We apply the multicanonical Monte Carlo (MMC) method to compute the probability distribution of the received voltage in a chirped return-to-zero system. When computing the probabilities of very rare events, the MMC technique greatly enhances the efficiency of Monte Carlo simulations by biasing the noise realizations. Our results agree with the covariance matrix method over 20 orders of magnitude. The MMC method can be regarded as iterative importance sampling that automatically converges toward the optimal bias so that it requires less *a priori* knowledge of the simulated system than importance sampling requires. A second advantage is that the merging of different regions of a probability distribution function to obtain the entire function is not necessary in many cases. © 2003 Optical Society of America

The accurate computation of bit error rates and the probability distribution function (pdf) of the received voltage in optical communications systems depends on modeling very rare events with probabilities of the order of  $10^{-16}$ – $10^{-6}$ . When forward error correction is used, it is still important to accurately model the voltage pdfs before correction.<sup>1</sup> One traditional way of computing bit error rates and eye diagrams is to run Monte Carlo simulations and extrapolate the results under the assumption that the electrical voltage at the receiver after narrowband filtering is distributed in a Gaussian shape in the marks (ones) and spaces (zeros). If the noise realizations in the Monte Carlo simulation are picked in an unbiased way, as is commonly done, this method cannot yield information about the tails of the pdf within a reasonable computational time. As a consequence, system designers often use a simplified approach in which they assume that the optical noise spectrum at the receiver is white, effectively neglecting the nonlinear signal–noise interaction in the fiber. This simplification is inappropriate for many long-haul optical communications systems. In contrast, the covariance matrix method does take into account the nonlinear signal–noise interaction and works for nonlinear systems.<sup>2–4</sup> However, it can fail in principle when the nonlinear noise–noise interaction in the fiber becomes large.

In this Letter we apply the multicanonical Monte Carlo (MMC) simulation technique that was proposed by Berg and Neuhaus<sup>5</sup> in 1992. The MMC method is closely related to importance sampling<sup>6</sup> in the sense that both methods increase the number of events in the tail region of the pdf by biasing them. In standard importance sampling one needs to guess which regions of the state space are the major source of the bit errors and devise a set of biases that will preferentially sample these regions. The MMC method automatically determines the bias with an iterative procedure. The iterative procedure uses a control

quantity to update the set of biases for the next iteration, so that, as the iteration number increases, there tends to be an approximately equal number of hits in each bin of the histogram of the control quantity.<sup>5</sup> Moreover, the merging of different regions of a distribution<sup>7</sup> is not necessary in many cases. Recently, Yevick<sup>8</sup> successfully applied the MMC method to compute polarization-mode-dispersion emulator statistics, demonstrating that the MMC method can be applied to any continuous probability distribution as opposed to density of state functions for discrete spin systems that Berg had studied in Refs. 5 and 9. In this Letter we outline the MMC algorithm, and we then employ it to compute the received-voltage pdfs in an optical communications system and compare these pdfs with the pdfs that we previously computed with the covariance matrix method.<sup>3</sup>

We introduce a state space  $\Gamma$  with a probability density  $\rho$ , i.e.,  $\rho(\mathbf{z}) \geq 0$  and  $\int_{\Gamma} \rho(\mathbf{z}) d\mathbf{z} = 1$ . When computing bit errors due to noise,  $\Gamma$  is the space of all possible amplified-spontaneous-emission noise inputs at all amplifiers and all frequencies. We want to compute the pdf  $p(V)$  for each value of the received voltage  $V$ . We partition  $\Gamma$  into  $M$  subspaces  $\Gamma_k = \{\mathbf{z} \in \Gamma \mid (k-1)\Delta V \leq V(\mathbf{z}) < k\Delta V\}$ , where  $\Delta V$  is a small voltage difference and  $1 \leq k \leq M$ . If  $P_k = \int_{(k-1)\Delta V}^{k\Delta V} p(V) dV$  is the probability that  $(k-1)\Delta V \leq V(\mathbf{z}) < k\Delta V$ , then

$$P_k = \int_{\Gamma} \chi_k(\mathbf{z}) \rho(\mathbf{z}) d\mathbf{z}, \quad (1)$$

where  $\chi_k(\mathbf{z}) = 1$  if  $\mathbf{z} \in \Gamma_k$ , and  $\chi_k(\mathbf{z}) = 0$  otherwise. One can use a standard Monte Carlo simulation to approximate  $P_k$  by

$$P_k \approx \frac{1}{N} \sum_{i=1}^N \chi_k(\mathbf{z}^i), \quad (2)$$

where the  $\mathbf{z}^i$  are  $N$  random sample points in  $\Gamma$ , selected according to the probability density  $\rho$ .

