## Abstract

The development of high brightness X-ray free electron laser (XFEL), such as hard X-ray self-seeding FEL and XFEL oscillator (XFELO), brings a severe challenge to the crystal monochromator due to strong non-uniform thermal load. The distortion caused by spatial temperature gradients can severely affect the optical performance of crystals. Therefore, this paper presents a model to estimate the performance of non-uniform thermally distorted crystals. The model not only takes into account thermal strain, slope error, and incident angle deviation but also considers temperature-dependent factors such as the Debye-Waller factor and electric susceptibility. Our investigation indicates that the Debye-Waller factor reduces the height and bandwidth of rocking curves and the impact of the electric susceptibility is tiny. The proposed model can describe the distortion of the reflectivity and transmissivity curves of non-uniform thermally loaded crystals and can be applied in the design of crystal monochromators, crystal splitters, crystal compressors, and XFELOs.

**Keywords:** thermal load; X-ray diffraction; free electron laser; crystal monochromator

## 1. Introduction

X-ray free electron lasers (XFEL) are capable of producing high brightness, ultra-short, fully coherent pulses, and provide an unparalleled tool to explore fundamental questions in chemistry, biology, atomic, molecular, and materials science. Several hard X-ray FEL user facilities are currently in operation or under construction, including LCLS<sup>[1]</sup>, SACLA<sup>[2]</sup>, PAL-XFEL<sup>[3]</sup>, SwissFEL<sup>[4]</sup>, European XFEL<sup>[5]</sup>, and SHINE<sup>[6]</sup>. However, the high peak power of XFELs creates a severe thermal load on X-ray optics, such as crystal monochromators, crystal splitters, and mirrors. This thermal load issue has been a concern for several decades with the development of synchrotron radiation light sources (SRLS) and XFELs. The optical beamline system aims to focus the beam, preserve the wavefront, and purify the spectrum, but thermal load results in wavefront disturbance, efficiency degradation, and crystal lattice distortion. More generally, the thermal load is non-uniform, which brings distortion to

the rocking curve, decreases the efficiency, shifts the central photon energy, and broadens the bandwidth. For XFELs, the brightness is about 10 orders of magnitude higher than that of SRLS, and the thermal load effect is severe. The high brightness brings challenges to the design of X-ray optics, such as hard X-ray self-seeding monochromator<sup>[7]</sup>, X-ray free electron laser oscillator (XFELO) cavity<sup>[8,9]</sup>, crystal compressors<sup>[10]</sup>, and crystal beam splitter<sup>[11,12]</sup>. The difficulties arising from non-uniform thermal load urgently call for the investigation of X-ray diffraction by distorted crystals.

The distortion and central wavelength shift of rocking curves have attracted much attention for decades<sup>[13,14]</sup>. Researchers have realized that the central wavelength shift can be estimated by the maximum thermal strain, and the rocking curve distortion can be attributed to the slope error caused by non-uniform thermal load. However, there is still a lack of theoretical descriptions of X-ray diffraction by thermally loaded crystals. Bushuev developed a theoretical model<sup>[15]</sup> to calculate the rocking curves of non-uniform thermally loaded crystals by analytically solving

the equation of thermal conduction under spatiotemporal dependences of the distribution of temperature. In this model, Bushuev first treated the thermal properties of crystal as constant, and then expanded to temperature-dependent thermal properties<sup>[16]</sup>. Bushuev applied his model to estimate the performance of the self-seeding crystal monochromator of European XFEL. Yang et al. investigated the transient thermal stress wave and vibration to describe the thermomechanical issues for thin diamond crystals under high-repetition-rate operation of an X-ray FEL<sup>[17]</sup>, but no further analysis is carried out about the distortion of the rocking curve induced by non-uniform thermal load. Based on Bushuev's work, Qu et al. further formulated the factors (such as the maximum strain and non-uniform thermal load) that affect the central wavelength shift and the distortion of rocking curve<sup>[18]</sup>, and they discussed these effects separately and quantitatively by an analytical method. They applied their method to estimate the thermal load on the self-seeding monochromator<sup>[19,20]</sup>. The above theoretical methods have successfully illustrated the central wavelength shift and the distortion of rocking curves. However, these methods are developed under the assumption that the Debye-Waller factor and electric susceptibility are temperature independent.

