first published online 24 June 2019)

We present large-eddy simulation (LES) of flow past different airfoils with Re_c , based on the free-stream velocity and airfoil chord length, ranging from 10^4 to 2.1×10^6 . To avoid the challenging resolution requirements of the near-wall region, we develop a virtual wall model in generalized curvilinear coordinates and incorporate the non-equilibrium effects via proper treatment of the momentum equations. It is demonstrated that the wall model dynamically captures the instantaneous skin-friction vector field on arbitrary curved surfaces at the resolved scale. By combining the present wall model with the stretched-vortex subgrid-scale model, we apply the wall-modelled LES approach to three different airfoil cases, spanning different geometrical parameters, different attack angles and low to high Re_c . The numerical results are verified with direct numerical simulation (DNS) at low Re_c , and validated with experiment data at higher Re_c , including typical aerodynamic properties such as pressure coefficient distributions, velocity components and also more challenging measurements such as skin-friction coefficient and Reynolds stresses. All comparisons show reasonable agreement, providing a measure of validity that enables us to further probe simulation results into aspects of flow physics that are not available from experiments. Two techniques to quantify hitherto unexplored physics of flows past airfoils are employed: one is the construction of the anisotropy invariant map, and the second is skin-friction portraits with emphasis on flow transition and unsteady separation along the airfoil surface. The anisotropy maps for all three Re_c cases, show clearly that a portion of the flow field is aligned along the axisymmetric expansion line, corresponding to the turbulent boundary layer log-law behaviour and the appearance of turbulent transition. The instantaneous skin-friction portraits reveal a monotonic shrinking of the near wall structure scale. At $Re_c = 10^4$, the interaction between the primary separation bubble and the secondary separation bubble contributes to turbulent transition, similar to the case of flow past a cylinder. At higher $Re_c = 10^5$, the primary separation breaks into several small separation bubbles. At even higher $Re_c = 2.1 \times 10^6$, near the turbulent separation, the skin-friction lines show small-scale reversal flows that are similar to those observed in DNS of the flat plate turbulent separation. A notable feature of turbulent separation in flow past an airfoil is the appearance of turbulence structures and small-scale reversal flows in the spanwise direction due to the vortex shedding behaviour.

Key words: boundary layer separation, turbulence simulation

1. Introduction

External flow past an isolated airfoil is relevant in the context of a variety of engineering applications, such as micro or unmanned air vehicles, small wind turbines and low-speed aircraft. Key aerodynamic quantities such as the lift and drag coefficients, of relevance to engineering applications, have been the focus of several experimental investigations (Abbott, Doenhoff & Stivers 1945; Lissaman 1983; Laitone 1997) at different Reynolds numbers (Re_c) and angles of attack (AoA). Recently, a growing body of experimental studies focusing on the boundary layer separation and transition process have been reported (Nakano, Fujisawa & Lee 2006; Yarusevych, Sullivan & Kawall 2006, 2009; Boutilier & Yarusevych 2012). It is found that the complex flow patterns (i.e. separation, transition and reattachment) on the suction side deteriorate aerodynamic performance by negatively affecting airfoil lift and drag (Yarusevych *et al.* 2009). These studies imply that a detailed analysis of the unsteady flow dynamics is required for further shape optimization and flow control.

High Reynolds unsteady flow past an airfoil is characterized by boundary layer separation, laminar–turbulent transition, wall-bounded turbulence under pressure gradients and turbulent wake flow. Methods to simulate this full three-dimensional (3-D) unsteady flow include: direct numerical simulation (DNS), large-eddy simulation (LES), detached-eddy simulation (DES) and Reynolds-averaged Navier–Stokes models (RANS). All the near-wall turbulent scales are resolved in DNS, requiring mesh resolution that scales as $Re^{37/14}$ (Choi & Moin 2012): this restriction on resolution proves to be untenable for high Re wall-bounded flows. Recently, Hosseini *et al.* (2016) performed DNS of flow past a NACA4412 airfoil at a Reynolds number based on free-stream velocity U_∞ and chord length C of $Re_c = 4 \times 10^5$. To the best of our knowledge, this is by far the highest Re_c airflow case simulated with DNS. A viable alternative to DNS is LES in which the large scales are resolved while the effects of small scales are modelled using a subgrid-scale (SGS) model. LES of wall-bounded turbulent flows can be classified into wall-resolved large-eddy simulations (WRLES) and wall-modelled large-eddy simulations (WMLES). In wall-bounded turbulent flows, the near-wall eddies scale with wall units, imposing a significant computational cost to sufficiently resolve them in practical simulations. The near-wall resolution problem is exacerbated for high Re turbulent flows. Choi & Moin (2012) estimated that the number of mesh points for WRLES is $O(Re^{13/7})$, while for WMLES, the mesh points requirement scales linearly with increasingly Re , i.e. $N_{wm} \sim O(Re)$, where N_{wm} is the number of mesh points needed in WMLES. Hence, the wall-modelling approach is a tenable solution for LES of high Re wall-bounded turbulent flows.

In the past four decades, several wall models have been proposed for canonical flows in simple geometries (Schumann 1975; Grötzbach 1987; Piomelli *et al.* 1989; Marusic, Kunkel & Porté-Agel 2001; Piomelli & Balaras 2002). However, there are a couple of primary challenges when it comes to practical engineering simulations. First, most wall models follow the equilibrium stress assumption and imply a log-law profile in the near-wall region, which is a questionable assumption for turbulent boundary layers subjected to strong adverse pressure gradients (APG) leading to separation, extra strains due to curvature, etc. (Diurno 2001). Second, most wall-modelling strategies including DES fall into the hybrid RANS/LES methodology in complex geometries, which solves the simplified or full RANS equations in the inner layer and provides wall shear stress boundary conditions for the outer LES region (Cabot & Moin 1999; Piomelli & Balaras 2002; Kawai & Asada 2013; Park & Moin 2016). This hybrid method is not only sensitive to the choice of the RANS model and its associated model coefficients, but also leads to the so-called ‘scale disparity’ problem

on the nominal interfaces between the RANS and LES regions (Germano 2004; Piomelli 2008). Recently, Bose & Moin (2014) proposed a differential filter-based wall model with a specific choice of the filter kernel, in which a local slip length parameter is introduced and computed via a dynamic procedure. This differential model offers the Robin (slip) boundary condition, and has been tested in both canonical flows and NACA4412 airflows (Bose & Moin 2014; Bae *et al.* 2019). Although no *a priori* coefficients are specified, the accuracy of the slip wall model is not only limited by the robustness of the dynamic procedure to compute the slip length, but also sensitive to the SGS models and numerical methods (Bose & Park 2018).

An alternative to the hybrid RANS/LES approach is the virtual wall model proposed by Chung & Pullin (2009). In this approach one dynamically couples the outer resolved LES region with the inner wall region, and offers a slip velocity boundary condition for the filtered LES velocity field on the ‘virtual wall’. This wall model was successfully applied in canonical flows without separation (Inoue & Pullin 2011; Saito, Pullin & Inoue 2012), and then extended by Cheng, Pullin & Samtaney (2015) to simulate the flat-plate turbulent boundary layer flows with separation and reattachment. Although the above wall models developed by Pullin and co-authors have been shown to successfully predict flat-plate wall-bounded flows and related phenomena, a missing part, which plays a key role in aerodynamical applications, is the effect of curvature due to the local geometry, and corresponding effects such as pressure gradient and turbulent transition. Development of a systematic framework for wall models of turbulent flows around extruded two-dimensional (2-D) or 3-D bodies with arbitrary geometry, would constitute an essential contribution to turbulent flow simulations, paving the way for WMLES for more realistic aerodynamic applications. Indeed, the present study is a starting point for the development of a general WMLES framework.

In the present investigation, we emphasize two main objectives. One of the main objectives of this work is to extend the virtual wall model to the generalized curvilinear coordinates. Since we incorporate both momentum equations for both wall-parallel directions, the present general wall model naturally possesses the ability to handle most of the significant turbulent flow features along a curved surface, not only the wall attached flows with either a zero pressure gradient (ZPG) or varying pressure gradient, but also the separation/reattachment and its related phenomena such as turbulent transition on the top side of a separation bubble. The present implementation is on body-fitted structured meshes that are commonly employed for complex geometries. We emphasize strong validation of our WMLES results. By ‘strong’ we mean going beyond the comparisons of pressure coefficient, and lift and drag coefficients and present detailed comparisons of our results with experiments of skin-friction coefficient and Reynolds stresses wherever available.

Another major objective of this work is to examine the details of unsteady separation for turbulent flow past airfoils. Recent work by Cheng *et al.* (2017), Cheng, Pullin & Samtaney (2018a) in WRLES of flow past a smooth and grooved cylinder at subcritical and supercritical Reynolds numbers, emphasized the role of unsteady separation and the dynamics of separation bubbles in the phenomenon of the drag crisis. Their explanation is that the drag crisis, mainly due to a large change in form drag, is due to the topology change induced by the movement of the location of curvature-controlled large-scale separation. Furthermore, although near-wall shear-layer turbulent transition is observed in flow over a smooth cylinder, it does not occur in flow past a grooved cylinder. In the present study, we note the

airfoil geometry may be considered as a combination of large curvature (near the front stagnation part) and small curvature near the trailing edge portion of the airfoil. This geometric complexity, accompanied by different AoA , will no doubt result in rich flow physics, especially insofar as separation and transition are concerned. We employ several diagnostic tools, including instantaneous surface skin-friction lines and invariant maps of anisotropy, to reveal the flow patterns due to dynamic interaction of local separation and transition. These flow analyses aim to provide a clear physical flow description of high Reynolds number airfoil flow up to $Re_c = 2.1 \times 10^6$, in ways that has not been fully examined in past several decades. In addition, we place a strong emphasis on validating our results against previous experiments.

The paper is organized as follows: in §2, we provide a brief summary on the LES of flow past airfoils, analysing the available datasets in cited references, and emphasize the important flow properties examined in the present study. In §3, the general formulation of the wall model for arbitrary curvilinear coordinate system is developed, with some details relegated to appendices A and B. Following the wall model formulation, we briefly explain the SGS model and the numerical methods employed for implementation of the wall model in LES of flow over airfoils. Large-eddy simulation results are summarized in the next several sections. In §5, the proposed model is verified against corresponding DNS (for case at $Re_c = 10^4$), followed by detailed validation by comparing time- and spanwise-averaged quantities against experiments (for higher Reynolds number cases at $Re_c = 10^5$ and 2.1×10^6). In §6, we analyse the anisotropy of the near-wall flow based on the time- and spanwise-averaged Reynolds stresses. This part provides a clear physics of the flow pattern transition around the airfoil. Later in §7, instantaneous flow field in the form of surface streamlines is analysed, with emphasis on local and large-scale separation, and also related turbulent transition behaviour. Some conclusions are finally drawn in §8.

2. LES of flow past an airfoil: background

To facilitate the presentation of our results, three coordinate systems are employed, as shown in figure 1: $(x, y, z) = (x_1, x_2, x_3)$ are Cartesian coordinates with corresponding velocity components $(u_1, u_2, u_3) = (u, v, w)$; $(\xi, \eta, \zeta) = (\xi^1, \xi^2, \xi^3)$ are generalized curvilinear coordinates. The spanwise geometry is uniform in the present research, thus the ζ -direction is congruent with the z -direction. In addition, we denote (s, y_n, z) as coordinates with origin located at the leading edge (same as the Cartesian coordinates), where the s -coordinate denotes the streamwise direction (parallel to the airfoil surface), and y_n denotes the local wall normal to the airfoil surface. The corresponding velocity components are (u_s, u_n, w) .

For flows past airfoils, aerodynamic quantities of interest are the integrated forces characterized by the overall lift coefficient C_L and drag coefficient C_D ; and surface quantities such as pressure coefficient scalar C_p and surface skin friction (2-D vector on the airfoil surface) $C_f(C_f, C_{fz})$, where C_f and C_{fz} denote the streamwise and spanwise skin friction coefficients, respectively. These aforementioned quantities require the flow field on the surface and near wall for computations of gradients. The off-wall flow quantities of interest include velocity vector $\mathbf{u}(u, v, w)$ and Reynolds stress tensor with key components $u'u', v'v'$ and $u'v'$. In both numerical and experimental studies of airfoil flows, $C_p, C_f, \overline{u'u'}, \overline{v'v'}$ and $\overline{u'v'}$ are computed by both spanwise and time averaging (the overbar indicates averaging for Reynolds stress tensor components). We further note that available data of velocity components and Reynolds stress components may be presented in Cartesian coordinate or body-fitted coordinates.

FIGURE 1. Sketch of the coordinate systems.

TABLE 1. Summary of LES performed in flow past an airfoil at high Re_c . Here suffix ‘M’ refers to million; \bar{u} denotes the velocity, $\overline{u'v'}$ refers to the Reynolds stress tensor components, C_p is the pressure coefficient, C_f is the skin-friction coefficient and L_z/C is the ratio of the spanwise domain size to chord length.

Although many LES have been performed to investigate the flow dynamics past an airfoil at low Re_c , few results have been published at high Re_c ($Re_c \geq 10^6$). Here we tabulate previous LES studies of flows past isolated airfoils for $Re_c \geq 10^6$ (see table 1). It is noted that the skin-friction coefficient (C_f) and Reynolds stress ($\overline{u'v'}$) are mostly reported for wall-resolved LES, whereas most wall-modelled LES focus on the mean quantities, i.e. velocity profiles (\bar{u}), lift coefficient (C_L), drag coefficient (C_D) and pressure coefficient (C_p). Notable exceptions are Kawai & Asada (2013) which reports C_f and $\overline{u'v'}$ in WMLES of flow past the A-airfoil, and George & Lele (2014) which reports on diagonal components of the Reynolds stress tensor in WMLES of flow past a NACA0012 airfoil. One may discern from these studies that accurate predictions of the skin-friction coefficient and Reynolds stresses are somewhat challenging. Also listed in table 1 is the spanwise domain extent L_z/C . It was noted in DNS of flow past an airfoil (Zhang & Samtaney 2016), that the spanwise domain size has a significant impact on the results.

3. Wall modelling in complex geometry

In this section, starting with the Navier–Stokes equations in the generalized curvilinear coordinates, we apply near-wall filtering along with the assumption of

inner scaling to derive an ordinary differential equation (ODE) governing the local wall-normal velocity gradient, and a slip Dirichlet boundary condition for velocity at a virtual wall.