The goal of any biasing scheme, including the MMC method, is to reduce the variance of the sum in relation (2) by introducing a positive biasing pdf  $\rho^*(\mathbf{z})$ . We rewrite Eq. (1) and relation (2) as<sup>6</sup>

$$P_k = \int_{\Gamma} \chi_k(\mathbf{z}) \frac{\rho(\mathbf{z})}{\rho^*(\mathbf{z})} \rho^*(\mathbf{z}) d\mathbf{z} \approx \frac{1}{N} \sum_{i=1}^N \chi_k(\mathbf{z}^{*,i}) \frac{\rho(\mathbf{z}^{*,i})}{\rho^*(\mathbf{z}^{*,i})}, \quad (3)$$

where the  $\mathbf{z}^{*,i}$  are sampled from  $\rho^*(\mathbf{z})$  instead of  $\rho(\mathbf{z})$ . The ratio  $L = \rho(\mathbf{z}^{*,i})/\rho^*(\mathbf{z}^{*,i})$  is called the likelihood ratio. The variance of the sum in relation (3) is zero if the optimal biasing pdf  $\rho^*(\mathbf{z}) = \rho_{\text{opt}}^*(\mathbf{z}) = \chi_k(\mathbf{z})\rho(\mathbf{z})/P_k$  is used. However,  $\rho_{\text{opt}}^*(\mathbf{z})$  depends on  $P_k$  and hence is initially unknown. In standard importance sampling one uses physical intuition to guess a biasing pdf that is close to  $\rho_{\text{opt}}^*$ . The MMC algorithm instead iterates over biasing pdfs  $\rho^{*,j}$  that approach  $\rho_{\text{opt}}^*$ . We define  $\rho^{*,j}$  for the  $j$ th iteration by

$$\rho^{*,j}(\mathbf{z}) = \frac{\rho(\mathbf{z})}{c^j P_k^j}, \quad \mathbf{z} \in \Gamma_k. \quad (4)$$

The quantities  $P_k^j$  satisfy  $P_k^j > 0$  and  $\sum_{k=1}^M P_k^j = 1$ , where we recall that  $M$  is the number of partitions of the state space and  $c^j$  is an unknown constant that ensures  $\int_{\Gamma} \rho^{*,j}(\mathbf{z}) d\mathbf{z} = 1$ . The vector of  $P_k^j$  is the key quantity in the MMC algorithm and completely determines the bias.  $P_k^j$  are updated after each iteration such that, after a number of iterations, the expected number of samples in each bin of the histogram is  $\langle \sum_{i=1}^N \chi_k(\mathbf{z}^{*,i}) \rangle = N/M$  and is hence independent of  $k$ .<sup>9</sup> Substituting this value in relation (3) and Eq. (4) yields  $c^j \rightarrow M$  and  $P_k^j \rightarrow P_k$ .<sup>10</sup> We will discuss the assumptions under which this convergence can be achieved in a later publication.

Within each MMC iteration  $j$  we employ the Metropolis algorithm<sup>11</sup> to produce a random walk of samples  $\mathbf{z}^{*,i}$  whose distribution equals  $\rho^{*,j}(\mathbf{z})$ . We consider a Markov chain of transitions consisting of small steps in the noise space. Each transition goes from  $\mathbf{z}^{*,i} = \mathbf{z}_a^* \in \Gamma_k$  to  $\mathbf{z}_b^* = \mathbf{z}_a^* + \epsilon^j \Delta \mathbf{z}$ , where  $\Delta \mathbf{z}$  is random and symmetric; i.e., it does not favor any direction in  $\Gamma$ , and the transition is accepted with probability  $\pi_{ab}$ . If a transition from  $\mathbf{z}^{*,i} = \mathbf{z}_a^*$  to  $\mathbf{z}_b^*$  is accepted, we set  $\mathbf{z}^{*,i+1} = \mathbf{z}_b^*$ ; otherwise we set  $\mathbf{z}^{*,i+1} = \mathbf{z}^{*,i} = \mathbf{z}_a^*$ .