In this study, we focus the investigation on the temperature dependence in X-ray diffraction via the Debye-Waller factor and electric susceptibility. For a thermally loaded crystal, the vibration of atoms at different temperatures contribute to the Debye-Waller factor and further affect the form factor of atoms and the structure factor of crystals. Besides, thermal expansion changes the volume of the unit cell, which results in the perturbation of the structure factor and eventually impacts the electric susceptibility. This paper is organized as follows. In Sec. 2, we briefly review the dynamical theory of X-ray diffraction, the electric susceptibility, and the Debye-Waller factor. Then, we establish a numerical model to estimate rocking curves of thermally loaded crystals while considering the temperature dependence of the Debye-Waller factor and electric susceptibility. We also consider the thermal strain and incident angle deviation. These factors have a combined impact on the central photon energy shift and distortion of rocking curves. In Sec. 3, under the assumption of uniform thermal load, the impact of temperature dependence on the electric susceptibility and the Debye-Waller factor in X-ray diffraction is analyzed. In Sec. 4, we make a comparison between our method and Bushuev's approach. Finally, we apply this model to estimate the pulse-to-pulse performance of thermally loaded diamond crystal. This work can provide a guidance to the design work of crystal monochromators, crystal splitters, crystal compressors, and XFELO cavities.

## 2. The calculation model of X-ray diffraction by thermally loaded crystals

In this section, we first briefly review the dynamical theory of X-ray diffraction<sup>[21–23]</sup>. Then, we review the electric susceptibility and Debye-Waller factor<sup>[24]</sup>. Finally, we establish a model to estimate the rocking curves of thermal-load crystals by combining the Debye-Waller factor, the electric susceptibility, thermal strain, and slope error.

### 2.1. Dynamical theory of X-ray diffraction

The dynamical theory of X-ray diffraction can accurately describe X-rays diffraction from a perfect crystal<sup>[21–23]</sup>. According to this theory, the Bragg diffraction  $R_{0H}$  and forward Bragg diffraction  $R_{00}$  amplitudes by a perfect thin crystal can be expressed as

$$R_{0H} = R_1 R_2 \frac{1 - e^{-i(\mathbf{R}_1 - \mathbf{R}_2)l}}{R_2 - R_1 e^{-i(\mathbf{R}_1 - \mathbf{R}_2)l}}, \quad (1a)$$

$$R_{00} = e^{-i\mathbf{R}_1 l} \frac{R_2 - R_1}{R_2 - R_1 e^{-i(\mathbf{R}_1 - \mathbf{R}_2)l}}, \quad (1b)$$

where

$$R_j = \frac{S(\gamma_h)}{\sqrt{|\gamma|}} \cdot \frac{\sqrt{\chi_h \chi_{\bar{h}}}}{\chi_{\bar{h}}} \left[ y \pm \sqrt{y^2 + S(\gamma_h)} \right], \quad (j = 1, 2) \quad (2a)$$

$$\mathbf{R}_j = \frac{k\chi_0}{2\gamma_0} + \frac{S(\gamma_h)}{2A_0} \left[ y \pm \sqrt{y^2 + S(\gamma_h)} \right], \quad (j = 1, 2) \quad (2b)$$

$$y = \frac{kA_0}{2\gamma_h} (-\alpha + \alpha'), \quad A_0 = \frac{\lambda \sqrt{\gamma_0 |\gamma_h|}}{P \sqrt{\chi_h \chi_{\bar{h}}}}, \quad (2c)$$

and

$$\alpha = 2 \sin 2\theta_B \left[ \Delta\theta + \left( \frac{\Omega}{\omega_0} + \frac{\Delta d}{d} \right) \tan \theta_B \right], \quad (3a)$$

$$\alpha' = \chi_0 (\gamma - 1), \quad (3b)$$

and the intensities of Bragg diffraction (reflectivity) and forward Bragg diffraction (transmissivity) can be written as

$$I_{0H} = \gamma |R_{0H}|^2, \quad I_{00} = |R_{00}|^2. \quad (4)$$

Here, the parameter  $\alpha$  is introduced to account for a small perturbation that causes a deviation from the Bragg condition. Such perturbation may stem from various sources, such as deviations in incident angle ( $\Delta\theta$ ), angular frequency ( $\Omega$ ), and lattice spacing ( $\Delta d$ ). The parameter  $\alpha'$  specifically characterizes the deviation from the Bragg diffraction, which arises from the refraction of the crystal.  $\gamma$  is the asymmetry ratio, and is given by