3.1. Navier–Stokes equations

The incompressible Navier–Stokes (N–S) equations in the generalized curvilinear coordinates are

$$\frac{\partial U^m}{\partial \xi^m} = 0, \tag{3.1}$$

$$\frac{\partial(\sqrt{g}u_i)}{\partial t} + \frac{\partial F_i^m}{\partial \xi^m} = 0, \tag{3.2}$$

where U^m (the volume flux normal to the surface of constant ξ^m) and F_i^m are given by

$$\left. \begin{aligned} U^m &= \sqrt{g} \frac{\partial \xi^m}{\partial x_j} u_j, \\ F_i^m &= U^m u_i + \sqrt{g} \frac{\partial \xi^m}{\partial x_i} p - \nu G^{mn} \frac{\partial u_i}{\partial \xi^n}, \\ \sqrt{g} = J^{-1} &= \det \left[\frac{\partial x_i}{\partial \xi^j} \right], \quad G^{mn} = \sqrt{g} \frac{\partial \xi^m}{\partial x_r} \frac{\partial \xi^n}{\partial x_r}, \end{aligned} \right\} \tag{3.3}$$

where p is the pressure, u_i is the velocity in the Cartesian coordinates, ν is the kinematic viscosity, J^{-1} is the Jacobian of the transformation, G^{mn} is the mesh skewness tensor.

Applying a nominal filter to the N–S equations, the filtered LES equations have a form similar to (3.1) and (3.2), and are written below in terms of the resolved velocity field,

$$\tilde{U}^m = \sqrt{g} \frac{\partial \xi^m}{\partial x_j} \tilde{u}_j, \tag{3.4}$$

$$\tilde{F}_i^m = \tilde{U}^m \tilde{u}_i + \sqrt{g} \frac{\partial \xi^m}{\partial x_i} \tilde{p} - \nu G^{mn} \frac{\partial \tilde{u}_i}{\partial \xi^n} + \sqrt{g} \frac{\partial \xi^m}{\partial x_j} T_{ij}, \tag{3.5}$$

where \sim denote filtered quantities, $T_{ij} = \widetilde{u_i u_j} - \tilde{u}_i \tilde{u}_j$ is the SGS stress tensor.

3.2. Near-wall filtering

Following Chung & Pullin (2009), we define two near-wall filters in the near-wall region,

$$\tilde{\phi}(\xi, \eta, \zeta, t) = \iint \phi(\xi, \eta, \zeta, t) G(\xi - \xi', \Delta_f) G(\zeta - \zeta', \Delta_f) d\xi' d\zeta', \tag{3.6}$$

$$\langle \phi \rangle = \frac{1}{h} \int_0^h \tilde{\phi}(\xi, \eta, \zeta, t) d\eta, \tag{3.7}$$

where (3.6) and (3.7) define the wall-parallel filter and the wall-normal averaging filter, respectively. The planar filtering (with filtering function G) is purely formal;

we do not perform such a filtering operation and indeed no explicit filtering of the velocity or pressure fields is employed in the present approach. It should be noted that, consistent with other approaches involving body-fitted mesh computations, the computational mesh is constrained to be locally orthogonal to the airfoil surface for wall-normal averaging, and the wall-normal distance is denoted as y_n . As shown in figure 2, the distance, h above is typically chosen as the distance of the first grid point from the airfoil surface or the solid wall; and h_0 is the height of the virtual wall that is further discussed below. Applying the wall-parallel filter (3.6) to the momentum equations (3.2), we obtain

$$\frac{\partial \tilde{u}}{\partial t} = -\frac{1}{\sqrt{g}} \frac{\partial}{\partial \xi^m} \left(\widetilde{U^m u} + \sqrt{g} \frac{\partial \xi^m}{\partial x} \tilde{p} - \nu G^{mm} \frac{\partial \tilde{u}}{\partial \xi^n} \right), \tag{3.8a}$$

$$\frac{\partial \tilde{v}}{\partial t} = -\frac{1}{\sqrt{g}} \frac{\partial}{\partial \xi^m} \left(\widetilde{U^m v} + \sqrt{g} \frac{\partial \xi^m}{\partial y} \tilde{p} - \nu G^{mm} \frac{\partial \tilde{v}}{\partial \xi^n} \right), \tag{3.8b}$$

$$\frac{\partial \tilde{w}}{\partial t} = -\frac{1}{\sqrt{g}} \frac{\partial}{\partial \xi^m} \left(\widetilde{U^m w} + \sqrt{g} \frac{\partial \xi^m}{\partial z} \tilde{p} - \nu G^{mm} \frac{\partial \tilde{w}}{\partial \xi^n} \right), \tag{3.8c}$$

where $(u, v, w) = (u_1, u_2, u_3)$ denote the velocity components in the Cartesian coordinates.

3.3. Inner scaling assumption and governing equation for η_0

The virtual wall model formulation is essentially based on the inner scaling ansatz, which states that the near-wall turbulent statistics are characterized by the kinematic viscosity ν and the local friction velocity $u_\tau(x, y, z, t)$. For attached boundary layers, the inner scaling ansatz works well until the end of the log-law region (15% of boundary layer thickness and somewhat less for APG boundary layers), which is certainly sufficient for WMLES. For separated flows, a modified wall model, still essentially based on the inner scaling ansatz, was successfully tested by Cheng *et al.* (2015) for a flat-plate turbulent boundary layer with separation/reattachment.

Presently, we define the magnitude of the resultant velocity \tilde{q} and velocity angle θ on the wall-parallel plane as

$$\tilde{q} = \sqrt{\tilde{u}_s^2 + \tilde{w}^2}, \quad \theta = \arccos(\tilde{u}_s/\tilde{q}), \tag{3.9a,b}$$

where \tilde{u}_s is the streamwise velocity along the airfoil surface (as shown in figure 2),

$$\tilde{u}_s = \tilde{u} \cos \theta_w + \tilde{v} \sin \theta_w, \tag{3.10}$$

where θ_w denotes the local angle between the airfoil surface and the x -coordinate. We assume \tilde{q} follows inner scaling, i.e.

$$\tilde{q}(\xi, \eta, \zeta, t) = u_\tau(\xi, \zeta, t) F(y_n^+), \quad y_n^+ = u_\tau y_n / \nu, \tag{3.11}$$

where $F(y_n^+)$ is an unknown function of the normal distance from the airfoil in wall units, $u_\tau = \sqrt{\nu \eta_0}$ is the friction velocity and $\eta_0(\xi, \zeta, t)$ is the wall-normal gradient of \tilde{q} defined as

$$\eta_0 \equiv \left. \frac{\partial \tilde{q}}{\partial y_n} \right|_w. \tag{3.12}$$

FIGURE 2. (Colour online) Sketch of the near-wall velocity components. The dashed line upon the solid wall denotes the virtual wall, and the blue point denotes the centre of the first grid cell off the solid wall.

The following ODEs can then be derived as

$$\frac{\partial u_\tau}{\partial \eta_0} = \frac{v}{2u_\tau} = \frac{1}{2} \sqrt{\frac{v}{\eta_0}}, \quad \frac{\partial y_n^+}{\partial \eta_0} = \frac{y_n^+}{2\eta_0}. \tag{3.13a,b}$$

Applying the wall-normal averaging filter (3.7) to the governing equation of \tilde{q} results in

$$\frac{\partial \langle q \rangle}{\partial t} = \frac{\tilde{q}|_h}{2\eta_0} \frac{\partial \eta_0}{\partial t}, \tag{3.14}$$

where $\tilde{q}|_h = u_\tau F(h^+)$ is the resolved resultant velocity at a distance h from the solid wall (see figure 2). It should be noted that (3.14) is an exact consequence of (3.7) and (3.11). Moreover, an explicit form of $F(y_n^+)$ is not required owing to cancellation.

From the definition of \tilde{q} , (3.9), we have

$$\frac{\partial \langle q \rangle}{\partial t} = \frac{1}{h} \int_0^h \left(\frac{\tilde{u}_s}{\tilde{q}} \frac{\partial \tilde{u}_s}{\partial t} + \frac{\tilde{w}}{\tilde{q}} \frac{\partial \tilde{w}}{\partial t} \right) dy_n. \tag{3.15}$$

Some terms in the above equation may be analytically integrated (see details in appendix A). Then combining (3.14) and (3.15), we arrive at the governing equation for η_0 ,

$$\frac{\partial \eta_0}{\partial t} = C_1 \eta_0 - C_2 \eta_0^2, \tag{3.16}$$

where

$$C_1 = \frac{2}{\tilde{q}|_h} \left(F_\xi + F_\zeta + M \frac{vG^{22}}{\sqrt{gh}} \frac{\partial \tilde{q}}{\partial y_n} \Big|_h \right), \quad C_2 = \frac{2vG^{22}}{\sqrt{gh}\tilde{q}|_h}. \tag{3.17a,b}$$

Detailed expressions for F_ξ , F_ζ and M are given by equations (A3) and (A5) and (A7), respectively, in appendix A.

3.4. Near-wall treatment and solution of the ODE

On the right-hand side of (3.17), F_ξ , F_ζ and M are unknown, both of which are estimated by resolved-scale quantities at the first grid point ($y_n = h$) above the wall. For example, the first term on the right-hand side of (A3) is approximated by LES

resolved-scale values at $y_n = h$ as

$$\begin{aligned}
 & -\frac{1}{h} \int_0^h \frac{\tilde{u}_s \cos \theta_w}{\tilde{q}} \frac{\partial}{\sqrt{g}} \frac{\partial}{\partial \xi^1} \left(\widetilde{U^1 u} + \sqrt{g} \frac{\partial \xi^1}{\partial x} \tilde{p} - \nu \mathbf{G}^{11} \frac{\partial \tilde{u}}{\partial \xi^1} \right) dy_n \\
 & \approx -\frac{\tilde{u}_s \cos \theta_w}{\tilde{q}} \frac{\partial}{\sqrt{g}} \bigg|_h \frac{\partial}{\partial \xi^1} \left[\widetilde{U^1 u}|_h + \left(\sqrt{g} \frac{\partial \xi^1}{\partial x} \tilde{p} \right) \bigg|_h - \left(\nu \mathbf{G}^{11} \frac{\partial \tilde{u}}{\partial \xi^1} \right) \bigg|_h \right], \quad (3.18)
 \end{aligned}$$

where

$$\left. \begin{aligned}
 \widetilde{U^1 u}|_h &= \sqrt{g} \frac{\partial \xi^1}{\partial x_1} \widetilde{uu} \bigg|_h + \sqrt{g} \frac{\partial \xi^1}{\partial x_2} \widetilde{uv} \bigg|_h + \sqrt{g} \frac{\partial \xi^1}{\partial x_3} \widetilde{uw} \bigg|_h, \\
 \widetilde{uu}|_h &\approx \tilde{u}\tilde{u}|_h + T_{xx}|_h, \quad \widetilde{uv}|_h \approx \tilde{u}\tilde{v}|_h + T_{xy}|_h, \quad \widetilde{uw}|_h \approx \tilde{u}\tilde{w}|_h + T_{xz}|_h,
 \end{aligned} \right\} \quad (3.19)$$

where T_{xx} , T_{xy} and T_{xz} are the SGS stress tensor components (discussed in §4.1). The other terms in F_ξ (A3) and F_ζ (A5) and M (A7) are approximated in a similar manner.

If coefficients C_1 and C_2 in equation (3.16) are weakly dependent on t , then assuming these to be constant, equation (3.16) may be interpreted as a second-order linear ODE for η_0 which can be solved analytically (details are in appendix B).

Once $\eta_0(\xi, \zeta, t)$ is known, and the velocity angle $\theta(\xi, \zeta, t)$ is estimated as $\arccos(\tilde{u}_s|_h/\tilde{q}|_h)$ (meaning that streamline orientation on the virtual wall is determined by the first grid cell from the resolved LES field, an approximation justified below based on the work of Cheng *et al.* (2015)), the local wall shear stress components may then be computed as

$$\tau_{w,s} = \mu \eta_0 \cos \theta, \quad \tau_{w,z} = \mu \eta_0 \sin \theta. \quad (3.20a,b)$$

Here $\mu = \rho \nu$ is the dynamic viscosity, and $\boldsymbol{\tau}_w \equiv (\tau_{w,s}, \tau_{w,z})$ is the LES representation of the surface stress vector. Above, we make the approximation that the velocity angle θ is assumed to be constant within the first grid cell, $0 \leq y_n \leq h$. Cheng *et al.* (2015) proposed an algebraic model for θ in turbulent boundary layer simulations and concluded that there is little difference between the constant velocity angle model and the algebraic model. In the present paper, the constant velocity angle model is adopted for simplicity.

3.5. Slip velocity boundary conditions

Once η_0 is solved using (3.16), we complete the wall model with a slip velocity at a raised virtual wall plane located at $\eta = h_0$, which scales with the boundary layer thickness but remains small, i.e. $h_0 \leq 0.1\delta$. Typically, h_0 is chosen as a small fraction of the near-wall cell size. In previous studies, both in channel flow by Chung & Pullin (2009) and turbulent boundary layer flows (ZPG and APG) by Inoue & Pullin (2011) and Cheng *et al.* (2015), $h_0/\Delta\eta = 0.18$ is fixed with respect to the first off-wall grid cell and the sensitivity to changes was documented in Chung & Pullin (2009). Their verifications and validations capture the near-wall flow physics well, and we follow this choice in the present research.

We model the resultant slip velocity $\tilde{q}|_{h_0}$ on the virtual wall as

$$\tilde{q}|_{h_0} = \begin{cases} \left\{ \begin{aligned} u_\tau \left(\frac{1}{\mathcal{X}_1} \log \left(\frac{h_0^+}{h_v^+} \right) + h_v^+ \right), & h_0^+ > h_v^+, \\ u_\tau h_0^+, & h_0^+ < h_v^+, \end{aligned} \right. & \tau_{w,s} > 0, \\ u_\tau h_0^+, & \tau_{w,s} \leq 0, \end{cases} \quad (3.21)$$

where $h_0^+ = u_\tau h_0/\nu$, h_v^+ is the intercept between the linear and log components in the law of the wall. Experimental research shows that the outer edge of the viscous sublayer is located at $h_v^+ \approx 11$, which is approximately equivalent to the offset ($= 5.0$) in the classical log law. This value was adopted by Chung & Pullin (2009) and Inoue & Pullin (2011), and also by Cheng *et al.* (2015) in modelling the turbulent boundary layer flows with separation and reattachment. Presently, $h_v^+ = 11$ is used as an empirical parameter in the wall model. In the attached region ($\tau_{w,s} > 0$), the linear–log relation is essentially the same as Chung & Pullin (2009), which is derived from stretched-vortex SGS model (discussed below) based on the detached/attached eddy concepts of Townsend (1976). The Kármán-like constant \mathcal{K}_1 is dynamically computed (refer to Chung & Pullin (2009) for more details). In the separated region, ($\tau_{w,s} \leq 0$), the log-like relation is no longer valid and Cheng *et al.* (2015) proposed a linear relationship which appears to work reasonably well in regions of flow separation. Presently, we follow the linear law by Cheng *et al.* (2015).