In our simulations  $\rho$  is the product of the pdfs of all amplified-spontaneous-emission noise inputs at each amplifier and each frequency, which we assume to be independent identical Gaussian pdfs  $\rho_l$  with  $\rho = \prod_{l=1}^d \rho_l$ , where  $d$  is the dimension of  $\Gamma$ . We consider the perturbation of the noise component in each bit  $z_{a,l}^*$  of  $\mathbf{z}_a^*$  separately and accept or reject it independently with the probability  $\min[\rho_l(z_{b,l}^*)/\rho_l(z_{a,l}^*), 1]$ . We pick each perturbation  $\Delta z_l$  from a zero-mean symmetric pdf. We obtain a trial state  $\mathbf{z}_b^*$  in which only some of the components are different from their previous values in  $\mathbf{z}_a^*$ . Next we compute  $k_b$  and finally accept the step from  $\mathbf{z}_a^*$  to  $\mathbf{z}_b^*$  with the probability  $\min(P_{k_a}^j/P_{k_b}^j, 1)$ . The compound transition probability

is hence

$$\pi_{ab} = \left\{ \prod_{l=1}^d \min \left[ \frac{\rho_l(\mathbf{z}_{b,l}^*)}{\rho_l(\mathbf{z}_{a,l}^*)}, 1 \right] \right\} \min \left( \frac{P_{k_a}^j}{P_{k_b}^j}, 1 \right). \quad (5)$$

The probability ratio  $\pi_{ab}/\pi_{ba}$  equals  $\rho^{*,j}(\mathbf{z}_b^*)/\rho^{*,j}(\mathbf{z}_a^*)$ , which is the detailed balance condition that ensures that the limiting (stationary) distribution for infinitely many steps of this random walk is  $\rho^{*,j}$ .<sup>11</sup>

In each iteration the perturbation coefficient  $\epsilon^j$  is constant for all samples. After each iteration, we adjust  $\epsilon^j$  so that the acceptance ratio  $\alpha$ , which is the ratio of the number of accepted steps to the total number of steps  $N$ , is close to 0.3. The minimum required number of samples  $N$  of this random walk depends on the average step size  $\alpha \epsilon^j \langle |\Delta \mathbf{z}| \rangle$  and is hence system dependent. The noise realizations are recorded in the histogram  $H^{*,j}$ , where  $H_k^{*,j} = \sum_{i=1}^N \chi_k(\mathbf{z}^{*,i})$  is the number of the  $\mathbf{z}^{*,i}$  in iteration  $j$  that fall into  $\Gamma_k$ .  $P_k^j$  are updated after each MMC iteration with the recursion relations given in Ref. 9 based on the histogram  $H^{*,j}$ . As  $j$  increases, the expected number of samples  $\langle H_k^{*,j} \rangle$  becomes independent of the bin number  $k$ , which implies that  $P_k^j \rightarrow P_k$ .

We note that we could in principle also pick all perturbations at the same time and accept the entire step with the probability  $\min[\rho(\mathbf{z}_b^*)P_{k_a}^j/\rho(\mathbf{z}_a^*)P_{k_b}^j, 1]$ . The advantage of our individual perturbation method is that we can use significantly larger perturbations  $\epsilon^j$ . However, this method works only in problems in which the pdf  $\rho$  factors into independent pdfs  $\rho_l$ .

In the first iteration one can set  $P_k^1 = 1/M$  or use an initial guess for the  $P_k^1$ . We have used both approaches. To update the  $P_k^j$  at the end of iteration  $j$ , we initially set  $P_1^{j+1}$  to an arbitrary positive value and use the recursion relations<sup>9</sup>

$$P_{k+1}^{j+1} = \frac{P_k^{j+1} P_{k+1}^j}{P_k^j} \left( \frac{H_{k+1}^{*,j}}{H_k^{*,j}} \right)^{\hat{g}_k^j}, \quad (6a)$$

$$\hat{g}_k^j = \frac{g_k^j}{\sum_{l=1}^j g_k^l}, \quad g_k^l = \frac{H_k^{*,l} H_{k+1}^{*,l}}{H_k^{*,l} + H_{k+1}^{*,l}}, \quad (6b)$$

where, in addition, we define  $\hat{g}_k^j = 0$  if  $g_k^j = 0$  and  $g_k^l = 0$  if  $H_k^{*,l} + H_{k+1}^{*,l} = 0$ . The exponent  $0 \leq \hat{g}_k^j \leq 1$  hence depends on all previous iterations. Finally, we normalize the  $P_k^{j+1}$  so that  $\sum_{k=1}^M P_k^{j+1} = 1$ .