$$\gamma = \frac{\gamma_h}{\gamma_0} = \frac{\cos \Psi_h}{\cos \Psi_0}, \quad (5a)$$

$$\Psi_0 = \eta + \theta_B - \frac{\pi}{2}, \quad \Psi_h = \eta - \theta_B - \frac{\pi}{2}, \quad (5b)$$

where  $\eta$  is the asymmetry angle which describes the angle between the crystal surface and the parallel reflecting atomic planes.  $S(\gamma_h)$  denotes the sign of  $\gamma_h$ .

## 2.2. Electric susceptibility and Debye-Waller factor

In a crystal, both the charge density function  $\rho(\mathbf{r})$  and the electric susceptibility  $\chi(\mathbf{r})$  are triply periodic function of the space coordinates  $\mathbf{r}$ , and the electric susceptibility can be expressed as

$$\chi(\mathbf{r}) = -\frac{r_e \lambda^2}{\pi} \rho(\mathbf{r}) = \sum_{\mathbf{h}} \chi_h \exp(i\mathbf{h} \cdot \mathbf{r}). \quad (6)$$

The coefficients  $\chi_h$  of the Fourier expansion can be related to the structure factor  $F_h$  of crystal, then we have

$$\chi_h = -\frac{r_e \lambda^2}{\pi V_c} F_h, \quad (7a)$$

$$F_h = \int \rho(\mathbf{r}) \exp(-i\mathbf{h} \cdot \mathbf{r}) d\mathbf{r}. \quad (7b)$$

It is easy to have a picture that atoms are arranged in a periodic lattice in a crystal. The vibration of the atoms can be thermally excited inside a crystal. Therefore, the vibration is temperature dependent, and can result in the decrease of the intensity of the scattered wave. The structure factor of a vibratory crystal can be expressed as

$$F_h = \sum_j [f_j(\mathbf{h}) + f'_j + f''_j] \exp(-M_j) \exp(-i\mathbf{h} \cdot \mathbf{r}), \quad (8)$$

where  $f_j(\mathbf{h})$  is the form factor of atom  $j$ .  $f'$  and  $f''$  are the dispersion corrections.  $\exp(-M_j)$  is the Debye-Waller factor<sup>[24]</sup>, and  $M_j$  is given by

$$M_j = B_T^j \left( \frac{\sin \theta}{\lambda} \right)^2. \quad (9)$$

If the atom vibrates isotropically and only one type of atom is considered, the thermal factor  $B_T$  can be written as

$$B_T = \frac{6h^2}{m_A k_B \Theta} \left[ \frac{\phi(\Theta/T)}{\Theta/T} + \frac{1}{4} \right], \quad (10a)$$

$$\phi(x) = \frac{1}{x} \int_0^x \frac{\xi}{e^\xi - 1} d\xi, \quad (10b)$$

where  $m_A$ ,  $k_B$ ,  $\Theta$ , and  $h$  are the mass of the atom, Boltzmann constant, Debye temperature, and Planck constant, respectively. The detailed derivation of Eq. (9) and Eq. (10) can be found in<sup>[24]</sup>.

## 2.3. Model of X-ray diffraction by thermally loaded crystals

In this subsection, we establish a numerical model to estimate X-ray diffraction performance of thermally loaded crystals. In this model, we take the Debye-Waller factor, the electric susceptibility, thermal strain, incident angle deviation, and slope error into consideration.