3.6. Summary of the wall model

The wall model is summarized as follows: in the near-wall region, equation (3.16) is solved for η_0 , in which the coefficients on the right-hand side are approximated with the resolved LES field at the first grid cell, i.e. $h = h_0 + \Delta y_n/2$, equation (3.21) is then used to compute the resultant velocity $\tilde{q}|_{h_0}$ on the virtual wall with the streamwise and spanwise velocity components given by

$$\tilde{u}_s|_{h_0} = \tilde{q}|_{h_0} \cos \theta, \quad \tilde{w}|_{h_0} = \tilde{q}|_{h_0} \sin \theta. \tag{3.22a,b}$$

The contribution of the wall-normal velocity component $\tilde{u}_n|_{h_0}$ to \tilde{u} and \tilde{v} is assumed to be small compared with $\tilde{u}_s|_{h_0}$, and presently we use $\tilde{u}_n|_{h_0} = 0$. Finally, the slip velocity boundary condition on the virtual wall $\eta = h_0$ is

$$\tilde{u}|_{h_0} = \tilde{q}|_{h_0} \cos \theta \cos \theta_w, \quad \tilde{v}|_{h_0} = \tilde{q}|_{h_0} \cos \theta \sin \theta_w, \tag{3.23a,b}$$

with the spanwise velocity component $\tilde{w}|_{h_0}$ given by (3.22).

4. SGS model and numerical set-up

4.1. Stretched-vortex SGS model

The stretched-vortex SGS model has been previously widely deployed in LES of wall-bounded turbulent flows by Pullin and co-workers. Here, for the sake of completeness, we present the essential features of this structure-based SGS model, which assumes that the turbulent fine scales are composed of tube-like structures with spiral vortices (Lundgren 1982). In each computational cell, the ensemble dynamics is dominated by a stretched vortex with orientation e^v , taken from a delta-function probability density function (Misra & Pullin 1997). Consequently, the SGS stress tensor T_{ij} is modelled as (Chung & Pullin 2009)

$$T_{ij} = (\delta_{ij} - e_i^v e_j^v)K, \quad K = \int_{k_c}^{\infty} E(k) dk, \tag{4.1a,b}$$

where K is the SGS kinetic energy, $k_c = \pi/\Delta_c$ is the cutoff wavenumber ($\Delta_c = (\Delta_x \Delta_y \Delta_z)^{1/3}$) and $E(k)$ is the SGS energy spectrum given by Lundgren (1982). The integration of the energy spectrum gives

$$K = \frac{1}{2} \mathcal{K}'_0 \Gamma[-1/3, \kappa_c^2], \quad \mathcal{K}'_0 = \mathcal{K}_0 \epsilon^{2/3} \lambda_v^{2/3}, \quad \lambda_v = (2\nu/3|\tilde{a}|)^{1/2}, \quad \kappa_c = k_c \lambda_v, \tag{4.2a-d}$$

where Γ is the incomplete gamma function, $\tilde{a} = e_i^v e_j^v \tilde{S}_{ij}$ is the stretching felt along the subgrid vortex axis imposed by the resolved scales and \tilde{S}_{ij} is the resolved SGS strain tensor. The composite parameter \mathcal{K}'_0 is obtained dynamically by structure-function matching at the grid-scale cutoff (Voelkl, Pullin & Chan 2000), i.e. $\mathcal{K}'_0 = \langle F_2 \rangle / \langle Q(\kappa_c, d) \rangle$, where $\langle \cdot \rangle$ denotes a local-averaging operator computed from the neighbouring 26 points, F_2 is the second-order velocity structure function from the resolved LES field, and the calculation of $Q(\kappa_c, d)$ is similar to Voelkl *et al.* (2000), Chung & Pullin (2009) with $\kappa_c = r/\Delta_c$ and r is the distance from the neighbouring point to the vortex axis.

The stretched-vortex SGS model coupled with the virtual wall model have been together applied to several canonical turbulent flows relevant to the present flow: Chung & Pullin (2009) for turbulent channel flow; Inoue & Pullin (2011) for turbulent boundary layer flow at arbitrarily large Re ; Inoue *et al.* (2012) for combining a predictive-wall model with LES; Inoue *et al.* (2013) for adverse-pressure turbulent boundary layers; Saito *et al.* (2012), Saito & Pullin (2014) and Sridhar, Pullin & Cheng (2017) for rough-wall turbulent boundary layers; Cheng *et al.* (2015) for separated–reattached turbulent boundary layers. However, all the previous works based on this approach are applied to simple canonical geometries. The extension and testing of the models to complex geometries are necessary to pave the way to more engineering applications.

4.2. Numerical method

The governing equations (3.4) and (3.5) are discretized as

$$\left. \begin{aligned} \frac{\delta \tilde{U}^m}{\delta \xi^m} &= 0, \\ \sqrt{g} \frac{\tilde{u}_i^{n+1} - \tilde{u}_i^n}{\Delta t} &= \frac{3}{2}(C_i^n + S_i^n) - \frac{1}{2}(C_i^{n-1} + S_i^{n-1}) + R_i(\tilde{p}^{n+1}) + D_i(\tilde{u}^{n+1}), \end{aligned} \right\} \quad (4.3)$$

where $\delta/\delta \xi^m$ represents the energy conservative fourth-order finite difference operator (Morinishi *et al.* 1998), C_i and S_i represent the convective term and SGS term, D_i and R_i are discrete operators for the viscous term and the pressure gradient term, respectively. These quantities are

$$\left. \begin{aligned} C_i &= -\frac{\delta}{\delta \xi^m} (\tilde{U}^m \tilde{u}_i), & S_i &= -\frac{\delta}{\delta \xi^m} \left(\sqrt{g} \frac{\delta \xi^m}{\delta x_j} T_{ij} \right), \\ R_i &= -\frac{\delta}{\delta \xi^m} \left(\sqrt{g} \frac{\delta \xi^m}{\delta x_i} \right), & D_i &= \frac{\delta}{\delta \xi^m} \left(\nu G^{mn} \frac{\delta}{\delta \xi^n} \right), \end{aligned} \right\} \quad (4.4)$$

where the convective term is computed in the skew-symmetric form to minimize the aliasing error (Zang 1991; Morinishi *et al.* 1998). The fractional step method (Zang, Street & Koseff 1994; Zhang *et al.* 2015) is used to solve the governing equations. This method follows the predictor–corrector procedure, and the pressure Poisson equation is solved using the multigrid method with line-relaxed Gauss–Seidel as a smoother. The code is parallelized using standard MPI-protocol. To achieve near-optimal load balancing, the mesh is divided into blocks of equal size and each of them is assigned to a unique processor. All the simulations are performed on the Shaheen-Cray XC40 at KAUST. The DNS code (without the SGS stress terms) with the same method is described in Zhang *et al.* (2015) for flow past an airfoil, and is the one used for verification in the low Re_c case in the present paper. The WRLES code with the same method was previously applied successfully in flow past smooth and grooved cylinders (Cheng *et al.* 2017, 2018a).

FIGURE 3. Sketch of the numerical set-up and computational domain.

Airfoil	Method	Re_c	AoA (deg.)	$N_\xi \times N_\eta \times N_z$	$\Delta \xi_{max}^+$	$\Delta \eta_{max}^+$	Δz_{max}^+

TABLE 2. Summary of the performed numerical cases.

4.3. Numerical set-up

The numerical set-up and domain size are illustrated in figure 3. It should be noted that a sufficiently long spanwise domain size (L_z) is important for the proper development of 3-D turbulent structures, and the associated turbulent statistics. Kitsios *et al.* (2011) performed LES of flow past the NACA0015 airfoil at $Re_c = 3 \times 10^4$ with different L_z and found that $L_z = 0.66C$ was adequate. It was concluded that the impact of large-scale structures reduces as Re_c increases. Zhang & Samtaney (2016) presented a comprehensive assessment of domain size effects in DNS of flow past the NACA0012 airfoil at $Re_c = 5 \times 10^4$, and recommended a spanwise size of $L_z = 0.8C$. It is found that a smaller L_z tends to under-predict the turbulent fluctuations near the separation point but over-predict them inside the separation bubble. Presently, $L_z = 0.8C$ is adopted in all the simulations to enforce the correct spanwise periodicity and capture large-scale turbulent structures. It is by far the largest spanwise extent in LES of airfoil flows at high Re_c (see table 1).

For boundary conditions, a uniform flow $(\tilde{u}, \tilde{v}, \tilde{w}) = (U_\infty, 0, 0)$, $U_\infty = 1$ is imposed at the inlet, and the convective boundary condition $\partial \mathbf{u} / \partial t + U_B \partial \mathbf{u} / \partial x = 0$ is used at the outflow plane, where U_B is the bulk velocity. The slip velocity from the wall model is specified at the virtual wall, and the periodic boundary condition is assumed in the spanwise direction.

Three cases as summarized in table 2 are performed to verify and validate the wall model. The low Re_c case (NACA0012, $Re_c = 10^4$, $AoA = 5^\circ$) is performed with both DNS and WMLES, and the numerical results from DNS are utilized to verify the performance of the wall model at low Re_c . To check the effects of mesh resolution on the WMLES, a mesh convergence study of this case with WMLES

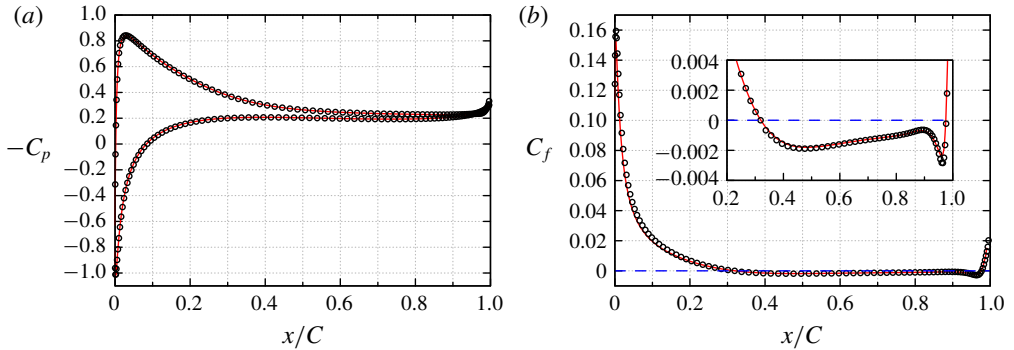

FIGURE 4. (Colour online) NACA0012, $Re_c = 10^4$. (a) Distribution of the pressure coefficient C_p around the airfoil, and (b) skin-friction coefficient C_f on the suction surface. —, present DNS; \circ , present WMLES. The - - - line $C_f = 0$ is shown for convenience: zero crossing of this line indicates separation and reattachment.

is presented in appendix C. For the higher Reynolds number cases, DNS becomes computationally prohibitive, and for these cases we compare results from WMLES with experiments with an emphasis on strong validation. This somewhat limits our choice of experiments to those which have presented skin-friction coefficient and Reynolds stress components. The relatively moderate Re_c case (NACA0018, $Re_c = 10^5$, $AoA = 5^\circ$) is validated with the experimental results from Boutilier & Yarusyevych (2012) and Kirk & Yarusevych (2017). The Aérospatiale A-airfoil near stall condition ($Re_c = 2.1 \times 10^6$, $AoA = 13.3^\circ$) is a benchmark case from the Brite-Euram project LESFOIL (Mellen, Frögrave & Rodi 2003; Mary & Sagaut 2002). This somewhat challenging case has been extensively used to assess RANS and LES models (Schmidt & Thiele 2003; Chaouat 2006; Kawai & Asada 2013), and is also for validation in the present paper. In the experiment of the A-airfoil, the boundary layer of the pressure surface is tripped at around $x/C = 0.3$ (Dahlstrom & Davidson 2001). These trips, whose height is smaller than the first wall-adjacent grid spacing, are not included in the our simulations. The numerical noise would act as the perturbation source, and allow natural transition to turbulence. This choice is same as Park & Moin (2014) in WMLES of the NACA4412 airfoil at $Re_c = 1.64 \times 10^6$, in which reasonable prediction of transition onset was reported without special treatment of the boundary layer trips.

5. Verification and validation

In this section, we provide verification of one case ($Re_c = 10^4$) with DNS, and then strong validation of the larger Re_c cases against experimental results.

5.1. Comparison between DNS and WMLES: $Re_c = 10^4$

The time- and spanwise-averaged pressure coefficient (C_p) and skin-friction coefficient (C_f) are computed as

$$C_p = \frac{\bar{p} - p_\infty}{\frac{1}{2}\rho U_\infty^2}, \quad C_f = \frac{\bar{\tau}_{w,s}}{\frac{1}{2}\rho U_\infty^2}, \quad (5.1a,b)$$

where \bar{p} and $\bar{\tau}_{w,s}$ are the time- and spanwise-averaged wall pressure and streamwise wall shear stress, p_∞ is the reference pressure taken at the outlet boundary. The C_p and C_f for this NACA0012 case are shown in figure 4. The present WMLES results

FIGURE 5. (Colour online) NACA0012, $Re_c = 10^4$. The mean streamwise velocity profiles along the wall-normal lines at nine locations. From left to right, $x/C = 0.1-0.9$ with equal distances of 0.1. The plots are shifted by 0, 2, \dots , 16 for clarity. —, present DNS; \circ , present WMLES.

FIGURE 6. (Colour online) NACA0012, $Re_c = 10^4$. Distribution of the time- and spanwise-averaged Reynolds stress $-\overline{u'v'}/U_\infty^2 = [0.001, 0.06]$: (a) DNS result, and (b) present WMLES result. The transition onset is indicated by the threshold value 0.001.

compare well with the DNS results with negligible difference. The skin-friction coefficient profile indicates separation and reattachment at $x/C = 0.32$ and $x/C = 0.98$, respectively. The streamwise mean velocity profiles at nine locations along the suction surface ($x/C = 0.1-0.9$ with equal distances of 0.1) are shown in figure 5. The present WMLES results indicate that its prediction of both separation and reattachment are in good agreement with that of the DNS predictions.