We applied the MMC algorithm to a 10-Gbit/s, single-channel chirped return-to-zero (CRZ) system of 6100-km length that resembles a submarine system. Previously, we computed the pdf of the received voltage in this system with the covariance matrix method and compared its results with standard Monte Carlo simulations.<sup>3</sup> However, we were able to show agreement over only approximately 6 orders of magnitude. In contrast, the MMC method allows us to show agreement over approximately 20 orders of magnitude.

The state space  $\Gamma$  is of dimension  $d = (34 \text{ dispersion map periods}) \times (4 \text{ amplifiers per period}) \times (140 \text{ relevant frequencies}) \times 2 = 38,080$ , where the last factor of 2 accounts for the real and imaginary parts of

Fig. 1. Pdfs of the low-pass-filtered received voltage for the marks and the spaces in the CRZ system. The circles and crosses represent results from the last iteration of MMC simulations with 55,000 and 100,000 samples, respectively; the solid line and curve represent the covariance matrix method.

the optical noise. We launch a 32-bit pseudorandom binary sequence signal and calculate the average pdf of the received voltage in the marks by averaging over all 16 marks, and we use the same procedure in the spaces. We consider  $v(t_{1,n})$  and  $v(t_{0,n})$ , where  $t_{1,n}$  and  $t_{0,n}$  with  $n = 1 \dots 16$  are the points in time at the centers of the bit slots that contain a mark or a space, respectively, and  $v(t)$  is the low-pass-filtered received voltage as a function of time. We record the average pdfs of  $v(t_{1,n})$  and  $v(t_{0,n})$  in weighted histograms by quantizing  $v(t_{1,n})$  and  $v(t_{0,n})$ . For each noise realization  $\mathbf{z}^{*,i}$  we increment the value of the histogram in the appropriate bin by the likelihood ratio  $L = \rho(\mathbf{z}^{*,i})/\rho^*(\mathbf{z}^{*,i}) = c^j P_k^j$ ,  $\mathbf{z}^{*,i} \in \Gamma_k$ , according to relation (3). The pdfs of  $v(t_{1,n})$  and  $v(t_{0,n})$  can be regarded as vertical slices through an eye diagram.

Figure 1 shows the average pdf of  $v(t_{1,n})$  and  $v(t_{0,n})$  in the last MMC iteration. The voltage is normalized by  $\max_n[v(t_{1,n})]$  in the absence of noise. The solid line and curve show the results of the covariance matrix method, and the crosses and circles show the pdf from the MMC simulations for the marks and the spaces. The agreement is excellent.

Next we summarize additional details of the algorithm. To bias the marks, we want to decrease the maximum voltage in the marks to close the eye. We therefore choose the control quantity to be  $V = \min_n[v(t_{1,n})]$  for each noise realization. Conversely, we want to increase the voltage in the spaces, and in that simulation we set  $V = \max_n[v(t_{0,n})]$ . In our simulations the voltage  $V$  thus merely plays the role of a control quantity and has no other use.

We set  $M = 50$ . In the first iteration we choose  $N = N^{j=1} = 5000$  samples. The simulation covers a larger voltage range with each new iteration, and, moreover, the Metropolis random walk tends to accept more steps at voltages where  $p(V)$  is large than in the tails of  $p(V)$ . We therefore increase the number of samples after each iteration so that  $N^{j+1} = 1.15N^j$ . In the simulation of the marks we needed 50,000 total samples in eight iterations, and to simulate the spaces, we needed 101,000 total samples in ten iterations. We considered the simulation to have sufficiently converged when  $\max_k |(P_k^j - P_k^{j+1})/P_k^{j+1}| < 0.1$ , which is hardly visible on a log scale.

In conclusion, we have applied the MMC simulation technique to a CRZ system with a transmission distance of 6100 km. We were able to compute the pdfs of the low-pass-filtered received voltage over a range of 20 orders of magnitude. We compared this result with the covariance matrix method<sup>2-4</sup> and obtained excellent agreement, fully validating the covariance matrix method for this system. This result also demonstrates the usefulness of the MMC method for calculating the complete voltage pdf in a receiver while accounting for the full nonlinear noise-noise interaction in the fiber.