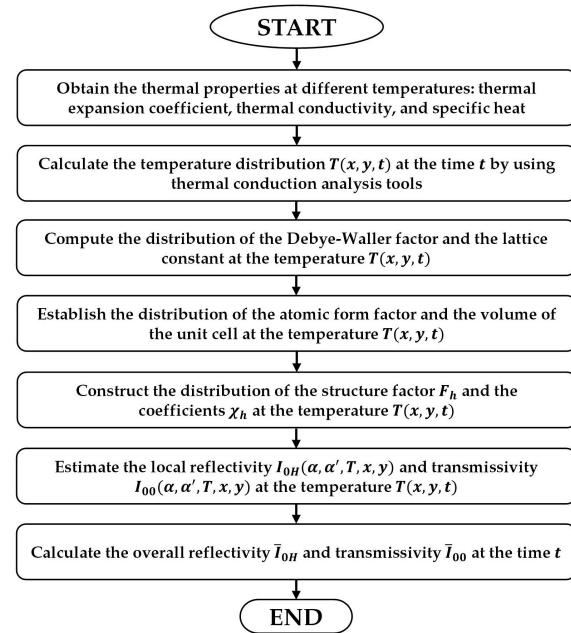

When a series of XFEL pulses are incident on a crystal, the thermal characteristics, such as thermal conductivity, thermal expansion coefficient, specific heat capacity, and Debye-

Waller factor, vary at different spatial locations due to non-uniform thermal loading. To estimate the overall reflectivity and transmissivity, we employ a weighted average method similar to that utilized in Bushuev's research.

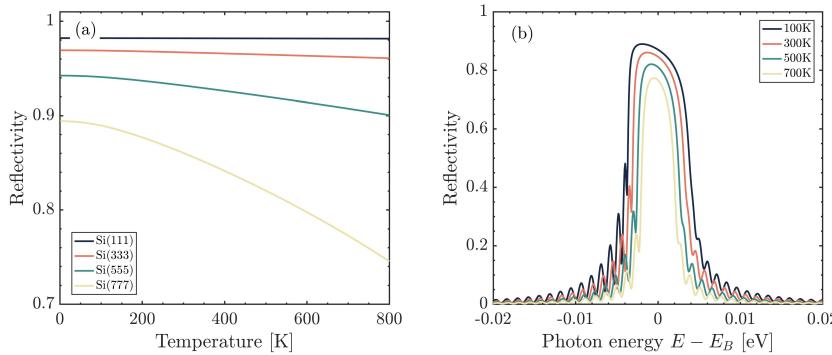

$$\bar{I}_{0H} = \frac{\iint_{-\infty}^{+\infty} I_{0H}(\alpha, \alpha', T, x, y) I(x, y) dx dy}{\iint_{-\infty}^{+\infty} I(x, y) dx dy}, \quad (11a)$$

$$\bar{I}_{00} = \frac{\iint_{-\infty}^{+\infty} I_{00}(\alpha, \alpha', T, x, y) I(x, y) dx dy}{\iint_{-\infty}^{+\infty} I(x, y) dx dy}, \quad (11b)$$

where  $I(x, y)$  is intensity distribution. To establish the local reflectivity  $I_{0H}(\alpha, \alpha', T, x, y)$  and transmissivity  $I_{00}(\alpha, \alpha', T, x, y)$ , we have devised a methodological framework as depicted in Fig. 1. First, we obtain the thermal properties of the crystal at different temperatures, including thermal expansion coefficient, thermal conductivity, and specific heat. Second, we calculate the temperature distribution  $T(x, y, t)$  through either a theoretical model<sup>[15,16]</sup> or thermal analysis software such as COMSOL. Third, we establish the distribution of the Debye-Waller factor and the lattice spacing at the given temperature  $T(x, y, t)$ , which also allows to derive the slope error distribution. Then, we can calculate the local volume of unit cell and the local atomic form factor. Afterwards, we construct the local structure factor  $F_h$  and the local Fourier coefficient of the electric susceptibility  $\chi_h$ . Next, by substituting the local  $F_h$  and  $\chi_h$  into Eq. (1), we can derive the local reflectivity and transmissivity. Finally, we obtain the overall reflectivity  $\bar{I}_{0H}$  and transmissivity  $\bar{I}_{00}$  by using Eq. (11).

**Figure 1.** The calculation framework of the local reflectivity and transmissivity.

**Figure 2.** (a) Reflectivity as a function of temperature for Si(111), Si(333), Si(555) and Si(777). (b) Rocking curve calculations of Si(777) at different temperatures (100K, 300K, 500K, and 700K).

### 3. Temperature dependence of electric susceptibility and Debye-Waller factor

In this section, we study the influence of the Debye-Waller factor and electric susceptibility on X-ray diffraction.