Colour contours of time- and spanwise-averaged off-diagonal Reynolds stress $-\overline{u'v'}/U_0^2$ within the range $[0.001, 0.06]$ superimposed on average streamline contours are shown in figure 6. Here the threshold value of 0.001 is chosen as an indicator for transition onset, which is commonly used in various numerical (Zhou & Wang 2012)

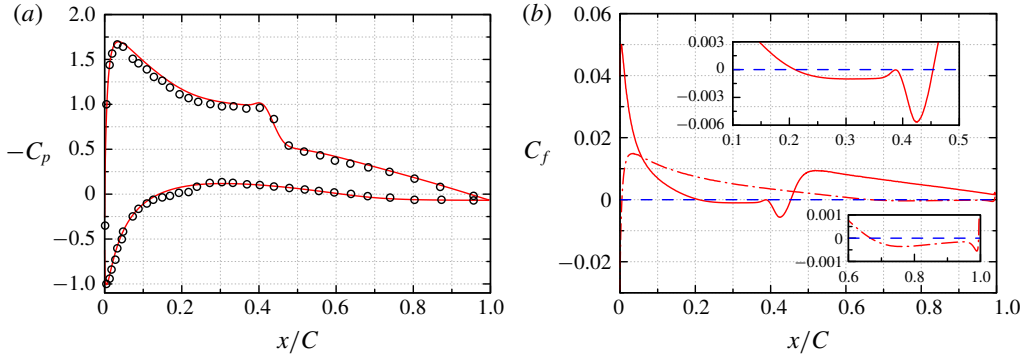

FIGURE 7. (Colour online) NACA0018, $Re_c = 10^5$. (a) Distribution of the pressure coefficient C_p , and (b) skin-friction coefficient C_f around the airfoil. \circ , experimental data from Kirk & Yarusevych (2017); —, corresponding results from the present WMLES; — · —, C_f on the pressure side from the present WMLES. The - - - line $C_f = 0$ is shown for convenience: zero crossing of this line indicates separation and reattachment. The experimental values of the separation and reattachment point on the suction side are estimated to be located at $x/C = 0.24 \pm 0.02$, 0.52 ± 0.02 , respectively (Kirk & Yarusevych 2017).

and experimental investigations (Buchmann and Atkinson & Soria 2013) of flow past bluff bodies. The transition onset occurs near the trailing edge, i.e. $x/C = 0.92$ and $x/C = 0.91$ for DNS and WMLES, respectively.

5.2. Validation of WMLES: $Re_c = 10^5$

The pressure coefficient C_p and skin-friction coefficient C_f for the NACA0018 case are shown in figure 7. The WMLES C_p results compare well with the experiment. The separation and reattachment on the pressure side occur at $x/C = 0.67$, 0.99 , and $x/C = 0.21$, 0.45 on the suction side. In the experiment by Kirk & Yarusevych (2017), the separation and reattachment points on the suction side are estimated to be located at $x/C = 0.24 \pm 0.02$, 0.52 ± 0.02 : these are inferred indirectly from the pressure distributions – a flat distribution is expected within the recirculating region. The trailing edge separation on the pressure side is not investigated in the experimental research, however, our WMLES predicts a trailing edge separation on the pressure side, in qualitative agreement with another experiment by Nakano *et al.* (2006) with the same airfoil geometry but slightly different $Re_c (= 1.6 \times 10^5)$ and $AoA (= 6^\circ)$.

The mean velocity profiles in the x -direction at different locations along the suction surface ($x/\bar{C} = 0.2–0.48$ with equal distances of 0.02) are shown in figure 8(a), here \bar{C} is the x -axis projection of the chord length. The mean velocity profiles in the attached zone, i.e. $x/C = 0.50$, 0.52 , 0.54 , 0.56 , 0.60 , 0.66 , 0.73 , 0.87 are shown in figure 8(b). Good agreement between our WMLES results and the experiment is noted.

The Reynolds stress component, $\sqrt{u'u'}/U_\infty$, on the suction side is shown in figure 9, at the same locations as the mean velocity profiles. The LES results match quite well with the experimental data in the range of $[0.2, 0.38]$ and $[0.5, 0.87]$. We note difference between LES and experiments in the range of $[0.38, 0.48]$, close to the reattachment point. It should be emphasized that both the present LES and experiments in this range show a sharp drop in pressure coefficient distributions (see

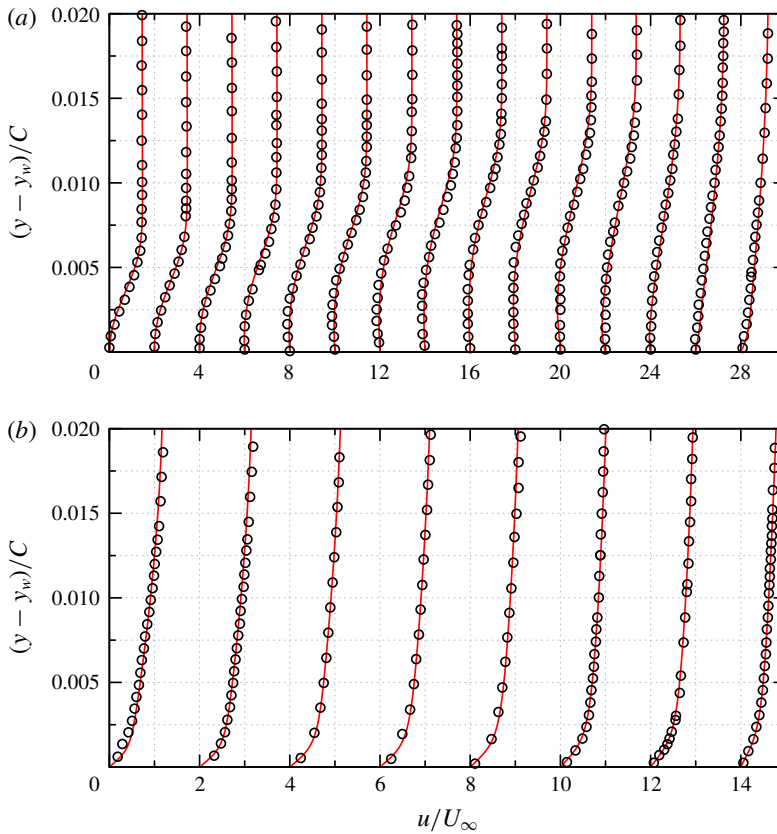

FIGURE 8. (Colour online) NACA0018, $Re_c = 10^5$. The mean velocity profiles in the x -direction, u along the vertical lines at different locations of the suction side. From left to right, (a) $x/\bar{C} = 0.2-0.48$ with equal distances of 0.02, shifted by 0, 2, \dots , 28; (b) $x/\bar{C} = 0.50, 0.52, 0.54, 0.56, 0.60, 0.66, 0.73, 0.87$, shifted by 0, 2, \dots , 14. —, present WMLES; \circ , experimental data from Kirk & Yarusevych (2017) and Boutilier & Yarusevych (2012).

figure 7a). This sharp drop may be explained by examining the LES results in detail: it is attributed to a separation bubble connected by turbulent transition as observed in the skin-friction plot in figure 7(b). It is reported in the experiment by Kirk & Yarusevych (2017) that the onset of turbulent transition occurs at $x/C = 0.44 \pm 0.02$, discerned from the dip in the C_p -profile. The WMLES shows larger fluctuations at locations $x/C \in [0.38, 0.48]$ in comparison with the experiment, and the source of this difference remains to be explored further.

5.3. Validation of WMLES: high Re_c case, $Re_c = 2.1 \times 10^6$

The time- and spanwise-averaged C_f and C_p for the high Reynolds number case of the A-airfoil are shown in figure 10 for the present WMLES, the experiment by Gleyzes (1988) and also WRLES results by Mary & Sagaut (2002) and Asada & Kawai (2018). The pressure coefficient compares well with the experiment, and the separation near the trailing edge, as indicated by C_f -plot (see figure 10b), is also well captured by

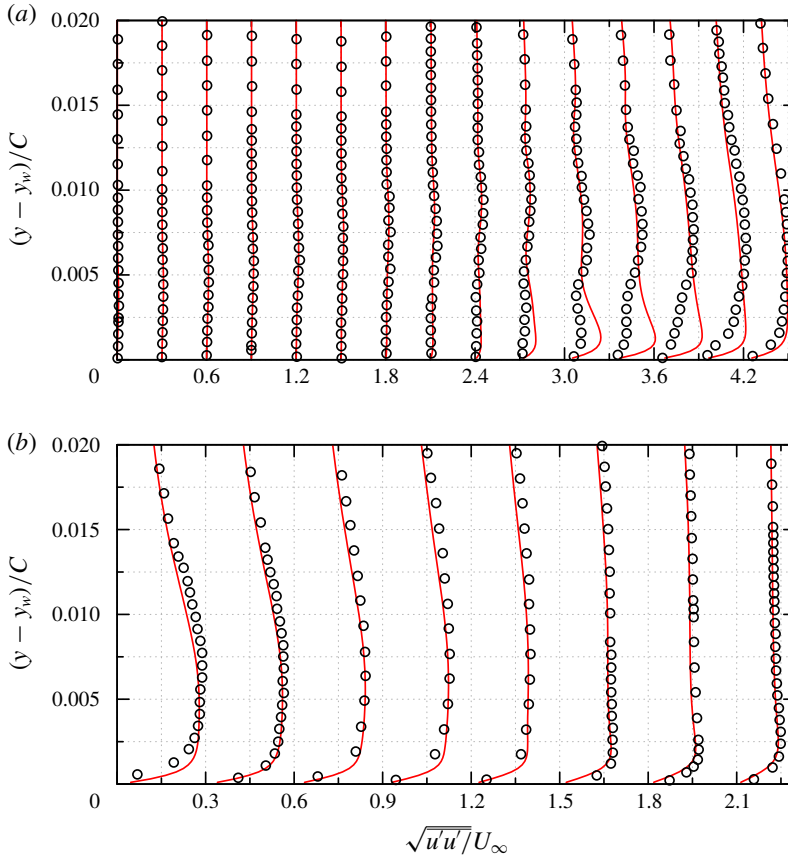

FIGURE 9. (Colour online) NACA0018, $Re_c = 10^5$. The Reynolds stress profiles, $\sqrt{u'u}/U_\infty$ along the vertical lines at different locations of the suction side. From left to right, (a) $x/\bar{C} = 0.2-0.48$ with equal distances of 0.02, shifted by 0, 0.3, \dots , 4.2; (b) $x/\bar{C} = 0.50, 0.52, 0.54, 0.56, 0.60, 0.66, 0.73, 0.87$, shifted by 0, 0.3, \dots , 2.1. —, present WMLES; \circ , experimental data from Kirk & Yarusevych (2017) and Boutilier & Yarusevych (2012).

the present WMLES. The trailing edge separation occurs at approximately $x/\bar{C} = 0.90$ compared with the experimental observation ($x/\bar{C} \approx 0.82$) (Gleyzes 1988). In the experiment a tiny separation bubble close to the leading edge, which reattaches at $x/\bar{C} = 0.12$ is observed. In the present WMLES, although instantaneous velocity contours clearly show a local reversal flow in this region, the time- and spanwise-averaged C_f does not capture this tiny separation bubble.

The streamwise mean velocity profiles on the suction side are shown in figure 11. The flow reversal in the separation zone ($x/\bar{C} = 0.93, 0.99$) is well captured by the WMLES. The Reynolds stress profiles corresponding to the root mean square (r.m.s.) streamwise fluctuations, wall-normal fluctuations and off-diagonal terms are shown in figure 12. Overall the WMLES predicted values of the Reynolds stress components are in general agreement and follow the trends in the experimental data.

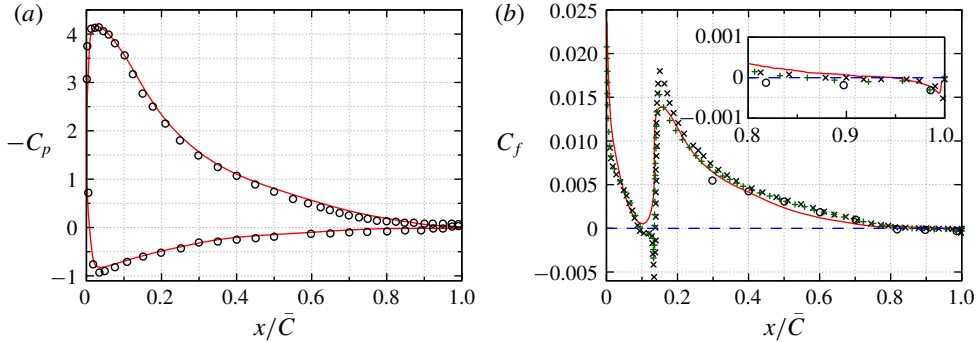

FIGURE 10. (Colour online) Aérospatiale A-airfoil, $Re_c = 2.1 \times 10^6$. (a) Distribution of the pressure coefficient C_p , and (b) skin-friction coefficient C_f on the suction surface. \circ , experimental data from Gleyzes (1988); \times , WRLES from Mary & Sagaut (2002); $+$, WRLES from Asada & Kawai (2018); —, present WMLES. Note that the profiles on the left-hand side of the vertical dashed lines use the left y-axis, while the others use the right y-axis.

6. Anisotropy of the flow

In the above section, we noted that the Reynolds stress components for all three WMLES cases (ranging from low to high Re_c) are found to be in reasonable agreement: the prediction location of transition onset is very close to DNS for $Re_c = 10^4$, the WMLES results agree with experimental data by Boutillier & Yarusevych (2012) and Kirk & Yarusevych (2017) for $Re_c = 10^5$ and follow the general trend of experiments by Gleyzes (1988) for $Re_c = 2.1 \times 10^6$. It is, therefore, interesting to further analyse the LES data to recognize the flow patterns around the airfoil. The objective of the present section is to examine the anisotropy in these wall-bounded flows.

