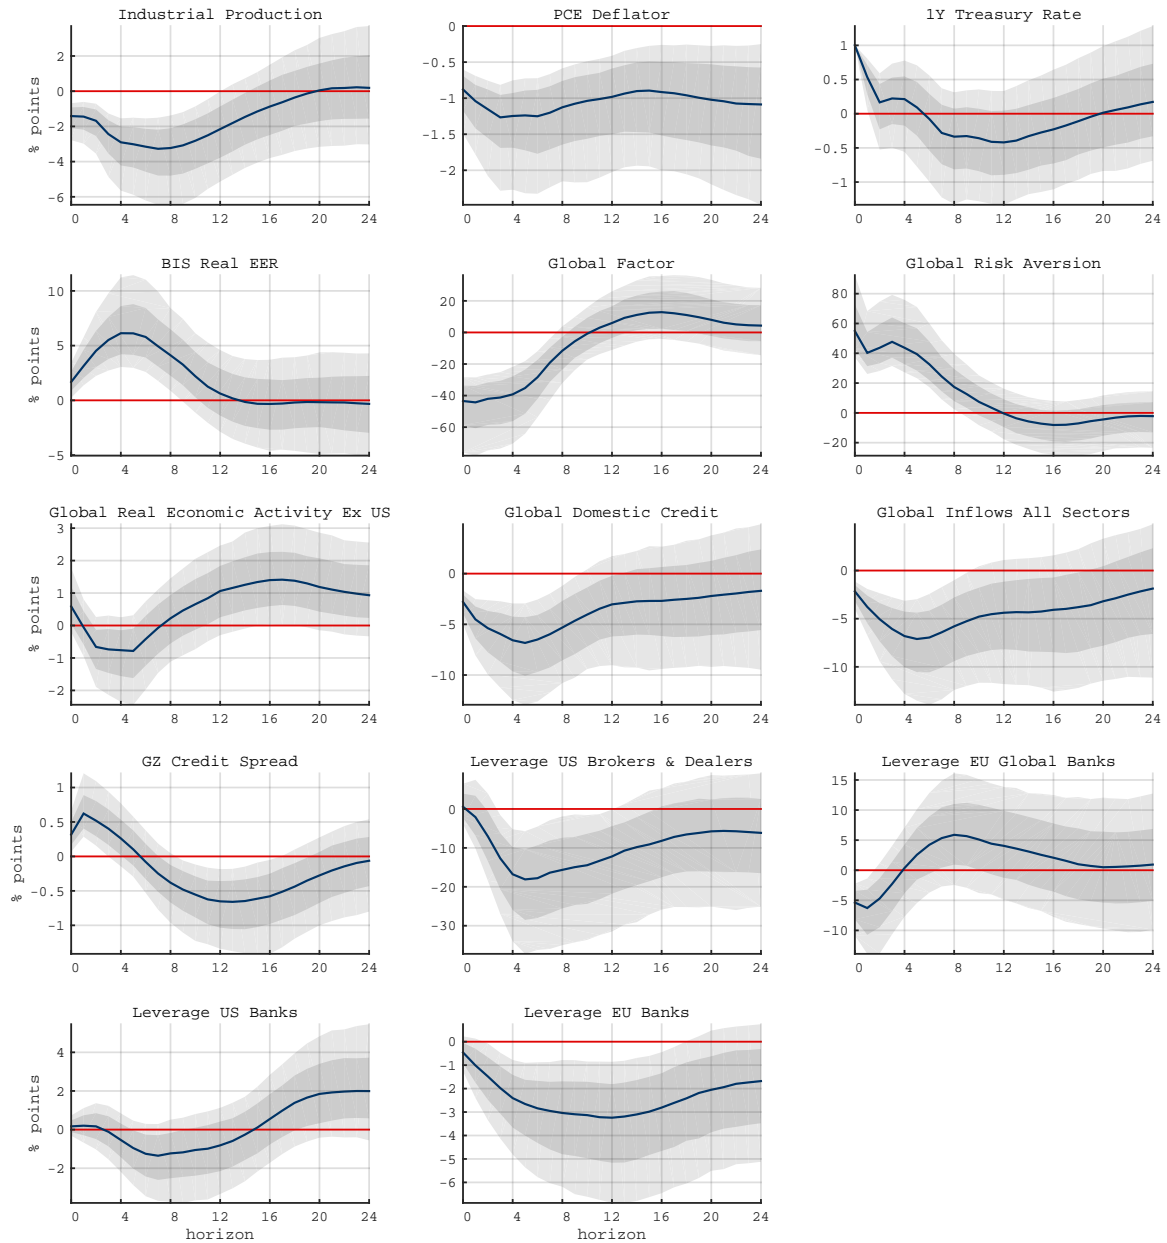

$$\mathbb{E}[(A_i)_{jk}] = \begin{cases} \delta_j & i = 1, j = k \\ 0 & \text{otherwise} \end{cases} \quad \text{Var}[(A_i)_{jk}] = \begin{cases} \frac{\lambda^2}{i^2} & j = k \\ \frac{\lambda^2}{i^2} \frac{\sigma_k^2}{\sigma_j^2} & \text{otherwise,} \end{cases} \quad (\text{C.4})$$

where $(A_i)_{jk}$ denotes the element in row (equation) j and column (variable) k of the coefficients matrix A at lag i ($i = 1, \dots, p$). When $\delta_j = 1$ the random walk prior is strictly imposed on all variables; however, for those variables for which this prior is not suitable we set $\delta_j = 0$ as in Bańbura et al. (2010). On the right hand side of Eq. (C.4), the variance of the elements in A_i is assumed to be proportional to the (inverse of the) square of the lag (i^2), and to the relative variance of the variables.

λ is the hyperparameter that governs the overall tightness of the priors. We follow Giannone et al. (2015) and treat the λ as an additional model parameter which we estimate in the spirit of hierarchical modelling.