#### 3.1. Efficiency degradation induced by Debye-Waller factor

In this subsection, we discuss the impact of the Debye-Waller factor in dynamical X-ray diffraction. Figure 2 shows examples of calculations by taking the Debye-Waller factor into account in X-ray diffraction. In order to include the effect of thermal expansion, we use the data by interpolating the thermal expansion coefficient of silicon in Table 1. The specific heat capacity of silicon crystal is fitted from Okhotin's work<sup>[25]</sup>. The thermal expansion coefficient is extracted and fitted from references<sup>[26,27]</sup>. The thermal conductivity is fitted from Kazan's work<sup>[28]</sup>. The X-ray photon energy is 15 keV, and the thickness of the crystal is 0.5 mm. The reflectivity curves of Si(111), Si(333), Si(555) and Si(777) are calculated at different temperatures in Fig. 2 (a). The rocking curves of Si(777) at temperatures of 100K, 300K, 500K, and 700K are shown in Fig. 2 (b).

It is evident that as temperature increases, the Debye-Waller factor exhibits a decline in the height of rocking curves and a narrowing of the bandwidth of rocking curves. Additionally, as illustrated in Figure 2(a), a more significant reduction in reflectivity is observed at higher Miller index reflections. Our findings are consistent with the study conducted by Chung<sup>[29]</sup>. Thus far, we can infer that the Debye-Waller factor plays a crucial role in X-ray diffraction. We have integrated this effect into our method of X-ray diffraction by non-uniform thermally loaded crystals.

#### 3.2. Photon energy shift caused by electric susceptibility

According to the dynamical theory of X-ray diffraction, the central photon energy shift of the rocking curve arises from two terms,  $\alpha$ , and  $\alpha'$ . The parameter  $\alpha$  can describe a small perturbation that results in a deviation from the Bragg

condition. The perturbation could derive from incident angle deviation  $\Delta\theta$ , angular frequency deviation  $\Omega$ , and lattice deviation  $\Delta d$ . The parameter  $\alpha'$  is the deviation from the Bragg condition due to the refraction of crystals. The refractive index is temperature dependence which is due to the electric susceptibility change with the temperature. In this subsection, we investigate the temperature dependence of electric susceptibility which may contribute to the central photon energy shift of the rocking curve.

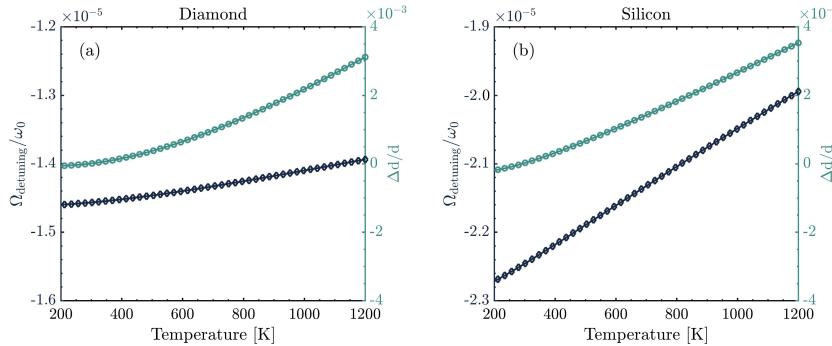

The coefficients  $\chi_h$  are related to the volume of the unit cell  $V_c$  and structure factor  $F_h$ . There is no doubt that  $\chi_h$  is temperature dependent, as  $V_c$  changes with the thermal expansion, and  $F_h$  changes with the Debye-Waller factor. Electric susceptibility  $\chi_h$  is associated with several physical quantities, such as refractive index  $n$ , crystal detuning effect  $\alpha'$ , Darwin width, and extinction length. The central photon energy shift caused by quantity  $\alpha$  has been investigated in references<sup>[15,16,18]</sup>. These studies show that the shift mainly attributes to the maximum thermal strain ( $\Delta d/d$ ). Here, we discuss the central photon energy shift arising from the quantity  $\alpha'$ . The shift can be expressed as

$$\frac{\Omega_{\text{detuning}}}{\omega_0} = \frac{\alpha'}{4 \sin^2 \theta_B}, \quad \alpha' = \chi_0 (\gamma - 1), \quad (12)$$

where  $\chi_0$  is temperature dependent. In general,  $\chi_0$  is a very small complex parameter. The imaginary part  $\text{Im}(\chi_0)$  and the real part  $\text{Re}(\chi_0)$  are related to the cross-section of photon absorption and the atomic Thomson scattering amplitude, respectively. Typically, for diamond and silicon crystals,  $\text{Re}(\chi_0) \gg \text{Im}(\chi_0)$ , and  $\text{Re}(\chi_0)$  is in the range of  $10^{-4} \sim 10^{-7}$  for 3~25keV.