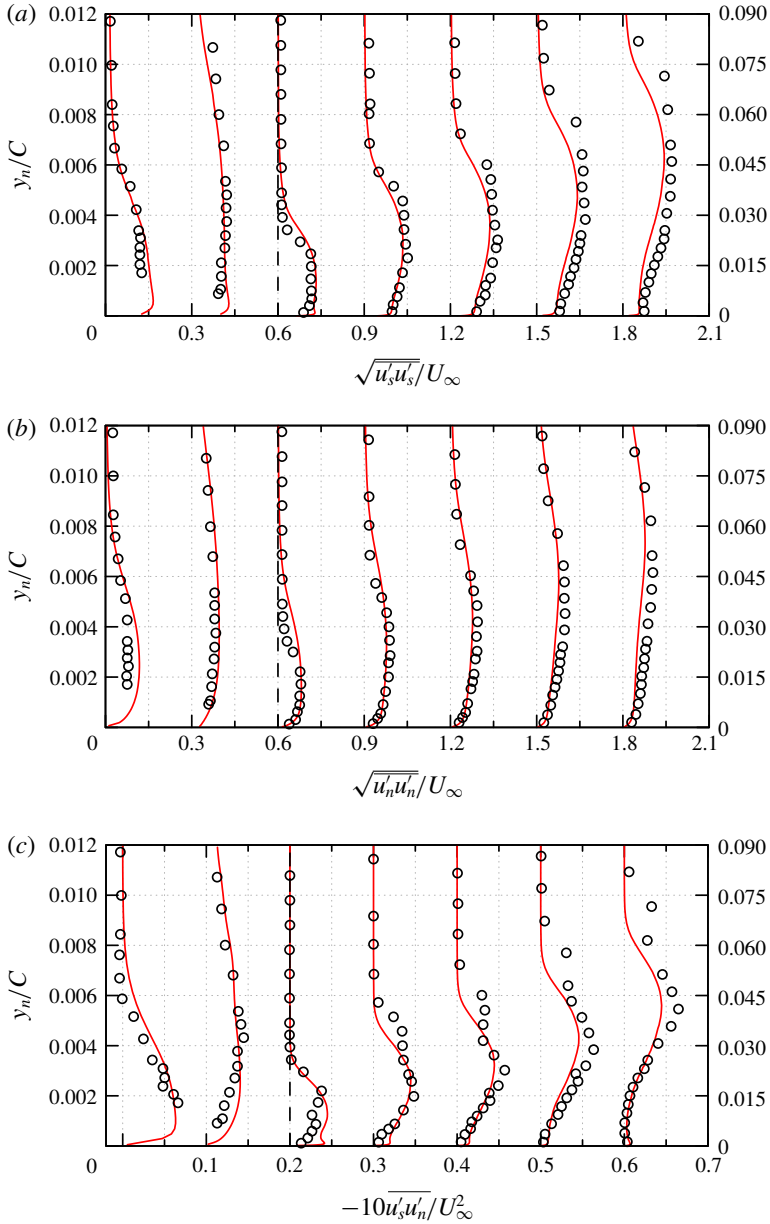

FIGURE 12. (Colour online) Aérospatiale A-airfoil, $Re_c = 2.1 \times 10^6$. The Reynolds stress profiles, (a) $\sqrt{u'_s u'_s} / U_\infty$, (b) $\sqrt{u'_n u'_n} / U_\infty$ and (c) $u'_s u'_n / U_\infty^2$ along the wall-normal lines at different locations of the suction side. From left to right, $x/\bar{C} = 0.3, 0.5, 0.7, 0.825, 0.87, 0.93, 0.99$. 6.1. Definition of anisotropy

The non-dimensional anisotropy tensor introduced by Lumley & Newman (1977) and Lumley (1979) is defined as

$$b_{ij} = \overline{u'_i u'_j} / \overline{u'_k u'_k} - \delta_{ij} / 3. \tag{6.1}$$

It has a zero trace ($b_{ii} = 0$) and is characterized by two invariants, viz.,

$$II = -b_{ij} b_{ij} / 2, \quad III = b_{ij} b_{jk} b_{ki} / 3, \tag{6.2a,b}$$

which allow a simple graphical evaluation, i.e. (III, II) -plane, of possible states of turbulence. It is more convenient to identify the anisotropy by

$$\phi = \left(\frac{III}{2} \right)^{1/3}, \quad \psi = \left(-\frac{II}{3} \right)^{1/2} \tag{6.3a,b}$$

(Pope 2000). At any location in a turbulent flow, ϕ and ψ are determined from the Reynolds stress components, which correspond to points in the (ϕ, ψ) -plane, as shown in figure 13. All realizable states of the anisotropy tensor are found within a triangular region in the (ϕ, ψ) -plane, which is the anisotropy invariant map (AIM) and often referred to as the Lumley triangle (figure 13). The origin of the triangle, i.e. $(0, 0)$ corresponds to 3-D isotropic turbulence, the left-hand corner point of the triangle, i.e. $(-1/6, 1/6)$ corresponds to two-component (2C) isotropic turbulence, the right-hand corner point of the triangle, i.e. $(1/3, 1/3)$ corresponds to one-component (1C) turbulence. The turbulence along the upper line connecting the 2C isotropic turbulence and 1C turbulence is the 2C turbulence state, in which

$$\psi = \left(\frac{1}{27} + 2\phi^3 \right)^{1/2}. \tag{6.4}$$

The left-hand line $\psi = -\phi$ and right-hand line $\psi = \phi$ correspond to the ‘axisymmetric contraction’ and ‘axisymmetric expansion’ state, respectively (Choi & Lumley 2001). This classification of turbulence is formally based on the shape of the energy ellipsoid, and details of the analysis may be obtained from Lumley (1979).

The above anisotropy invariants find many uses in the turbulence modelling community. First, they help to define realizable states of the Reynolds stress tensor, i.e. all physically realizable turbulence is bounded in the AIM. Second, it is desirable to ensure that the simulated turbulence field can only pass through a succession of realizable states, which helps improve the anisotropy-resolving turbulence closures especially at second-moment level. Furthermore, the invariants should satisfy some specific relations or bounds at the limiting states.

6.2. Low Reynolds number $Re_c = 10^4$ case

Figures 13 (WMLES) and 14 (DNS) show the loci associated with traversals in the vertical direction at six locations ($x/C = 0.8, 0.9, 0.92, 0.94, 0.96, 0.98$) along the suction surface of the NACA0012 airfoil. Overall, the loci behave similarly in both WMLES and DNS at the same locations. It is observed that all states indeed lie within the triangle, which is required by realizability constraints. For $x/C = 0.8$ as shown in figures 13(a) and 14(a), all the turbulence states are concentrated at the right corner of the Lumley triangle. This indicates that most of the turbulence at this location, before the transition onset occurs (see figure 6), corresponds to 1C and 2C turbulence.

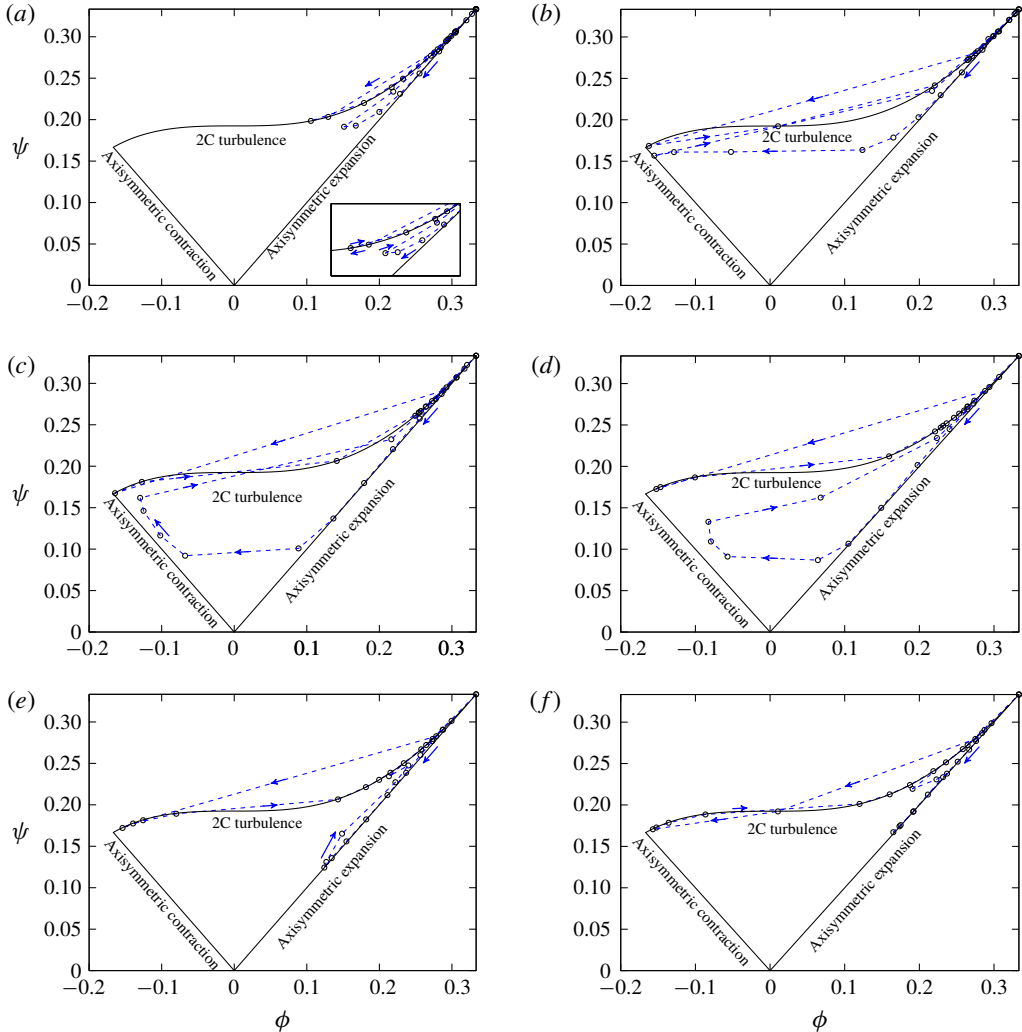

FIGURE 13. (Colour online) NACA0012, $Re_c = 10^4$. Invariant maps of WMLES results along vertical lines at six locations along the suction surface: (a) $x/C = 0.8$; (b) $x/C = 0.9$; (c) $x/C = 0.92$; (d) $x/C = 0.94$; (e) $x/C = 0.96$; (f) $x/C = 0.98$. \rightarrow denotes the direction away from the airfoil surface. The line partly outside the triangle at the upper boundary is due to the connection of two neighbouring points.

For the near-wall region, the turbulence state is seen to approach the two-component state at all six locations and then progresses along the ‘axisymmetric expansion’ line (similar to that in the log region of a channel flow (Pope 2000)) and ending in the upper portion of the ‘two-component turbulence’ line. However, the manner in which this process takes place varies at different locations. Within the separation zone close to the reattachment point, $x/C = 0.92$ and $x/C = 0.94$, some points are close to the ‘axisymmetric contraction’ line, similar to observations in a developed free shear layer (Bell & Mehta 1990). For flow close to the trailing edge ($x/C = 0.96$ and $x/C = 0.98$), the upper-right pointing arrow along the ‘axisymmetric expansion’ line (log-law region) signifies a state very different from that in a free shear layer.

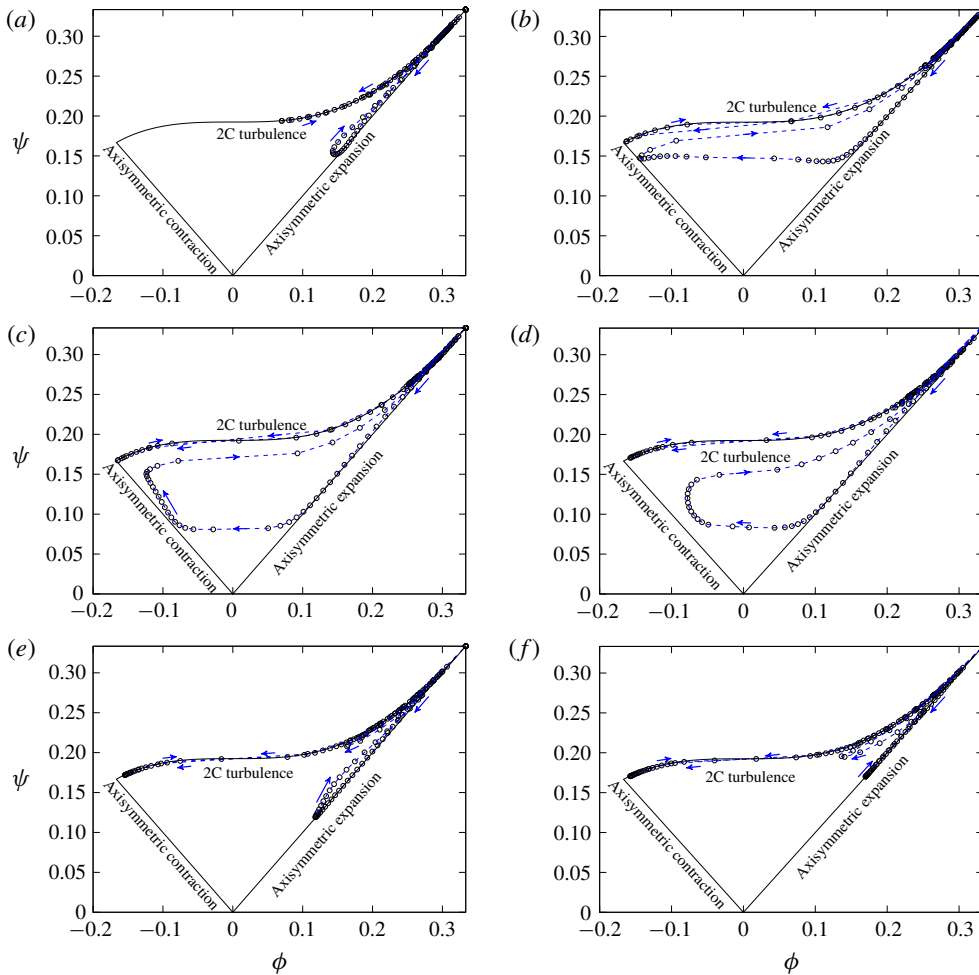

FIGURE 14. (Colour online) NACA0012, $Re_c = 10^4$. Invariant maps of DNS results along vertical lines at six locations along the suction surface: (a) $x/C = 0.8$; (b) $x/C = 0.9$; (c) $x/C = 0.92$; (d) $x/C = 0.94$; (e) $x/C = 0.96$; (f) $x/C = 0.98$. \rightarrow denotes the direction away from the airfoil surface. The line partly outside the triangle at the upper boundary is due to the connection of two neighbouring points.

6.3. Moderate Reynolds number $Re_c = 10^5$ case

Figure 15 shows the loci associated with traversals in the vertical direction at six locations ($x/C = 0.4, 0.45, 0.5, 0.65, 0.8, 0.95$) along the suction surface of the NACA0018 airfoil. Substantially, the state of turbulence follows the same locus as observed in the NACA0012 case. A point of difference is that most turbulence states are concentrated on the ‘two-component turbulence’ line in the NACA0012 case, while most points concentrate near the ‘axisymmetric expansion’ and ‘axisymmetric contraction’ lines except for the flow in the separation zone ($x/C = 0.4$). This is very similar to the observation in the post-recirculation zone of channel flow with periodic hills at $Re_h = 10\,595$ (Fröhlich *et al.* 2005). The backward-moving shear flow in the separation zone behaves similarly to a thin boundary layer as the wall is approached,

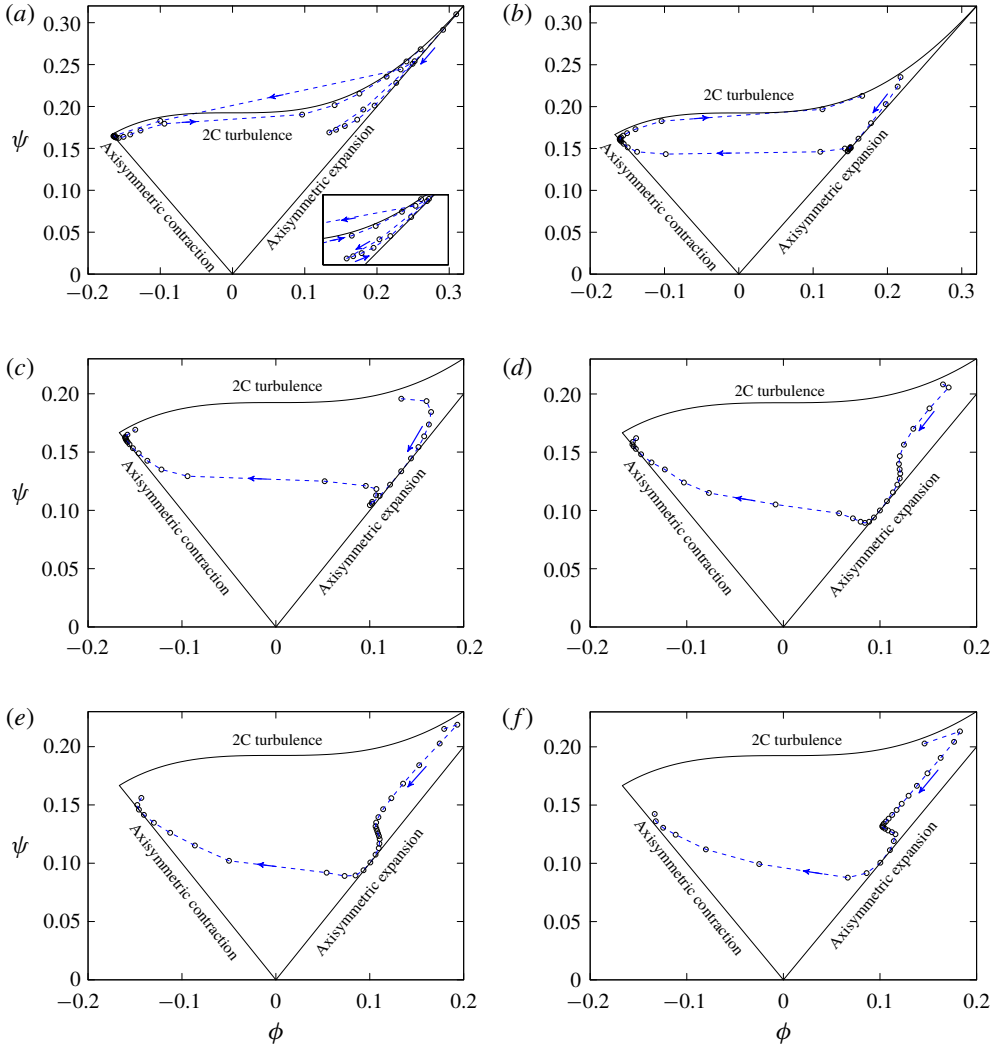

FIGURE 15. (Colour online) NACA0018, $Re_c = 10^5$. Invariant maps of WMLES results along vertical lines at six locations along the suction surface: (a) $x/C = 0.4$; (b) $x/C = 0.45$; (c) $x/C = 0.5$; (d) $x/C = 0.65$; (e) $x/C = 0.8$; (f) $x/C = 0.95$. \rightarrow denotes the direction away from the airfoil surface. The line partly outside the triangle at the upper boundary in (a) is due to the connection of two neighbouring points.

and thus the flow structure has to approach the two-component limit at the wall. After the separation bubble, the shear layer develops, with more points concentrated on the ‘axisymmetric contraction’ line after the log-law region.

6.4. High Reynolds number $Re_c = 2.1 \times 10^6$ case

Figure 16 shows the loci associated with traversals in the vertical direction at eight locations ($x/C = 0.35, 0.55, 0.7, 0.8, 0.85, 0.90, 0.94, 0.96$) along the suction surface of the A-airfoil. The loci vary significantly at different locations. In the attached

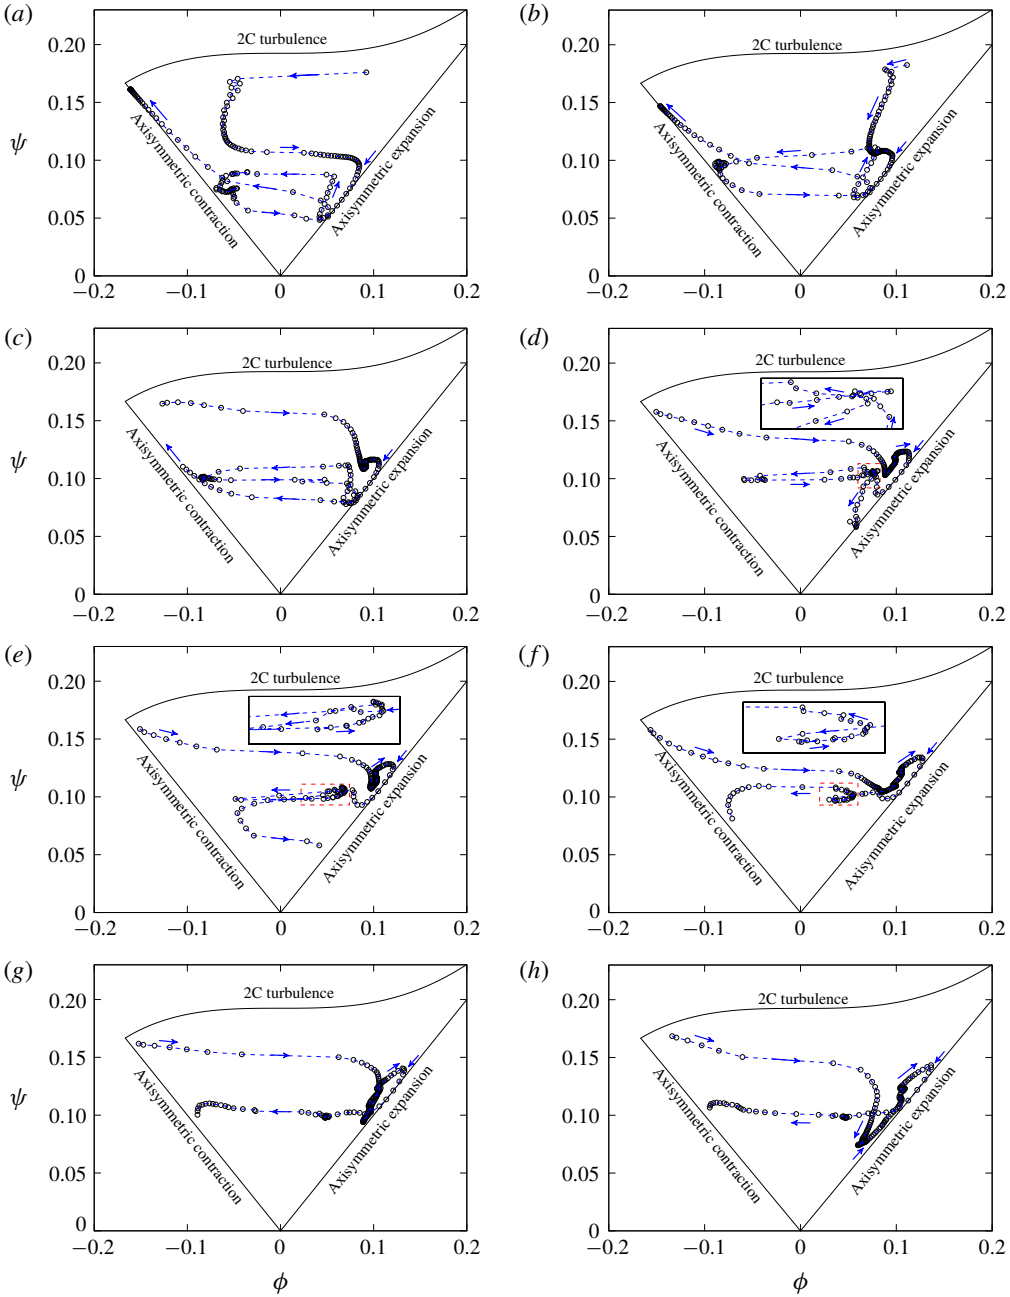

FIGURE 16. (Colour online) A-airfoil, $Re_c = 2.1 \times 10^6$. Invariant maps of WMLES results along vertical lines at eight locations along the suction surface: (a) $x/C = 0.35$; (b) $x/C = 0.55$; (c) $x/C = 0.70$; (d) $x/C = 0.80$; (e) $x/C = 0.85$; (f) $x/C = 0.90$; (g) $x/C = 0.94$; (h) $x/C = 0.96$. \rightarrow denotes the direction away from the airfoil surface.

zone, $x/C = 0.35, 0.55, 0.7, 0.8, 0.85$, the locus of the turbulence state follows a similar approach beyond the wall, i.e. from 2C turbulence to log-law region, and

then free shear-layer region. As the location moves closer towards the separation point fewer points concentrate along the ‘axisymmetric contraction’ line. In the recirculation zone, $x/C = 0.9, 0.94, 0.96$, most of the states are clustered along the ‘axisymmetric expansion’ line although a portion of the locus approaches the ‘axisymmetric contraction’ line. In the present case, the anisotropy in a free shear layer is considerably lower than that in a near-wall layer, and thus the turbulence state never approaches the two-component state at the end.

7. Unsteady flow separation and reattachment

It is evident that the time- and spanwise-averaged skin friction (i.e. C_f -plot) at the airfoil surface provides much useful information for interpreting separation and reattachment behaviour. However, these mean-flow concepts are insufficient to fully understand the flow physics in its entirety including the unsteady force load and temporal turbulent transition that are seen in these aerodynamic flows. Such unsteady flow behaviour manifested near the trailing edge may result in detrimental phenomena such as airfoil vibration. In the present section, we attempt to understand the unsteady flow behaviour through a presentation of skin-friction lines, i.e. curves tangent to the local skin-friction vector and interpreted as limiting streamlines for the near-wall flow. We also use the plot of the spanwise-averaged flow field to illustrate the skin-friction lines.

We briefly digress to discuss flow past circular smooth, and grooved cylinders referring to the recent work by Cheng *et al.* (2017, 2018a). In this series of study, the sudden change of aerodynamic force (the drag crisis) around the cylinder is ascribed to the unsteady interaction of primary separation and secondary separation behaviour. This unsteady separation interaction effect and the turbulent transition effect both appear in the drag crisis of flow past a smooth cylinder. On the other hand, for the grooved cylinder the unsteady separation interaction effect still dominates the flow and results in a similar drag crisis phenomenon, but the turbulent transition effect is difficult to discern. In the present study of flow past airfoils, we note that the airfoil itself has smoothly varying curvature along its surface ranging from large curvature near the stagnation point to zero curvature near the trailing edge (excluding the sharp trailing edge point). While the airfoil is clearly different from a smooth cylinder of constant curvature, and also different from a grooved cylinder with larger curvature change over short distances, it is nonetheless interesting and instructive to examine the instantaneous flow field. The discussion presented here focuses on time sequences of the flow and examines the correspondences between the spanwise-averaged streamlines, the spanwise-averaged skin-friction coefficient C_f and the surface streamlines on the upper or suction side of the airfoil under consideration.

Analysing the unsteady flow patterns is a challenging task owing to the vast amount of data generated in these unsteady 3-D simulations. A rational approach is warranted to identifying key time instants where the flow separation behaviour shows significant differences. Here we use a time evolution instantaneous $\tilde{u}(t)/U_\infty$ for all three cases at specified monitoring points (see figure 17) to aid the selection of specific time instances for a closer examination of surface streamlines (discussed in the ensuing sub-sections).

7.1. Data analysis for three cases

For the NACA0012 airfoil, the monitoring point is located at $x/C = 0.96$ inside the separation zone. As shown in figure 17(a), which shows a somewhat regular

FIGURE 17. (Colour online) Time history of $\tilde{u}(t)/U_\infty$ at the first grid point at specified streamwise locations. (a) NACA0012, $Re_c = 10^4$, $x/C = 0.96$; (b) NACA0018, $Re_c = 10^5$, $x/C = 0.35$; (c) Aérospatiale A-airfoil, $Re_c = 2.1 \times 10^6$, $x/C = 0.882$. The marked points denote the selected time instances for analysing the unsteady separation behaviour in the near-wall regions.

oscillation, four typical instantaneous snapshots of the near-wall flow field are chosen to analyse the surface skin-friction profiles: two corresponding to a local maximum and minimum, and one each corresponding to the upward and downward flow speed.

For the NACA0018 airfoil, where the flow is still regular but with more than one dominant frequency, the monitoring point is located at $x/C = 0.35$. Four typical instantaneous snapshot of the near-wall flow field are adopted, as shown in figure 17(b), similar to the choice of the NACA0012 airfoil.

For the A-airfoil, the monitoring point is located at $x/C = 0.882$. Only two typical instantaneous snapshot of the near-wall flow field are chosen: one at a local maximum and the other at a local minimum (see figure 17c), due to strongly random variations of $\tilde{u}(t)/U_\infty$.

For every time instant analysed in the next several plots, we use the spanwise-averaged wall-parallel skin-friction coefficient C_f , spanwise-averaged streamlines and skin-friction lines of the instantaneous skin-friction vector \mathbf{C}_f . These include figure 18 for the case of $Re_c = 10^4$, figure 19 for the case of $Re_c = 10^5$ and figure 20 for the case of $Re_c = 2.1 \times 10^6$.

In every plot, we show a dashed line to represent every zero-crossing point in the spanwise-averaged C_f plot, and label it as S_i if the flow is separating or R_i if reattaching. It should be emphasized that, due to the prevalence of many local separation/reattachment bubbles, sometimes it is difficult to recognize the separation point and reattachment for a given specific bubble and thus the subscript is not exactly related to a fixed bubble. We label the subscript i only for counting the critical points along the flow direction.