Figure 3 illustrates the variation of the photon energy shift that corresponds to  $\alpha'$  and the thermal strain ( $\Delta d/d$ ) as a function of temperature. The thermal expansion data can be acquired by interpolating the data presented in Table 1 and Table 2. The thermal expansion coefficient  $\alpha_L$  and specific capacity  $c_p$  of diamond crystal are extracted from Reeber's work<sup>[30]</sup>, and the thermal conductivity of diamond crystal is extracted and fitted from Wei's work<sup>[31]</sup>. Subsequently, the

## X-ray diffraction performance of thermally distorted crystals

**Figure 3.** (a) Temperature dependence of the photon energy shift induced by  $\alpha'$  and lattice expansion in C\*(400). (b) Temperature dependence of the photon energy shift induced by  $\alpha'$  and lattice expansion in Si(400). The calculation is performed under the assumption of a uniform thermal load.

photon energy shift caused by  $\alpha'$  at varying temperatures can be calculated by modifying the volume of the unit cell and the Debye-Waller factor. The lattice constants corresponding to different temperatures are calculated based on the thermal expansion coefficient and the lattice constant at the reference temperature. In Fig. 3, the reference temperatures of diamond and silicon are respectively specified as 293.15 °C and 298.15 °C. The numerical method utilized in this analysis is elaborated in Fig. 1. The computations presented in Fig. 3(a) and (b) pertain to C\*(400) and Si(400) at 9 keV, respectively. For a crystal with a specific Miller index and a given photon energy, the photon energy shift attributable to  $\alpha'$  is roughly three orders of magnitude lower than the shift caused by thermal strain. As a result, thermal strain predominantly governs the central photon energy shift of the rocking curve, and the influence of  $\alpha'$  can be disregarded.

#### 4. Comparison and Validation

In this section, a numerical validation of the proposed model is performed and compared with the model by Bushuev. Then, we applied the model to estimate X-ray diffraction performance in the dynamic pulse-to-pulse process.

##### 4.1. Comparison

Here, the analytical model developed by Bushuev<sup>[15,16]</sup> is employed to compute the temperature distribution under the assumption of a 2D infinite domain.

$$T(x, y, t) = \sum_{j=1}^n \frac{\Delta T_j}{\sqrt{\beta_x \beta_y}} \exp \left[ -\frac{x^2}{r_x^2 \beta_x} - \frac{y^2}{r_y^2 \beta_y} \right] \quad (13)$$

here,

$$\beta_x = 1 + \frac{\sin^2 \theta_B (t - t_j)}{\tau_T}, \quad \beta_y = 1 + \frac{(t - t_j)}{\tau_T}, \quad (14a)$$

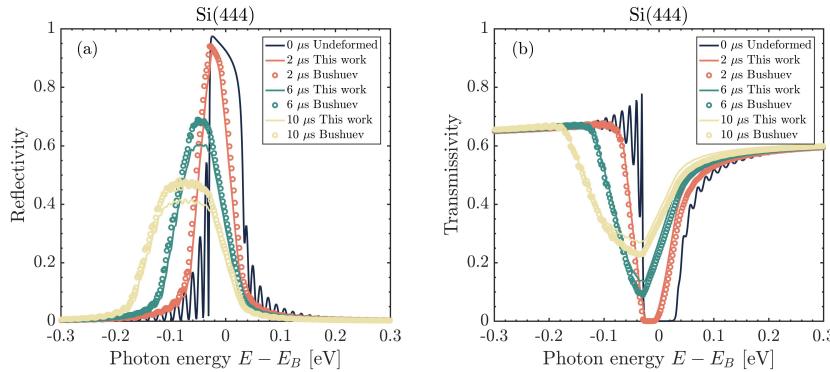

$$\Delta T_j = \frac{\mu Q_p}{\pi c_p r^2}, \quad \tau_T = \frac{r^2 c_p \rho}{4\kappa}, \quad (14b)$$

where  $\mu$ ,  $Q_p$ ,  $c_p$ ,  $\rho$ ,  $r$ , and  $\kappa$  are the absorption factor, pulse energy, specific heat capacity, density, transverse pulse radius, and thermal conductivity, respectively.  $n$  is the

number of pulse impingements on the crystal, and  $t_j$  is the arrival time of the  $j^{th}$  pulse.

Our study focuses on analyzing the rocking curve of a thermally loaded Si(444) with a thickness of 50 μm. The initial temperature of the crystal is set to 300 K. We consider the pulse repetition rate is 1 MHz, and the pulse energy is 200 μJ. The radius of the transverse beam profile is 800 μm. It is assumed that the bandwidth of the incident pulse is significantly wider than the width of the rocking curve. The photon energy is 10 keV, and with an absorption length of 134 μm. To conduct numerical simulations, we calculate the temperature-dependent spatial distribution of the Debye-Waller factor at  $T(x, y, t)$  by implementing the method outlined in Sec. 2. The temperature dependence parameters of silicon, such as the specific heat capacity, thermal conductivity, and thermal expansion coefficient, are obtained by interpolating the data provided in Table 1.

When heat is deposited into the crystal, non-uniform distortion occurs, leading to changes in the overall reflectivity and transmissivity curves at different time intervals, as illustrated in Figure 4 (a) and (b). The black curves represent diffraction by a perfect Si(444) crystal at 300K. The solid curves were obtained using our proposed method, while the circles represent results obtained using Bushuev's method which does not take into account the temperature dependence of the Debye-Waller factor. Both methods reveal that rocking curves shift and distort with heat accumulation. Compared to the dashed lines, the height of the rocking curve decreases, and the width becomes slightly narrower, which indicates the evident influence of the Debye-Waller factor. Specifically, when the heat accumulation time is 10 μs, the reflectivities of our proposed model and Bushuev's model are 40% and 48%, respectively. As the heat accumulation time increases, the differences in reflectivity and transmissivity between the two models are expected to become more significant. The numerical simulation results demonstrate that for a non-uniform thermally distorted crystal, the Debye-Waller factor plays a critical role in reducing the height and width of the rocking curves.

**Figure 4.** Comparative analysis of results obtained at 2  $\mu$ s, 6  $\mu$ s, and 10  $\mu$ s using Bushuev's method (circles) and our proposed method (solid lines). The black curve refers to the undeformed crystal at 300K.

#### 4.2. Dynamic pulse-to-pulse process

So far, we have developed a numerical model to describe X-ray diffraction from a thermally loaded crystal and have gained an understanding of the distortion of its rocking curve. To facilitate a more intuitive understanding of the properties of a thermally loaded crystal, we investigate the case of dynamic pulse-to-pulse thermal conduction processes in this subsection. Specifically, we investigate C\*(400) with an initial temperature of 200 K and a thickness of 110  $\mu$ m. The input pulse energy, repetition rate, photon energy, and transverse beam radius are set at 500  $\mu$ J, 1 MHz, 9 keV, and 800  $\mu$ m, respectively. The absorption length is 977  $\mu$ m. The temperature distribution of a diamond crystal is estimated using Eq. (13). The specific heat capacity, thermal conductivity, thermal expansion coefficient of diamond can be obtained by interpolating the data in Table 2.

In the simulation, the pulse interval is 1  $\mu$ s, and the thermal runaway characteristic time  $\tau_T$  (thermal exchange time) corresponding to the crystal at 200 K is 42.3  $\mu$ s. Therefore, under these conditions, the temperature of the crystal will continue to accumulate, and the performance of the crystal will become increasingly worse. Figures 5 (a) and (b) present the reflectivity and transmissivity records of C\*(400). The results indicate a notable widening of the bandwidth and a shift in the central photon energy over time. Moreover, a decrease in reflection efficiency is observed as a result of heat accumulation. The temperature evolution at the center of the crystal is depicted in Figure 5 (c), indicating a rapid temperature increase. Apparently, for this case, there is not enough time for the crystal to cool down due to high repetition rate. Consequently, the reflectivity decreases rapidly due to distortion and the shift of the rocking curve for a fixed diffraction geometry. To optimize the reflectivity, a strategy of tuning the pitch angle of the crystal can be employed, as shown in Figure 5 (c) for both tuned and untuned reflectivity curves. This strategy is implemented by controlling the proper angular speed of the motor to mitigate the shift of the central photon energy, as