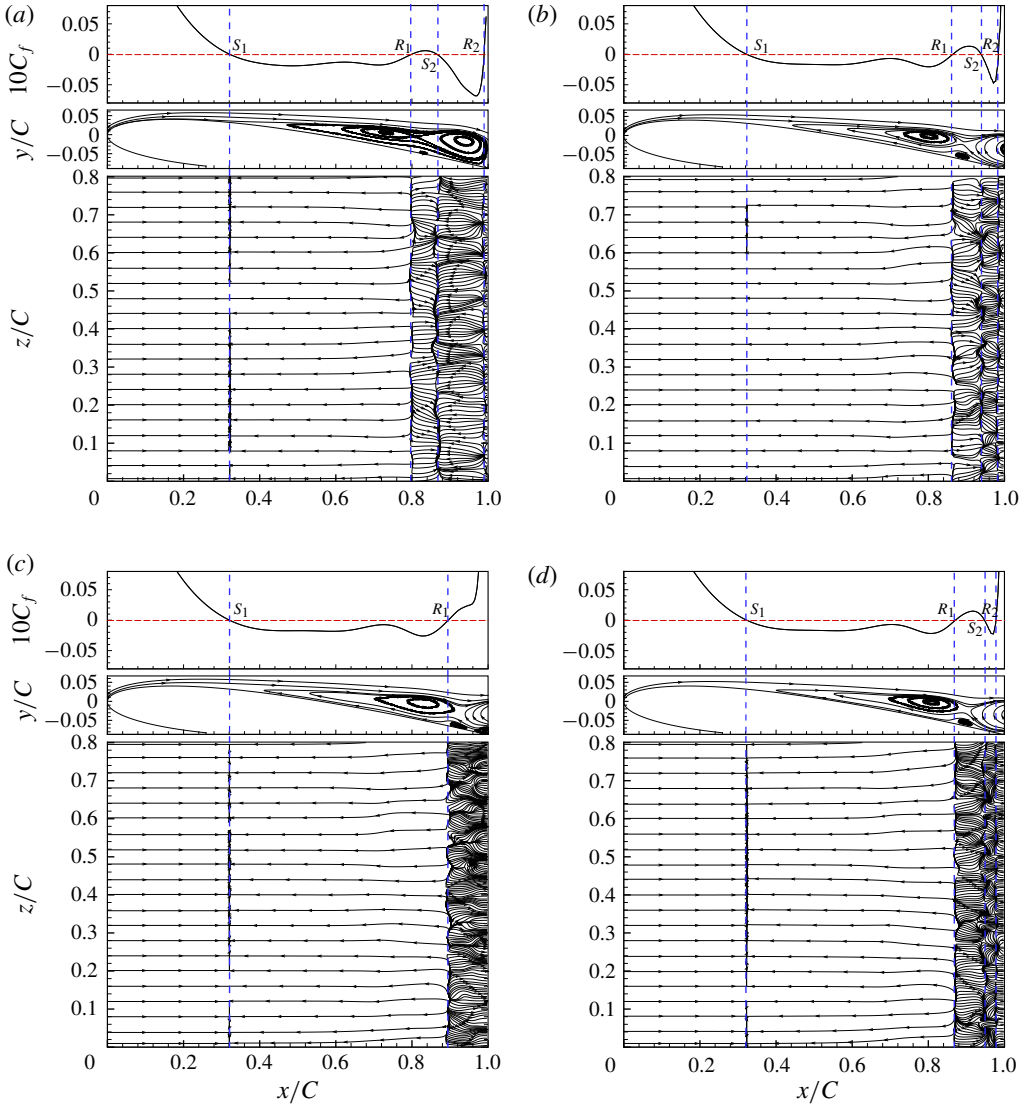

FIGURE 18. (Colour online) NACA0012, $Re_c = 10^4$. The separation behaviour on the suction side at different instants. (a) $t = 80.21C/U_\infty$; (b) $t = 82.16C/U_\infty$; (c) $t = 83.72C/U_\infty$; (d) $t = 85.22C/U_\infty$. For each panel: top, the instantaneous spanwise-averaged friction coefficient C_f ; middle, streamlines of the instantaneous spanwise-averaged flow field; bottom, the skin-friction trajectories.

7.2. $Re_c = 10^4$

In § 5.1 where the WMLES results are verified against DNS of the NACA0012 case at $Re_c = 10^4$, we observe shear layer turbulent transition at approximately $x/C = 0.92$, which is very close to the trailing edge. In figure 18, there is a primary separation point, denoted S_1 in all the figures at $x/C = 0.32$: this is identified as the first zero crossing of C_f and remains virtually unchanged for the entire time sequence. The correspondence between the spanwise-averaged streamlines, C_f and surface streamlines, marked by a dashed blue line, is clear. Moreover, in the neighbourhood

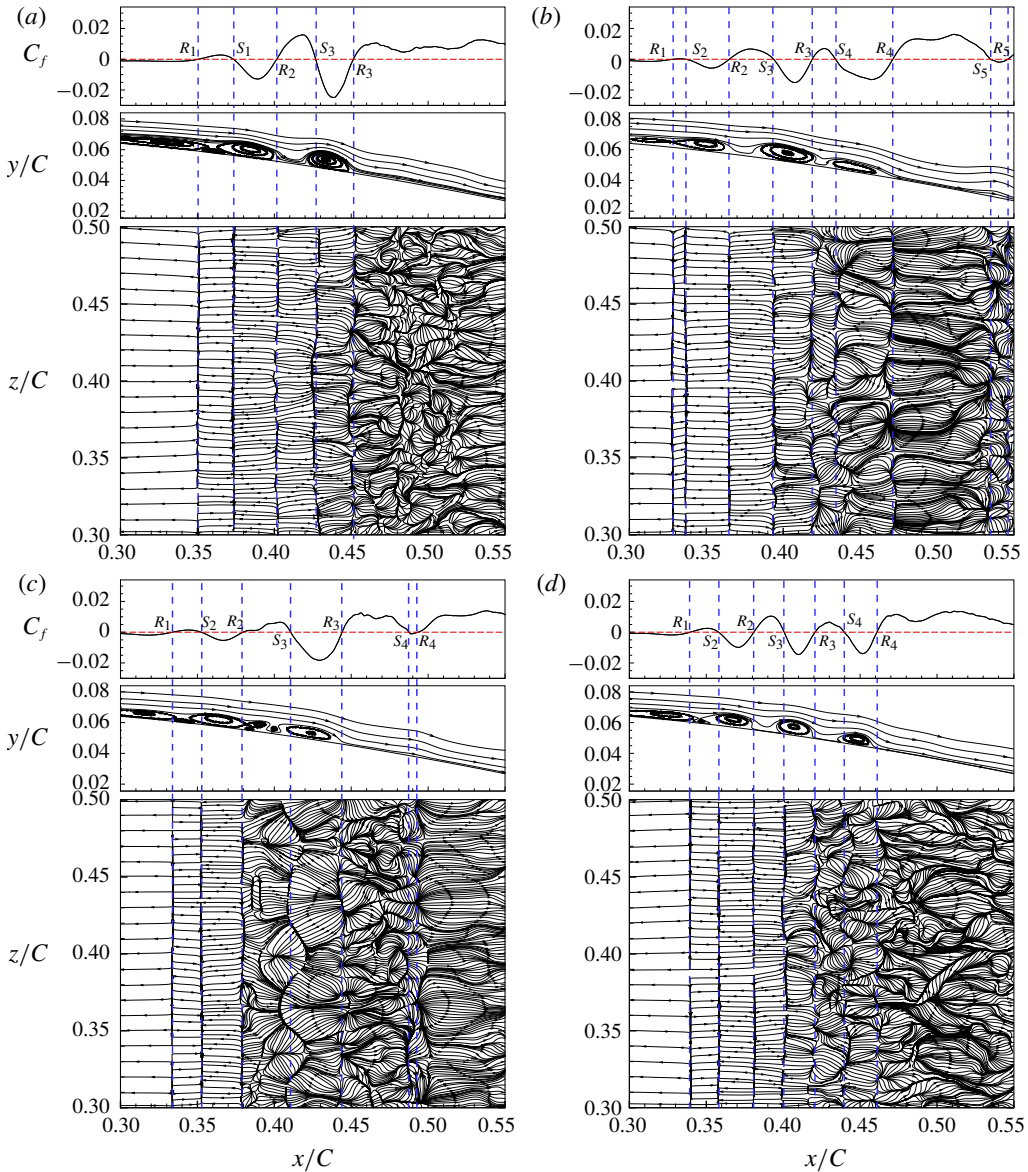

FIGURE 19. (Colour online) NACA0018, $Re_c = 10^5$. The separation behaviour on the suction side at different instants: (a) $t = 57.59C/U_\infty$; (b) $t = 57.74C/U_\infty$; (c) $t = 58.49C/U_\infty$; (d) $t = 59.13C/U_\infty$. For each panel: top, the instantaneous spanwise-averaged friction coefficient C_f ; middle, streamlines of the instantaneous spanwise-averaged flow field; bottom, the skin-friction trajectories.

of the separation line on the airfoil surface, the surface streamlines are straight with no spanwise components, and converge at $x/C = 0.32$. This is indicative of the fact that the flow is virtually two-dimensional with no spanwise variation until the primary separation line S_1 . This separation point S_1 marks the beginning of the globally separated flow, and constitutes the ‘primary separation bubble’ (PSB). This bubble reattaches near the trailing edge, at point R_2 in figure 18(a,b,d), but not in figure 18(c).

FIGURE 20. (Colour online) A-airfoil, $Re_c = 2.1 \times 10^6$. The separation behaviour on the suction side at different instants. (a) $t = 15.92C/U_\infty$; (b) $t = 16.91C/U_\infty$. For each panel: top, the instantaneous spanwise-averaged friction coefficient C_f ; middle, streamlines of the instantaneous spanwise-averaged flow field; bottom, the skin-friction trajectories.

Inside the PSB, the flow shows a small secondary separated zone which separates at S_2 and reattaches at R_1 . On surface streamline plots, these near-wall separation and reattachment flows degenerate to bundles of diverging/converging streamlines. This secondary separation bubble is also observed in figure 18(a,b,d), while it is not observed in 18(c). It is clear that during the shedding process, part of the vorticity is extracted from the primary separation bubble and the secondary separation bubble. We note that the separation points (S_2) of the secondary separation bubble, if it exists, remain at around $x/C = 0.87, 0.94, 0.96$; points which are close to the observed turbulent transition point through $-\overline{u'v'}$. From this viewpoint, it is plausible to conclude the secondary separation bubble is related to shear-layer turbulent transition. Instead of considering the secondary separation bubble as a signature of turbulent transition, we prefer to suggest that the wall-attached bubble is a source of perturbations leading to the shear layer turbulent transition.

7.3. $Re_c = 10^5$

Based on the time- and spanwise-averaged (C_p, C_f) as plotted in figure 7 for the NACA0018 airfoil case, the turbulent boundary layer flow forms starting at approximately $x/C = 0.45$. This turbulent boundary layer remains generally attached until the trailing edge. For this case, we mainly discuss the region of the transition part, which corresponding to the region $x/C \in [0.3, 0.55]$ on the suction side of the airfoil, as shown in each plot in figure 19. We note the separation point denoted S_1 , which is close to the leading edge, is not visible in the present plots.

A notable difference of the present case from the case of $Re_c = 10^4$ is the disappearance of the primary separation bubble. For the NACA0018 case at $Re_c = 10^5$, the flow exhibits strong unsteadiness, and the separated flow somewhat breaks up into several small bubbles. Among the four plots of figure 19, we can see points of R_1 , S_2 , R_2 , S_3 and R_3 at all instants, but points S_4 , R_4 , R_5 and R_5 are seen only at some instants. Hence for this case, the interaction of several separation bubbles contributes to the shear-layer turbulent transition, and the flow, while more complex, may be considered as an extension of the mechanism in the case of $Re_c = 10^4$ for NACA0012.

Another interesting phenomenon for this case at $Re_c = 10^5$ is the spanwise length scale. In figure 19(c), features with a length scale of a fraction of the spanwise domain size are observed in the plot of skin-friction lines. While the flow remains two-dimensional up to point R_2 at approximately $x/C = 0.38$, the spanwise variation beyond that point grows and a somewhat periodic behaviour in the spanwise direction is observed. At $x/C \approx 0.41$, structures with a scale of approximately $0.08C$ are noted. These structures keep breaking into small-scale structures in the downward region, until reaching the turbulent region. Here we briefly comment on our somewhat larger spanwise domain extent compared with other airfoil simulations in the literature. From the unsteady and irregular surface flow patterns in the higher Reynolds number case, we point out that airfoil simulations employing small spanwise domain sizes may not be able to faithfully reproduce the unsteady flow patterns observed in our LES.

7.4. $Re_c = 2.1 \times 10^6$

Flow at $Re_c = 2.1 \times 10^6$ endures not only shear-layer turbulent transition and corresponding attached turbulent boundary layer flow (shear-layer development and log-law region, see figure 16), but also turbulent separation, which is of interest here. In figure 20, we use data at two instants and plot the spanwise-averaged skin-friction coefficient, spanwise-averaged streamlines and surface streamlines, focusing on the turbulent separation region of $x/C \in [0.8, 1.0]$.

Skin-friction lines at this high Reynolds number show features of a distinct length scale. In both plots, we can observe two distinct flows, with some large-scale structures corresponding to typical turbulent flow, and some small-scale structures which are essentially local separation/reattachment cells and are signatures of local flow reversals. The aggregation of those local reversal flows forms separation lines. It should be emphasized in this high Re_c case, we do not discern clear instantaneous separation of the turbulent flow or small-scale reversal flows along the flow direction compared with the previous lower Reynolds number cases.

7.5. Comparisons with other turbulent flows

It is interesting to compare the skin-friction portraits of airfoil flows to other canonical flows. When turbulent separation phenomenon takes place in turbulent boundary layer flow, as described by Chong *et al.* (1998), although a clear separation line cannot be observed, a region of small reversal flows is visible around the mean flow separation point. In flow past a circular cylinder, unsteady separation phenomena, especially the secondary separation/reattachment, dominate the mean features of the flow. For high Reynolds number cases, the unsteady secondary separation/reattachment can also be observed from instantaneous skin-friction portraits, revealed by the aggregation of small-scale reversal flows as noted in Cheng *et al.* (2017), while the spanwise distribution does not show much difference. This kind of effect is artificially enhanced

in the grooved cylinder case of Cheng *et al.* (2018a), by using grooves distributed in the azimuthal direction while retaining the groove shape in the spanwise direction. Another case which also shows ordered small-scale reversal flows is that of a rotating cylinder as discussed in Cheng, Pullin & Samtaney (2018b). In rotating cylinder, the lift crisis phenomenon, or so-called reverse Magnus effect, is found to be a result of flow reorganization due to the aggregation of small-scale separation/reattachment cells on the under and leeward parts of the cylinder surface. In this way, an ordered dividing line, which clearly shows upstream attached flow, and downstream small-scale reversal flows, is found to show little difference in the spanwise direction. This is quite similar to the turbulent separation in turbulent boundary layer flows.

However, in the present study of flow over airfoils, we note a stronger dependence or flow distortion in the spanwise distribution. In cases with $Re_c = 10^4$ and 10^5 , along the flow evolution, we note the presence of local structures, with a variation in spanwise direction. Such structures show different intensities at different instants, for example, a strong deviation from separation point S_3 in figure 19 at around $x/C \approx 0.41$. Strong spanwise distribution is even obvious for the turbulent separation case at $Re_c = 2.1 \times 10^6$. In this case, a clear dividing line that separates the incoming flow and small-scale reversal flows is hardly observed, which is unlike what is seen in a flat-plate turbulent boundary layer and cylinder flows.

In summary, airfoil flow shows quite similar but still exhibit unique behaviour compared to classical flows such as flow over a cylinder and turbulent boundary layer flow. In the case of $Re_c = 10^4$, a primary separation bubble and a secondary separation bubble are clearly visible and their interaction forms the source of shear-layer turbulent transition, which is similar to the flow over a smooth cylinder. In the case of $Re_c = 10^5$, the separation region breaks into several unsteady bubbles and their interaction results in strong spanwise variation and further evolution into turbulence. This strong spanwise structure provides a reference length scale for reasonably predicting flows. For the case $Re_c = 2.1 \times 10^6$, besides the similar turbulent transition behaviour, the turbulent separation phenomenon is similar to flat-plate turbulent separation in the sense of small-scale reversal flows, but still possesses its own character due to vortex shedding.

8. Conclusion

In this study, we have presented results of wall-modelled large-eddy simulations of flow past three different airfoils (NACA0012, NACA0018 and A-airfoil) at Reynolds number varying from $Re_c = 10^4$ to 2.1×10^6 . A Dirichlet boundary condition for the tangential velocity components is derived at a virtual wall in generalized curvilinear coordinates, which is coupled with an ordinary differential equation governing the wall shear stress (which is integrated analytically in time after some simplifying assumptions are made). We employ the stretched spiral vortex model for the SGS tensor in the computational domain. The numerical methodology is based on fourth-order spatial differencing, with a multigrid Poisson solver for the pressure utilizing Gauss–Seidel line smoothers. The formulation presented in generalized curvilinear coordinates opens up the possibility of using the proposed LES methodology with the associated wall models for a complex geometry.

At relative low Reynolds number ($Re_c = 10^4$) detailed comparisons (velocity profiles, skin friction and Reynolds stresses) between the wall-modelled LES (WMLES) and DNS show excellent agreement including the capturing of a near trailing edge separation bubble on the suction side of the NACA0012 airfoil. For the NACA0018

airfoil case at moderately higher Reynolds number ($Re_c = 10^5$), comparisons with experiments of pressure coefficient, skin friction, average and r.m.s. velocity profiles show good agreement with the largest difference noted for the streamwise fluctuating velocity close to the reattachment point. For the A-airfoil, at even higher Reynolds number ($Re_c = 2.1 \times 10^6$), good agreement between WMLES and experiments is noted: the WMLES does not capture the tiny separation bubble near the leading edge after time and spanwise averaging although flow reversals in instantaneous velocity are noted; moreover, the WMLES Reynolds stresses show trends that are in agreement with experiments.

In the present study, we also examined the anisotropy of the flow in the context of the Lumley triangle. We note that all points lie within the triangle, as required by the realizability condition. For the low Reynolds number case, we note that in the near-wall region the turbulence approaches the two-component state progressing along the axisymmetric expansion line similar to the case of the log region in a channel flow. Within the separation zone, the behaviour is similar to that of free shear layers, as expected. The moderate Reynolds number case behaves similarly to the lower Reynolds number case, and once again several points lie on the log-law region. For the highest Reynolds number case, we see signatures of progress from 2C turbulence to log law to free shear-layer flow; although in this case the anisotropy in the free shear layer is considerably lower.

In this study, we examined the surface streamlines for three airfoils at the three different Reynolds numbers. For the low Reynolds number case, we noted that the surface streamlines remain approximately aligned with the streamwise direction over a significant portion of the airfoil surface before significant meandering in the spanwise direction is observed. As the Reynolds number is increased, the surface streamline plots show significant departures from the streamwise direction, with several secondary separation and reattachment points that are very unsteady compared with the nearly steady primary separation point. These unsteady secondary separation/reattachment bubbles were also noted in previous wall-resolved LES by Cheng *et al.* (2017) of flow past a circular cylinder. A reasonable conclusion is that the flow separation patterns show some coherence with separation/reattachment lines aligned along the spanwise direction before eventually becoming unsteady with no directional spanwise alignment in general for all cases.

Appendix A. Equation for $\langle q \rangle$

From the definition of \tilde{u}_s , (3.10) and combining (3.8a) and (3.8b), we can obtain the streamwise momentum equation along the wall,

$$\begin{aligned} \frac{\partial \tilde{u}_s}{\partial t} &= \frac{\partial \tilde{u}}{\partial t} \cos \theta_w + \frac{\partial \tilde{v}}{\partial t} \sin \theta_w \\ &= -\frac{\cos \theta_w}{\sqrt{g}} \frac{\partial}{\partial \xi^m} \left(\widetilde{U^m u} + \sqrt{g} \frac{\partial \xi^m}{\partial x} \tilde{p} - \nu G^{mn} \frac{\partial \tilde{u}}{\partial \xi^n} \right) \\ &\quad - \frac{\sin \theta_w}{\sqrt{g}} \frac{\partial}{\partial \xi^m} \left(\widetilde{U^m v} + \sqrt{g} \frac{\partial \xi^m}{\partial y} \tilde{p} - \nu G^{mn} \frac{\partial \tilde{v}}{\partial \xi^n} \right). \end{aligned} \quad (\text{A } 1)$$

Then combining (3.8c), (3.15) and (A 1), we can obtain

$$\frac{\partial \langle q \rangle}{\partial t} = F_\xi + F_\eta + F_\zeta, \tag{A 2}$$

where

$$\begin{aligned} F_\xi = & -\frac{1}{h} \int_0^h \frac{\tilde{u}_s \cos \theta_w}{\tilde{q}} \frac{\partial}{\sqrt{g}} \frac{\partial}{\partial \xi^1} \left(\widetilde{U^1 u} + \sqrt{g} \frac{\partial \xi^1}{\partial x} \tilde{p} - \nu G^{1n} \frac{\partial \tilde{u}}{\partial \xi^n} \right) d\eta \\ & -\frac{1}{h} \int_0^h \frac{\tilde{u}_s \sin \theta_w}{\tilde{q}} \frac{\partial}{\sqrt{g}} \frac{\partial}{\partial \xi^1} \left(\widetilde{U^1 v} + \sqrt{g} \frac{\partial \xi^1}{\partial y} \tilde{p} - \nu G^{1n} \frac{\partial \tilde{v}}{\partial \xi^n} \right) d\eta \\ & -\frac{1}{h} \int_0^h \frac{\tilde{w}}{\tilde{q}} \frac{1}{\sqrt{g}} \frac{\partial}{\partial \xi^1} \left(\widetilde{U^1 w} + \sqrt{g} \frac{\partial \xi^1}{\partial z} \tilde{p} - \nu G^{1n} \frac{\partial \tilde{w}}{\partial \xi^n} \right) d\eta, \end{aligned} \tag{A 3}$$

$$\begin{aligned} F_\eta = & -\frac{1}{h} \int_0^h \frac{\tilde{u}_s \cos \theta_w}{\tilde{q}} \frac{\partial}{\sqrt{g}} \frac{\partial}{\partial \xi^2} \left(\widetilde{U^2 u} + \sqrt{g} \frac{\partial \xi^2}{\partial x} \tilde{p} - \nu G^{2n} \frac{\partial \tilde{u}}{\partial \xi^n} \right) d\eta \\ & -\frac{1}{h} \int_0^h \frac{\tilde{u}_s \sin \theta_w}{\tilde{q}} \frac{\partial}{\sqrt{g}} \frac{\partial}{\partial \xi^2} \left(\widetilde{U^2 v} + \sqrt{g} \frac{\partial \xi^2}{\partial y} \tilde{p} - \nu G^{2n} \frac{\partial \tilde{v}}{\partial \xi^n} \right) d\eta \\ & -\frac{1}{h} \int_0^h \frac{\tilde{w}}{\tilde{q}} \frac{1}{\sqrt{g}} \frac{\partial}{\partial \xi^2} \left(\widetilde{U^2 w} + \sqrt{g} \frac{\partial \xi^2}{\partial z} \tilde{p} - \nu G^{2n} \frac{\partial \tilde{w}}{\partial \xi^n} \right) d\eta, \end{aligned} \tag{A 4}$$

$$\begin{aligned} F_\zeta = & -\frac{1}{h} \int_0^h \frac{\tilde{u}_s \cos \theta_w}{\tilde{q}} \frac{\partial}{\sqrt{g}} \frac{\partial}{\partial \xi^3} \left(\widetilde{U^3 u} + \sqrt{g} \frac{\partial \xi^3}{\partial x} \tilde{p} - \nu G^{3n} \frac{\partial \tilde{u}}{\partial \xi^n} \right) d\eta \\ & -\frac{1}{h} \int_0^h \frac{\tilde{u}_s \sin \theta_w}{\tilde{q}} \frac{\partial}{\sqrt{g}} \frac{\partial}{\partial \xi^3} \left(\widetilde{U^3 v} + \sqrt{g} \frac{\partial \xi^3}{\partial y} \tilde{p} - \nu G^{3n} \frac{\partial \tilde{v}}{\partial \xi^n} \right) d\eta \\ & -\frac{1}{h} \int_0^h \frac{\tilde{w}}{\tilde{q}} \frac{1}{\sqrt{g}} \frac{\partial}{\partial \xi^3} \left(\widetilde{U^3 w} + \sqrt{g} \frac{\partial \xi^3}{\partial z} \tilde{p} - \nu G^{3n} \frac{\partial \tilde{w}}{\partial \xi^n} \right) d\eta. \end{aligned} \tag{A 5}$$

For the purpose of modelling, we make the following two approximations within the first grid cell $0 \leq \eta \leq h$:

- (i) the velocity angle θ , i.e. \tilde{u}_s/\tilde{q} and \tilde{w}/\tilde{q} , is constant;
- (ii) the Jacobian of the transformation, i.e. \sqrt{g} , is constant.

Then we can reduce F_η to be

$$F_\eta = M + \frac{\nu G^{22}}{\sqrt{gh}} \frac{\partial \tilde{q}}{\partial \eta} \Big|_h - \frac{\nu G^{22}}{\sqrt{gh}} \eta_0. \tag{A 6}$$

where

$$\begin{aligned} M = & -\frac{1}{\sqrt{gh}} \left[\frac{\tilde{u}_s}{\tilde{q}} (\widetilde{U^2 u} \cos \theta_w + \widetilde{U^2 v} \sin \theta_w) + \frac{\tilde{w}}{\tilde{q}} \widetilde{U^2 w} \right] \Big|_h \\ & + \frac{\nu G^{21}}{\sqrt{gh}} \left[\frac{\tilde{u}_s}{\tilde{q}} \left(\frac{\partial \tilde{u}}{\partial \xi^1} \cos \theta_w + \frac{\partial \tilde{v}}{\partial \xi^1} \sin \theta_w \right) + \frac{\tilde{w}}{\tilde{q}} \frac{\partial \tilde{w}}{\partial \xi^1} \right] \Big|_h \\ & + \frac{\nu G^{23}}{\sqrt{gh}} \left[\frac{\tilde{u}_s}{\tilde{q}} \left(\frac{\partial \tilde{u}}{\partial \xi^3} \cos \theta_w + \frac{\partial \tilde{v}}{\partial \xi^3} \sin \theta_w \right) + \frac{\tilde{w}}{\tilde{q}} \frac{\partial \tilde{w}}{\partial \xi^3} \right] \Big|_h \end{aligned} \tag{A 7}$$

FIGURE 21. (Colour online) NACA0012, $Re_c = 10^4$. (a) Distribution of the pressure coefficient C_p around the airfoil, and (b) skin-friction coefficient C_f on the suction surface. —, WMLES with fine mesh; - · -, WMLES with coarse mesh. The - - - line $C_f = 0$ is shown for convenience: zero crossing of this line indicates separation and reattachment.

If the first wall layer is forced to be orthogonal, then the terms with $G^{ij} (i \neq j)$ can be neglected, and η -direction is congruent with the y_n -direction, i.e. $\partial \tilde{q} / \partial \eta|_h = \partial \tilde{q} / \partial y_n|_h$. If the spanwise geometry is uniform, then the terms with $\partial \xi^i / \partial z (i = 1, 2)$ can be neglected.

Appendix B. Analytical solution of the ODE for η_0

The ODE for η_0 , (3.16) can be rewritten as

$$\frac{\partial \eta_0}{\partial t} = (C_1 - C_2 \eta_0) \eta_0, \tag{B 1}$$

and then

$$\frac{\partial \eta_0}{\eta_0} + \frac{\partial \eta_0}{\frac{C_1}{C_2} - \eta_0} = C_1 \partial t. \tag{B 2}$$

If C_1/C_2 is weakly dependent on t , (B 2) can be solved analytically,

$$\eta_0(t) = \frac{C_0 C_1 e^{C_1 \Delta t}}{C_2 + C_0 C_2 e^{C_1 \Delta t}}, \tag{B 3}$$

where

$$C_0 = \frac{\eta_0(t_0)}{\frac{C_1}{C_2} - \eta_0(t_0)}, \quad t = t_0 + \Delta t, \tag{B 4}$$

and t_0 is the current time, Δt is the time interval in the simulations.

Appendix C. The effects of mesh resolution on WMLES

To evaluate the effects of mesh resolution on WMLES, another WMLES with a coarser mesh ($N_\xi \times N_\eta \times N_z = 512 \times 64 \times 32$) is performed for the NACA0012 case

($Re_c = 10^4$, $AoA = 5^\circ$, $L_z = 0.8C$). The wall-normal mesh size $\Delta\eta$ is doubled, and correspondingly the height of the virtual wall is doubled since we have fixed $h_0 = 0.18\Delta\eta$. We note that the maximum $\Delta\eta^+$ still lies in the logarithmic region, but also that care must be exercised to have a decent resolution of the very thin laminar boundary layer near the leading edge for the subsequent flow development, such as separation and shear-layer transition (Park & Moin 2014). To show convergence, in figure 21 we plot both the time- and spanwise-averaged pressure and skin-friction coefficients around the NACA0012 airfoil. It is evident from the C_p -plot that the peak value of WMLES with the coarse mesh is slightly larger than that with the fine mesh, as reported in § 5.1. A larger discrepancy is observed at the trailing edge, i.e. close to the reattachment point. Both these two meshes work well for the prediction of separation and subsequent reattachment, although the absolute peak value of C_f in the separation bubble of the coarse mesh WMLES is smaller than the fine mesh. Overall, these comparisons indicate that the present wall model can capture the separation bubble well even with the coarse mesh.