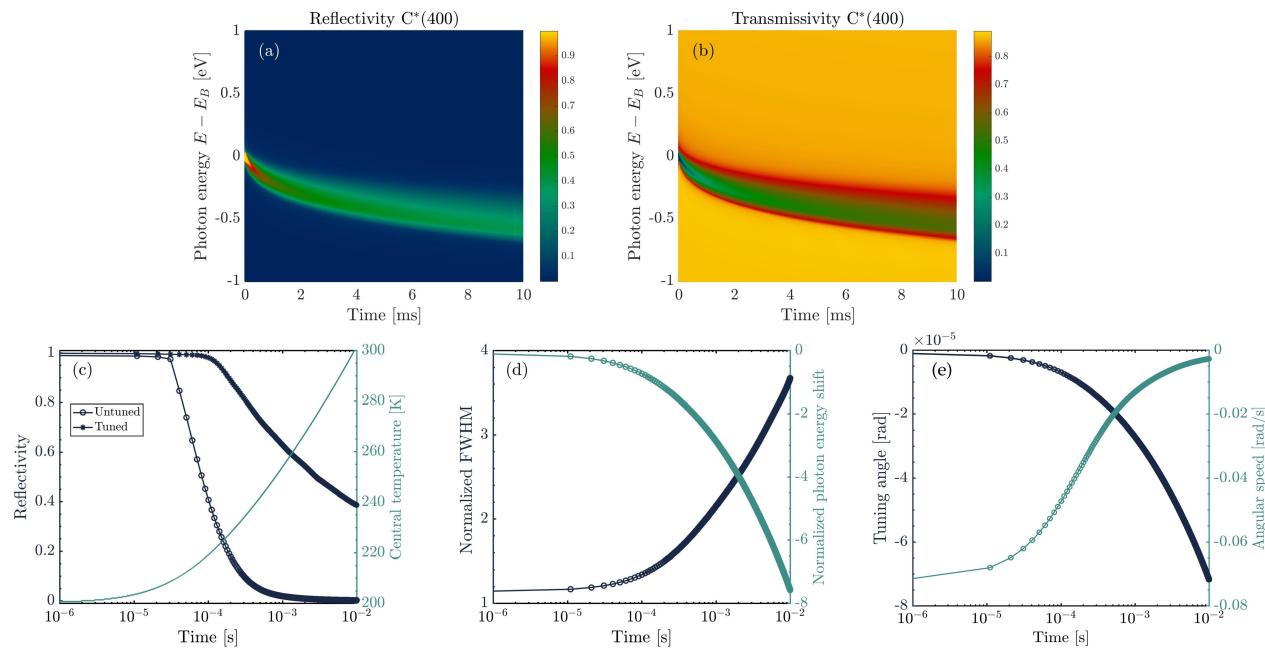

shown in Fig. 5 (e), and Qu et al. reported the strategy in their work<sup>[20]</sup>. Furthermore, Figure 5 (d) exhibits that the bandwidth and central photon energy shift increase with heat accumulation, where the latter can be compensated for by the tuning strategy, while the former can be reduced by decreasing the slope error.

#### 5. Summary

This study investigates X-ray diffraction by a crystal under thermal load and develops a comprehensive model that not only considers several key factors including thermal strain, incident angle deviation, and slope error but also includes the temperature dependence of the Debye-Waller factor and electric susceptibility. Our findings suggest that the influence of the Debye-Waller factor on efficiency degradation cannot be neglected, particularly in the case of high-order Miller index reflections at high temperatures. Although the Debye-Waller factor can potentially narrow the bandwidth of the rocking curve, non-uniform thermal load still dominates the bandwidth broadening. The central photon energy shift is primarily attributed to thermal strain and slope error, while the shift induced by the temperature dependence of electric susceptibility can be neglected. The non-uniform thermal load causes variations in the local Debye-Waller factor, thermal strain, and slope error, which further results in the distortion and degradation of the rocking curve. Proper cooling strategies, minimizing slope error, and tuning the incident angle can effectively mitigate the effects of thermal load.
